
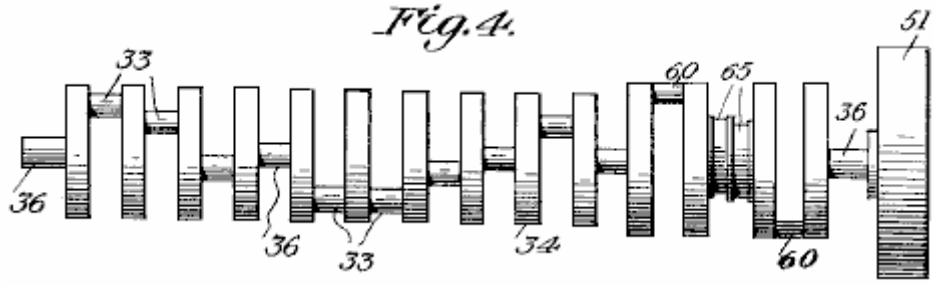

Fig.4 is a detail elevation of the crankshaft of the engine.

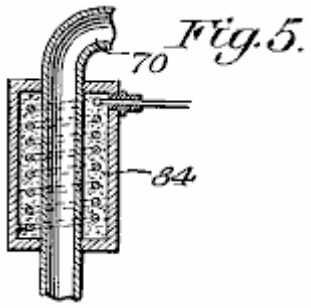

Fig.5 is an enlarged cross-sectional view through one of the electric heaters for the engine.

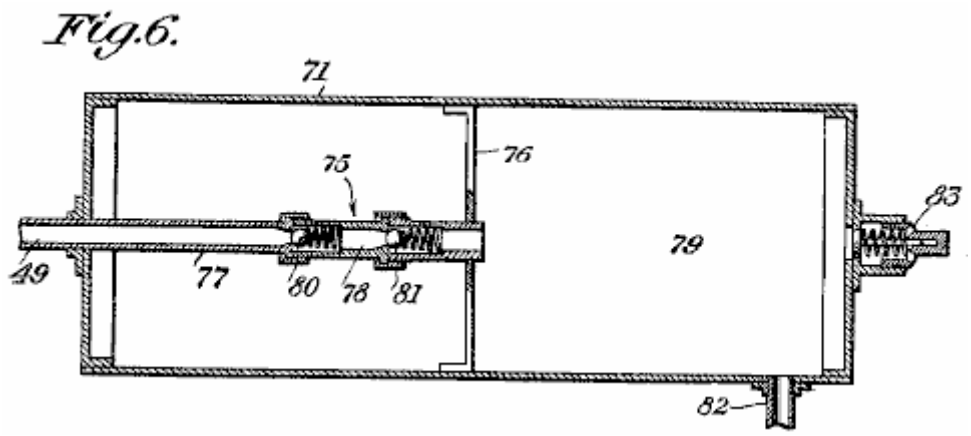

Fig.6 is a vertical, longitudinal, cross-sectional view through the air storage tank, including the equaliser.

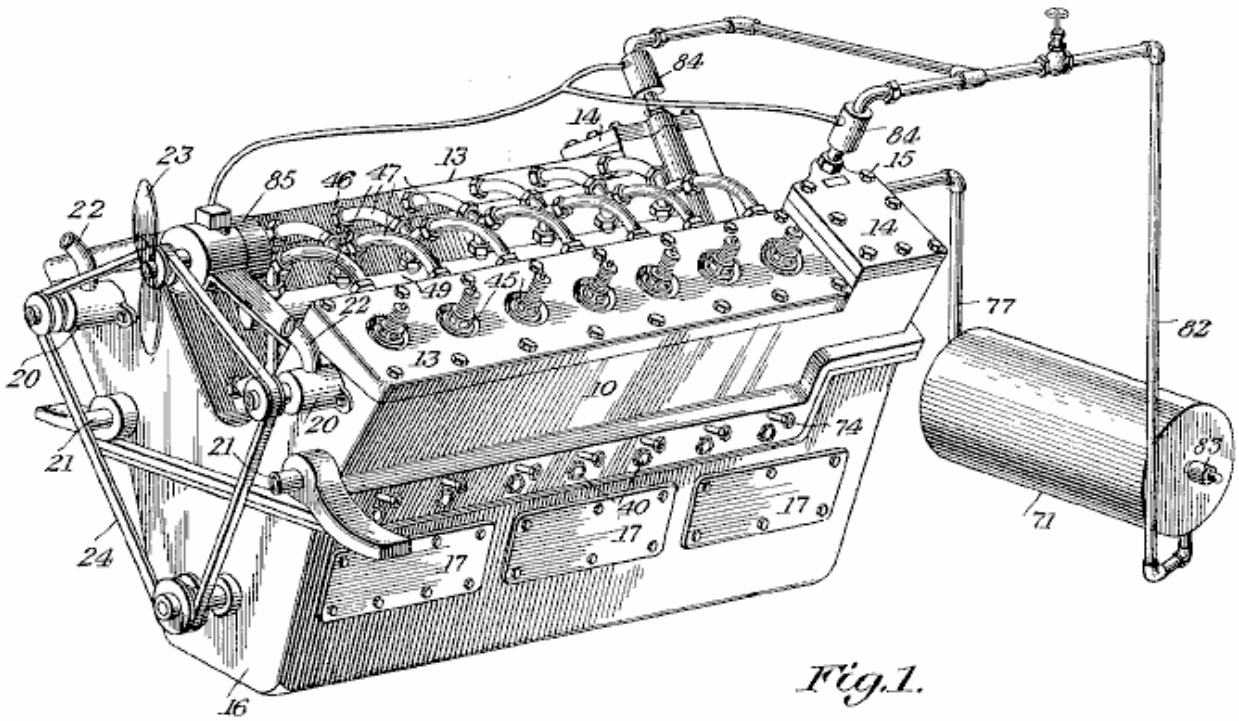
The same reference numbers are used for each individual part in every view in every drawing.



Referring to the drawings in detail, the engine in its entirety, composes a cylinder block **10** having inside it, the series of compressor cylinders **11** and the power cylinders **12**. The block **10** is of the V-type and the upper ends of the cylinders are closed off by the removable heads **13** and **14** which are held in place by conventional head bolts **15**. Beneath block **10** is the crank case **16**, which has detachable plates **17** at opposite sides, held in place by fasteners **18**, and seated so as to be leak proof. The block **10** is chambered to provide a water jacket **19** surrounding the cylinders, while at the forward end of the block are water pumps **20**, circulating water through the inlet pipe **21** which leads into the jacket and the water exits from the jacket through the outlet pipe **22**. Beside the pumps **20**, is a fan 23 which is operated from the same belt **24** which drives the pumps.

Working inside the cylinders **11**,are the reciprocating pistons **25**, their rods **26** sliding through packing glands **27** and fixed to crossheads **28** which slide on their mounting guides **29** which are secured to the walls of the crank case **16**. These crossheads **28** are fitted with wrist pins **30**, forming a pivoting connection with the connecting rods **31**, which are connected to their cranks **33** by their bearings **32**. The cranks **33** form part of a counter balanced crankshaft **34**, which is mounted in supports **35** attached to the crank case **16**, the shaft being provided with the required bearings **36**.

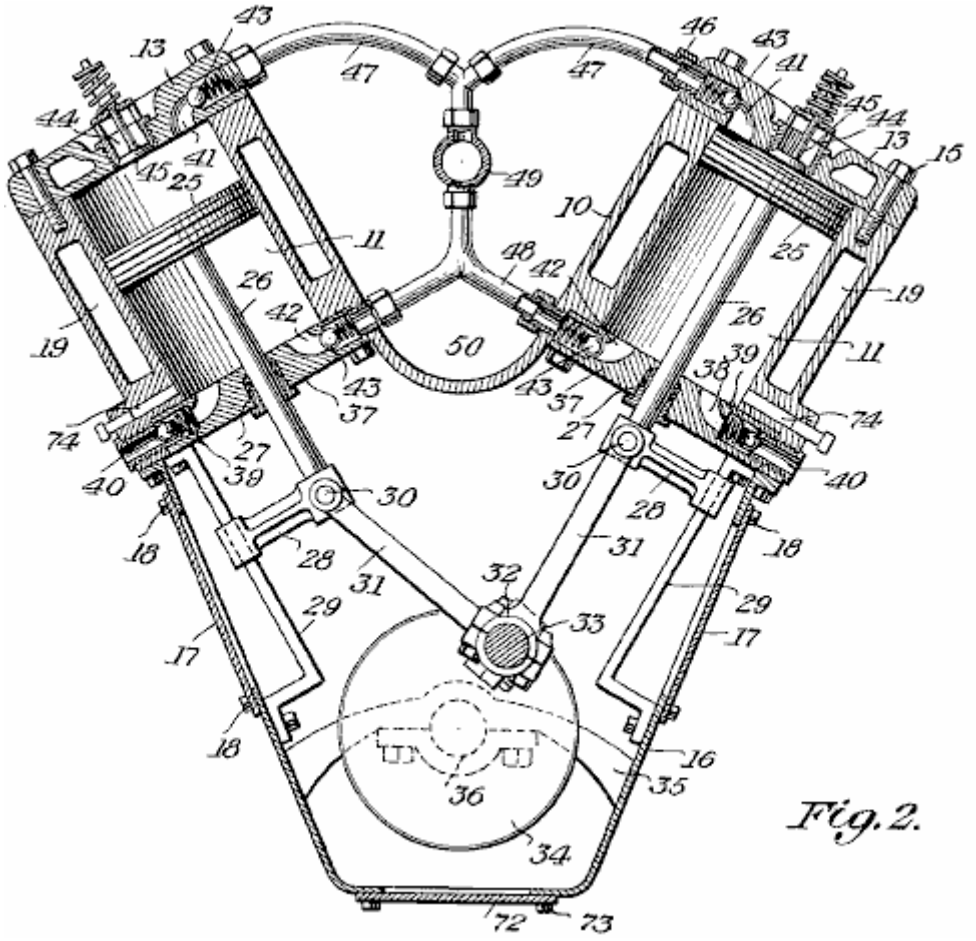


Fig. 2.

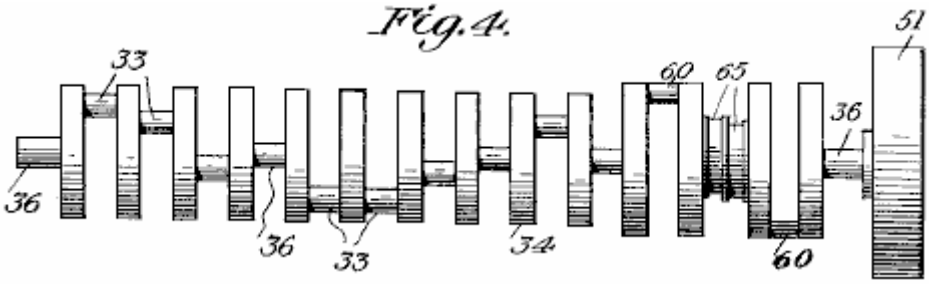
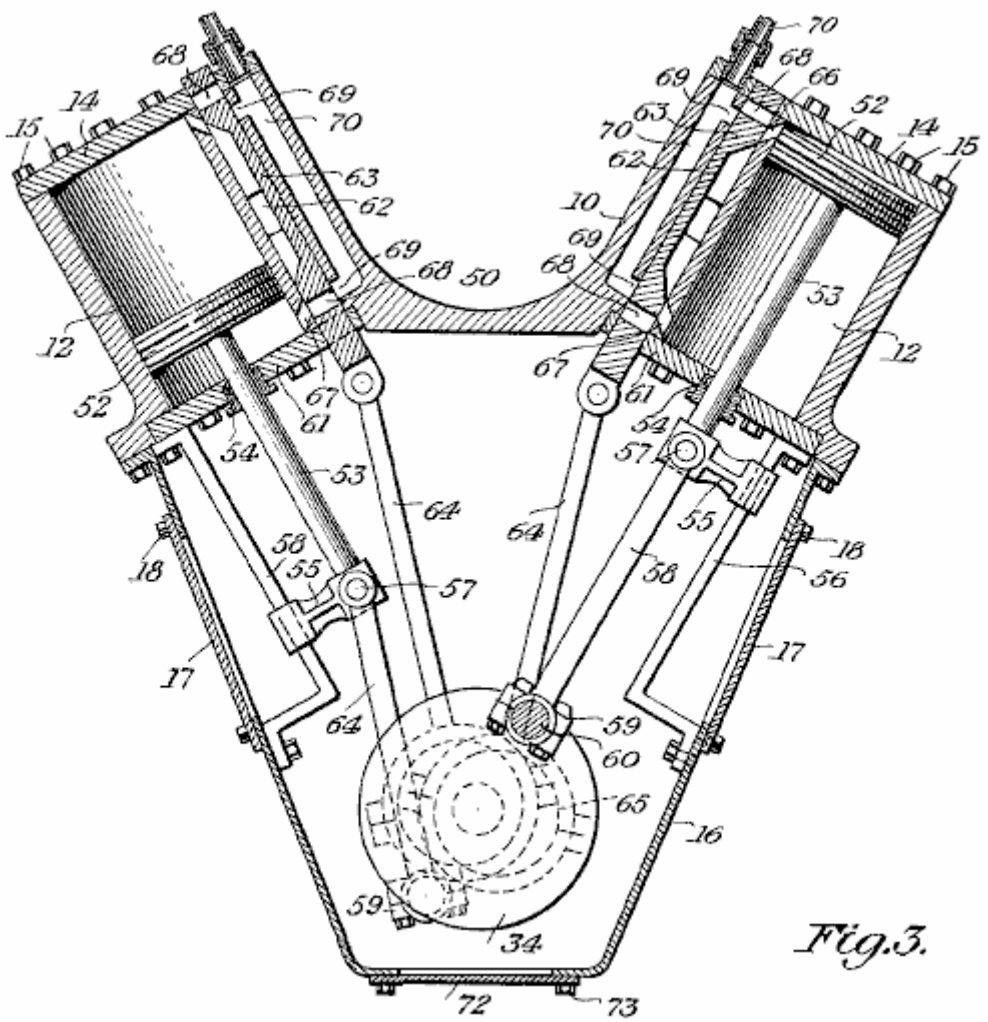
The inner ends of the cylinders **11** are fitted with inner end heads **37**, which are provided with air intake ports **38** fitted with spring ball inlet checks **39**, the air entering through passages **40** which open outside the block **10**. Glands **27** are mounted in the heads **37**.

The heads **13** and **37** are provided with the compressed air outlets **41** and **42**, which are fitted with spring ball checks **43**. The heads **13** are also provided with the central air inlets **44**, which are fitted with spring checks **45**. Couplings **46** attach the air outlets **41** and **42** to their outlet feed pipes **47** and **48**. These pipes lead to a main conduit **49** which is located in the centre channel **50** of the block **10**.

Fig. 4.



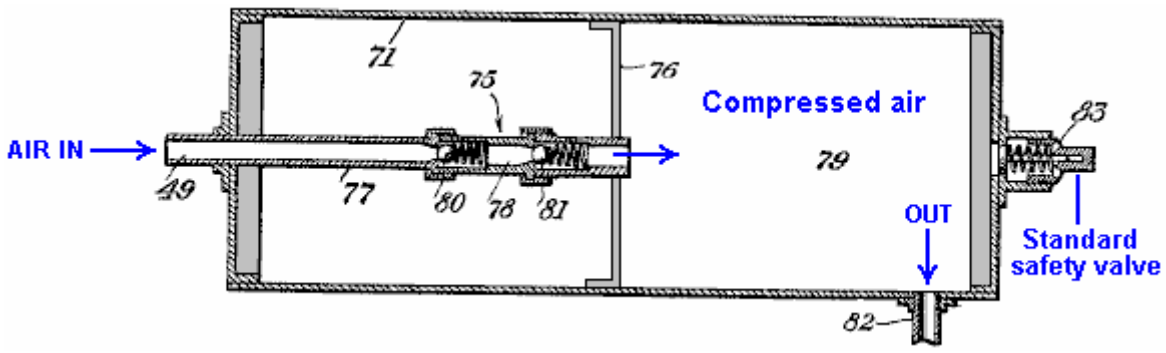
At the rear end of the block **10**, mounted on shaft **36**, there is a conventional flywheel **51**.



Working inside the cylinders **12** are the pistons **52**, with their piston rods **53** sliding through packing glands **54** and fixed in crossheads **55** which slide along their mounting guides **56**, mounted on the inner walls of the crank case **16**. The crossheads **55** have wrist pins **57** which provide a pivoting joint for the connecting rods **58** which are connected by their bearings **59** to their cranks **60** of the crank shaft **34**, the inner ends of the cylinders **12** being closed by the inner heads **61** and their associated glands **54**.

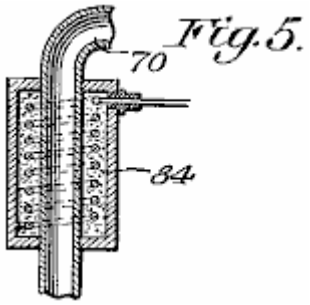
On the cylinders **12** are slide valve chests **62** in which are the slide valves **63**, these being operated by throw rods **64** actuated by cams **65** and the valves controlling the admission and exhaust of air into and out of the cylinders **12**, through the ports **66** and **67**, and these valves **63** are provided with ports **68** for the delivery of air under pressure from the inlet passages **69** common to a pipe **70** coming from a compressed air storage tank **71**.

The bottom of the crank case **16** is fitted with a removable plate **72** which is secured in place by fasteners **73**, and when this plate is removed, it provides access to the crank shaft **34** and the bearings for the engine, as well as other parts inside the crank case.



Leading into the cylinders **11** are the passages **74** of a lubricating system (not shown). The compressed air storage tank **71** has inside it a double-check discharge nozzle **75**, supported by member **76**. Leading to this equaliser is an air inlet pipe **77** which connects through its valved section **78** to the compressed air reservoir **79**.

In the equaliser **75**, are the spaced spring ball checks **80** and **81**, one being for the inlet side and the other for the outlet side of the equaliser. This pipe **77** is connected with the main conduit **49**, while a pipe **82** connects to pipe **70**. The tank is also fitted with an automatic relief valve **83** and this valve can be of any approved type.



Placed around the pipes **70** which connect to the air passages **69** (**Fig.3**) are electric heating units **84** to heat the pressurised air to above freezing temperature when delivered from tank **71** to the cylinders **12**. Supported on the block **10** is an electric generator **85** which is driven from the shaft **34** (**Fig.2**) through a belt **24** (**Fig.1**) and this generator is included in an electric circuit which also has the heaters **84** so that these will operate from current supplied by the generator.

The compressed air storage tank **71** with the equaliser is constructed so that it is possible to pump air into it while it contains an air pressure of 200 pounds per square inch while the compressors are only pumping against 15 pounds per square inch of (atmospheric) pressure. An outside air pressure source can be coupled with the tank to augment that pressure derived from the cylinders **11** of the engine.

CLAIMS

What is claimed is:
In a structure of the kind described, a V-shaped cylinder block provided with upwardly divergent cylinders, end heads fitted to said cylinders at opposite ends thereof, each head having valved inlets and outlets, a main outlet lead between the cylinders of the block for a storage tank and having lateral branches to the outlets at the inner sides of said heads, one inlet being located at the centre of each head at the outer ends of said cylinders while the remaining inlets are at the outer sides of the heads at the inner ends of said cylinders, a substantially V-shaped crank case fitted to the block beneath the cylinders, a counterbalanced crank shaft journaled in the crank case, pistons operating in the cylinders and having rods extended into the crank case, crosshead guides fitted to the interior sides of said case, crossheads connecting the rods with the guides and sliding on them and connecting rods operated by the crank shaft and pivoted at the crossheads in order to allow reciprocation of the pistons.

Leroy K. Rogers' Compressed Air Engine

Patent US 4,292,804 6th October 1980 Inventor: Leroy K. Rogers

METHOD AND APPARATUS FOR OPERATING AN ENGINE ON COMPRESSED GAS

ABSTRACT

The present invention relates to a method and apparatus for operating an engine having a cylinder containing a reciprocating piston driven by a compressed gas. The apparatus comprises a source of compressed gas connected to a distributor which conveys the compressed gas to the cylinder. A valve is provided to admit compressed gas to the cylinder when the piston is in an approximately Top Dead Centre position.

In one embodiment of the present invention, the timing of the opening of the valve is advanced so that the compressed gas is admitted to the cylinder progressively further before the Top Dead Centre position of the piston as the speed of the engine increases.

In a further embodiment of the present invention, a valve actuator is provided which increases the length of time over which the valve remains open to admit compressed gas to the cylinder as the speed of the engine increases.

A still further embodiment of the present invention relates to an apparatus for adapting a conventional internal combustion engine for operation on compressed gas.

DESCRIPTION

BACKGROUND AND SUMMARY OF THE PRESENT INVENTION

The present invention is a method and apparatus for operating an engine using a compressed gas as the motive fluid. More particularly, the present invention relates to a apparatus for adapting a pre-existing internal combustion engine for operation on a compressed gas.

Air pollution is one of the most serious problems facing the world today. One of the major contributors to air pollution is the ordinary internal combustion engine which is used in most motor vehicles today. Various devices, including many items required by legislation, have been proposed in an attempt to limit the pollutants which an internal combustion engine exhausts to the air. However, most of these devices have met with limited success and are often both prohibitively expensive and complex. A clean alternative to the internal combustion engine is needed to power vehicles and other machinery.

A compressed gas, preferably air, would provide an ideal motive fluid for an engine, since it would eliminate the usual pollutants exhausted from an internal combustion engine. An apparatus for converting an internal combustion engine for operation on compressed air is disclosed in U.S. Pat. No. 3,885,387 issued May 27, 1975 to Simington. The Simington patent discloses an apparatus including a source of compressed air and a rotating valve actuator which opens and closes a plurality of mechanical poppet valves. The valves deliver compressed air in timed sequence to the cylinders of an engine through adapters located in the spark plug holes. However, the output speed of an engine of this type is limited by the speed of the mechanical valves and the fact that the length of time over which each of the valves remains open cannot be varied as the speed of the engine increases.

Another apparatus for converting an internal combustion engine for operation on steam or compressed air is disclosed in U.S. Pat. No. 4,102,130 issued July 25, 1978 to Stricklin. The Stricklin patent discloses a device

which changes the valve timing of a conventional four stroke engine such that the intake and exhaust valves open once for every revolution of the engine instead of once every other revolution of the engine. A reversing valve is provided which delivers live steam or compressed air to the intake valves and is subsequently reversed to allow the exhaust valves to deliver the expanded steam or air to the atmosphere. A reversing valve of this type however does not provide a reliable apparatus for varying the amount of motive fluid injected into the cylinders when it is desired to increase the speed of the engine. Further, a device of the type disclosed in the Stricklin patent requires the use of multiple reversing valves if the cylinders in a multi-cylinder engine were to be fired sequentially.

Therefore, it is an object of the present invention to provide a reliable method and apparatus for operating an engine or converting an engine for operation with a compressed gas.

A further object of the present invention is to provide a method and apparatus which is effective to deliver a constantly increasing amount of compressed gas to an engine as the speed of the engine increases.

A still further object of the present invention is to provide a method and apparatus which will operate an engine using compressed gas at a speed sufficient to drive a conventional automobile at highway speeds.

It is still a further object of the present invention to provide a method and apparatus which is readily adaptable to a standard internal combustion engine, to convert the internal combustion engine for operation with a compressed gas.

Another object of the invention is to provide a method and apparatus which utilises cool expanded gas, exhausted from a compressed gas engine, to operate an air-conditioning unit and/or an oil-cooler.

These and other objects are realised by the method and apparatus of the present invention for operating an engine having at least one cylinder containing a reciprocating piston and using compressed gas as the motive fluid. The apparatus includes a source of compressed gas, a distributor connected it for conveying the compressed gas to the cylinder or cylinders. A valve is provided for admitting the compressed gas to the cylinder when the piston is in an approximately Top Dead Centre position within the cylinder. An exhaust is provided for exhausting the expanded gas from the cylinder as the piston returns to approximately the Top Dead Centre position.

In a preferred embodiment of the present invention, a device is provided for varying the duration of each engine cycle over which the valve remains open to admit compressed gas to the cylinder, dependent upon the speed of the engine. In a further preferred embodiment of the present invention, an apparatus for advancing the timing of the opening of the valve is arranged to admit the compressed gas to the cylinder progressively further and further before the Top Dead Centre position of the piston, as the speed of the engine increases.

Further features of the present invention include a valve for controlling the amount of compressed gas admitted to the distributor. Also, a portion of the gas which has been expanded in the cylinder and exhausted through the exhaust valve, is delivered to a compressor to be compressed again and returned to the source of compressed gas. A gear train can be engaged to drive the compressor selectively at different operating speeds, depending upon the pressure maintained at the source of compressed air and/or the speed of the engine. Still further, a second portion of the exhaust gas is used to cool a lubricating fluid for the engine or to operate an air-conditioning unit.

In a preferred embodiment of the present invention, the valve for admitting compressed gas to the cylinder is operated electrically. The device for varying the duration of each engine cycle, over which the intake valve remains open, as the speed of the engine increases, comprises a rotating element whose effective length increases as the speed of the engine increases, causing a first contact on the rotating element to be electrically connected to a second contact on the rotating element, for a longer period of each engine cycle. The second contact operates the valve causing it to remain in an open position for a longer period of each engine cycle, as the speed of the engine increases.

Still further features of the present invention include an adaptor plate for supporting the distributor above the intake manifold of a conventional internal combustion engine after a carburettor has been removed to allow air to enter the cylinders of the engine through the intake manifold and conventional intake valves. Another adaptor plate is arranged over an exhaust passageway of the internal combustion engine to reduce the cross-sectional area of the exhaust passageway.

BRIEF DESCRIPTION OF THE DRAWINGS

Preferred embodiments of a method and apparatus for operating an engine according to the present invention will be described with reference to the accompanying drawings in which components have the same reference numbers in each drawing.

Fig.1 is a schematic representation of an apparatus according to the present invention arranged on an engine:

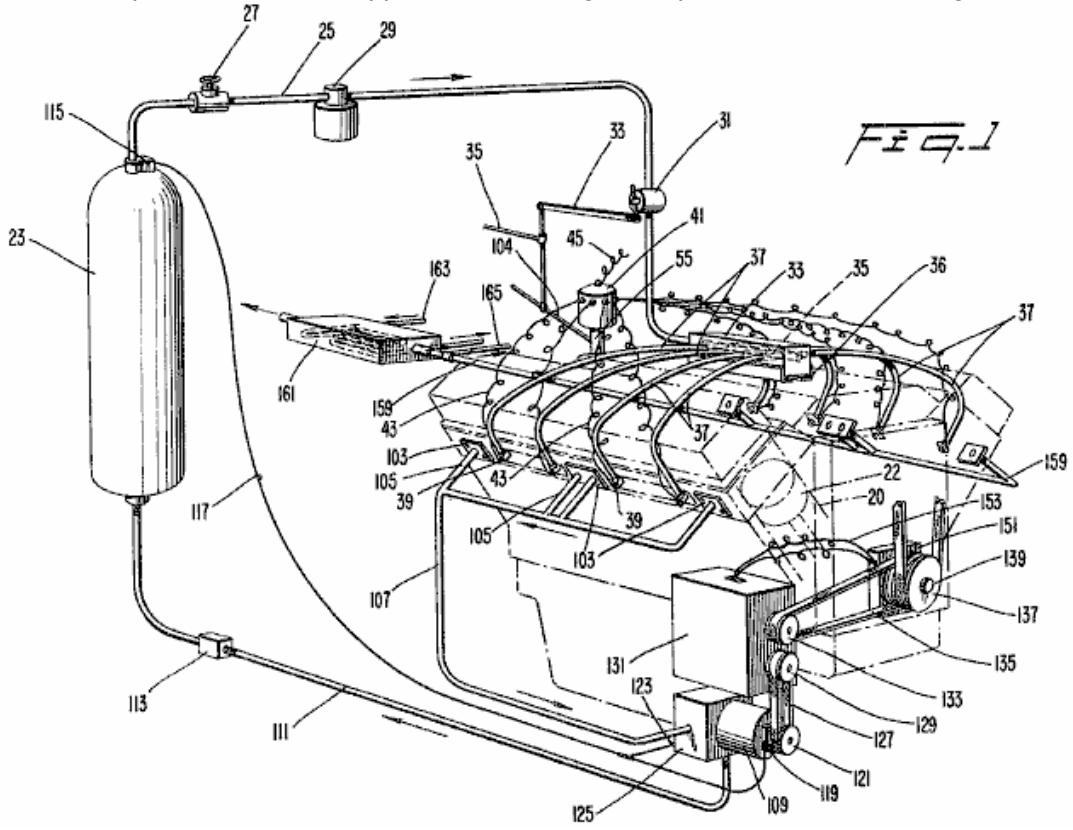

Fig.2 is a side view of one embodiment of a valve actuator according to the present invention.

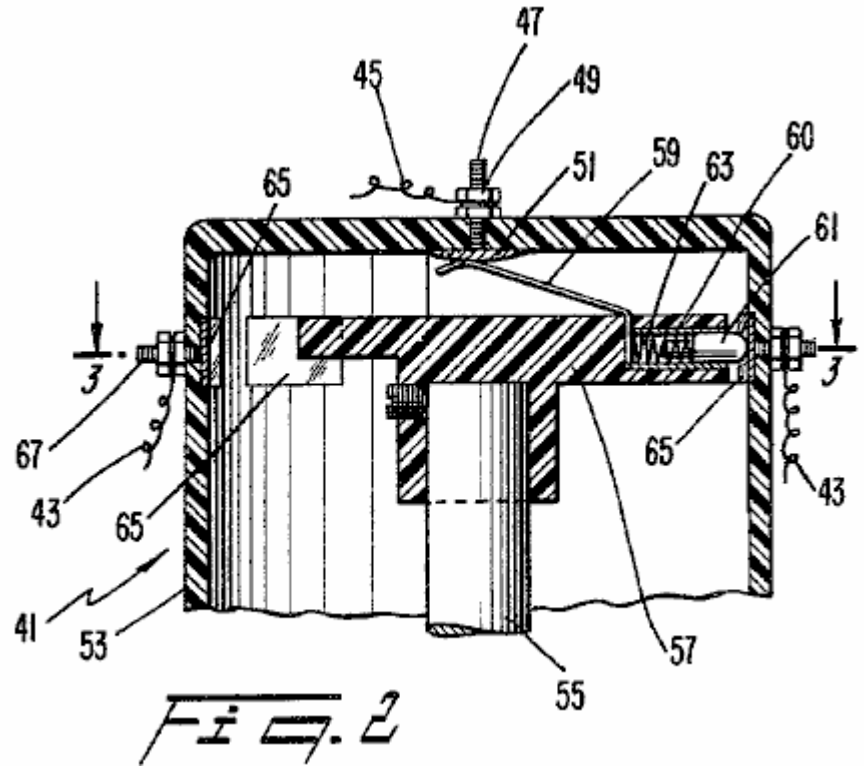

Fig.3 is a cross-sectional view taken along the line **3--3** in **Fig.2**.

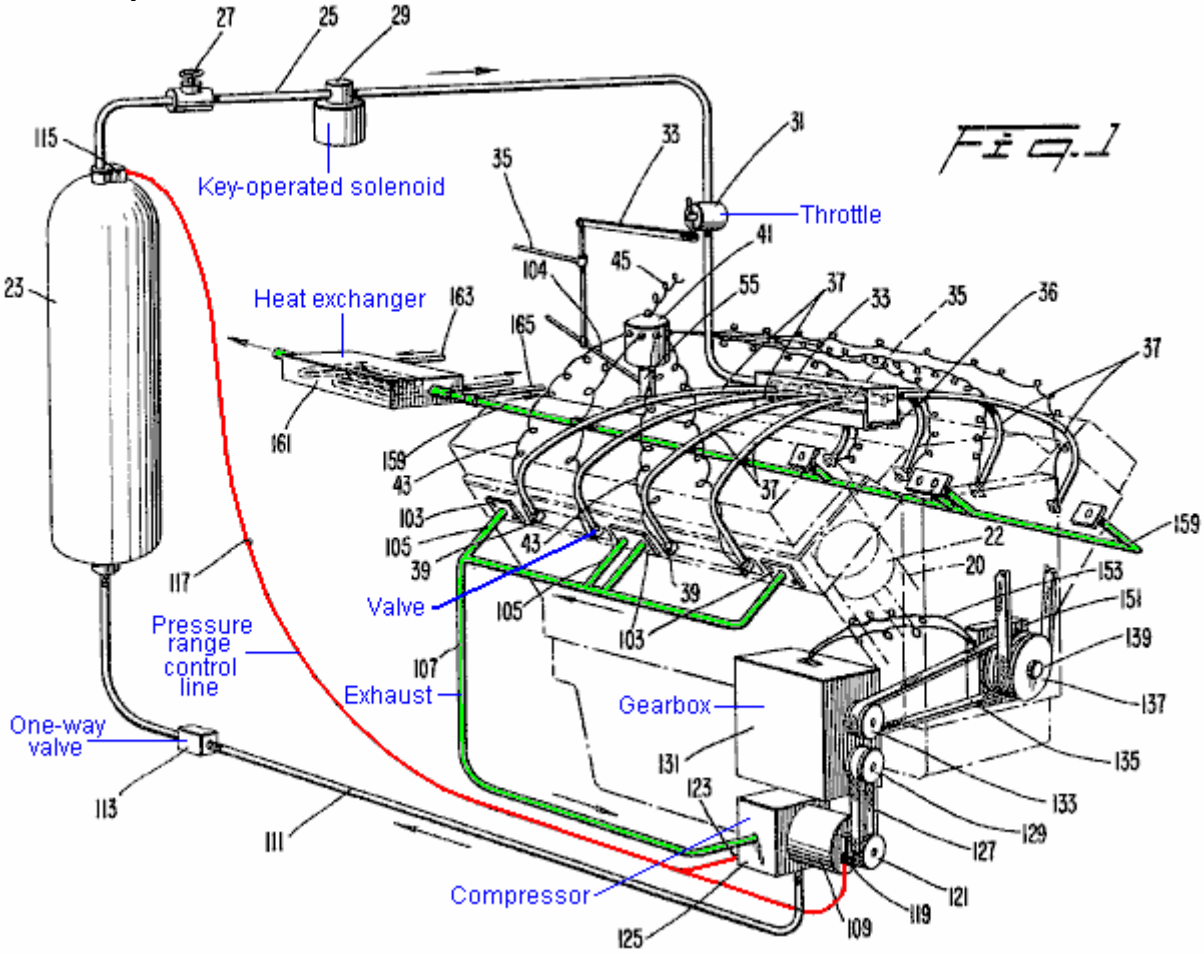
DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

With reference to **Fig.1**, an engine block **21** (shown in phantom) having two banks of cylinders with each bank including cylinders **20** having pistons **22** which reciprocate in them in a conventional manner (only one of which is shown in phantom). While the illustrated engine is a V-8 engine, it will be apparent that the present invention is applicable to an engine having any number of pistons and cylinders with the V-8 engine being utilised for illustration purposes only. A compressed gas tank **23** is provided to store a compressed gas at high pressure. It may also be desirable to include a small electric or gas compressor to provide compressed gas to supplement the compressed gas held in the tank **23**. In a preferred embodiment, the compressed gas is air which can be obtained from any suitable source.



A line **25** transports the gas withdrawn from the tank **23** when a conventional shut-off valve **27** is open. In addition, a solenoid valve **29** preferably operated by a suitable key-operated engine switch (not shown) is also placed in the line **25**. In normal operation, the valve **27** is maintained open at all times with the solenoid valve **29** operating as a selective shut off valve to start and stop the engine **21**.

A suitable regulating valve **31** is arranged downstream of the solenoid valve **29** and is connected by a linkage **33** to a throttle linkage **35** which is operator-actuated by any suitable apparatus such as a foot pedal (not shown). The line **25** enters an end of a distributor **33** and is connected to an end of a pipe **35** which is closed at the other end. A plurality of holes, which are equal to the number of cylinders in the engine **21**, are provided on either side of the pipe **35** along the length of the pipe **35**.

When the present invention is used to adapt a conventional internal combustion engine for operation on compressed gas, an adaptor plate **36** is provided to support the distributor **33** in spaced relation from the usual intake opening in the intake manifold of the engine after a conventional carburettor has been removed. In this way, air is permitted to enter the internal combustion engine through the usual passageways and to be admitted to the cylinders through suitable intake valves (not shown). The adaptor plate **36** is attached to the engine block **21** and the distributor **33** by any suitable apparatus, e.g., bolts.

Each of the holes in the pipe **35** is connected in fluid-tight manner to a single line **37**. Each line **37** carries the compressed gas to a single cylinder **20**. In a preferred embodiment, each of the lines **37** is 1/2 inch high pressure plastic tubing attached through suitable connectors to the distributor **33** and the pipe **35**. Each of the lines **37** is connected to a valve **39** which is secured in an opening provided near the top of each of the cylinders **20**. In the case of a conversion of a standard internal combustion engine, the valves **39** can be conveniently screwed into a

tapped hole in the cylinder **20** typically provided for a spark plug of the internal combustion engine. In a preferred embodiment, the valves **39** are solenoid actuated valves in order to provide a fast and reliable opening and closing of the valves **39**.

Each of the valves **39** is energised by a valve actuator **41** through one of a plurality of wires **43**. The valve actuator **41** is driven by a shaft of the engine similar to the drive for a conventional distributor of an internal combustion engine. That is, a shaft **55** of the valve actuator **41** is driven in synchronism with the engine **21** at one half the speed of the engine **21**.

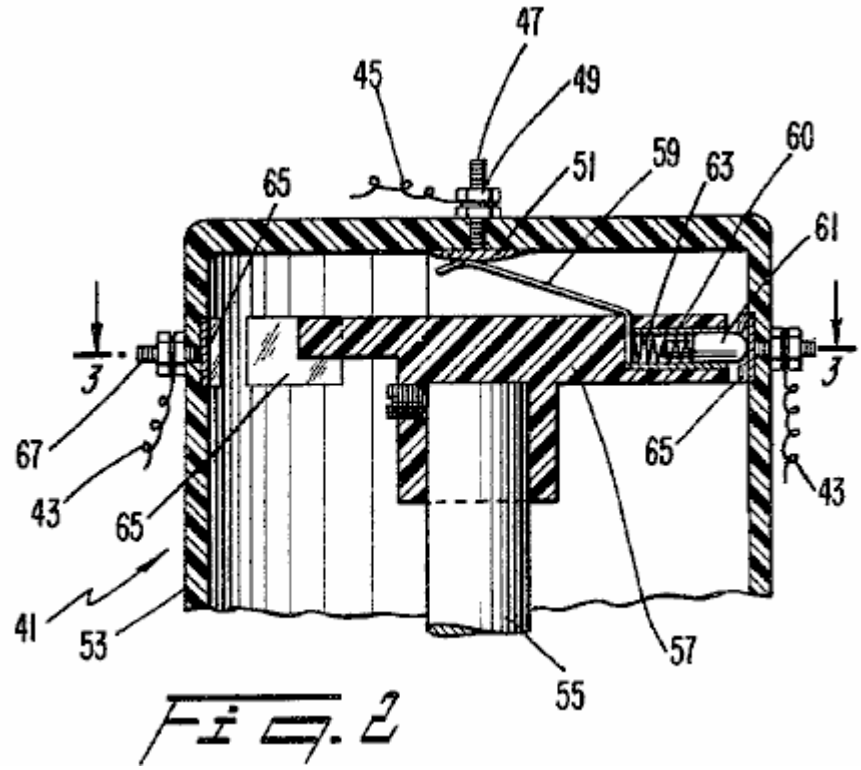


Fig. 2

A first embodiment of the valve actuator **41** (**Fig.2** and **Fig.3**), receives electrical power through a wire **45** which is energised in a suitable manner by a battery, and a coil if necessary (not shown) as is conventional in an internal combustion engine. The wire **45** is attached to a central post **47** by a nut **49**. The post **47** is connected to a conducting plate **51** arranged in a housing **53** for the valve actuator **41**. Within the housing **53**, the shaft **55** has an insulating element **57** secured to an end of the shaft **55** and rotates with it when the shaft **55** is driven by the engine **21**. A first end of a flexible contact **59** is continuously biased against the conducting plate **51** to receive electricity from the battery or other suitable source. The other end of the contact **59** is connected to a conducting sleeve **60** which is in constant contact with a spring biased contact **61** which is arranged within the sleeve **60**. The contact **61** is pressed by a spring **63** which pushes contact **61** towards a side wall of the housing **53**.

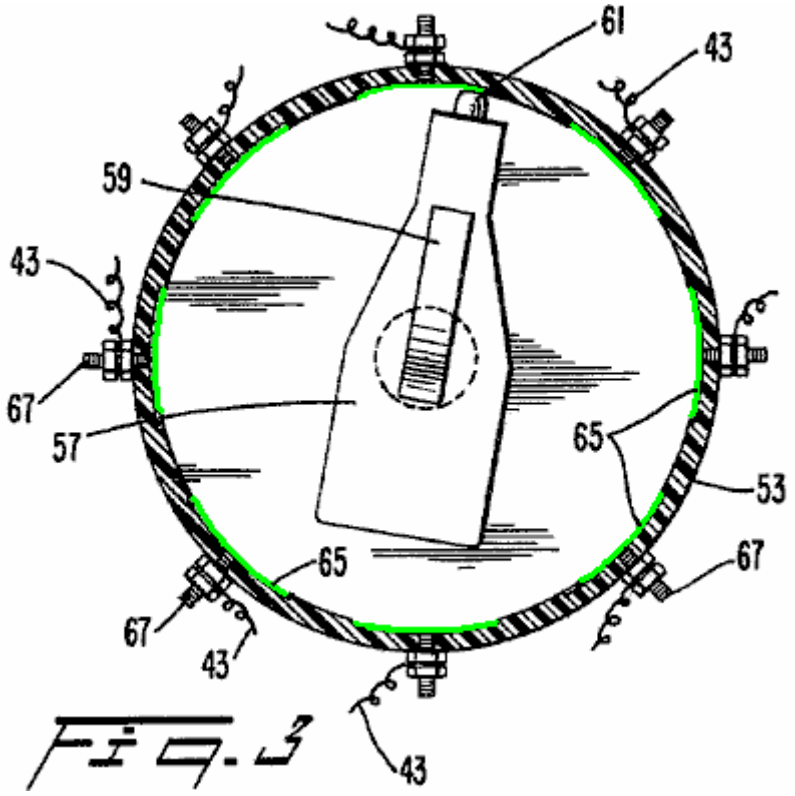

Fig. 3

With reference to **Fig.3**, a plurality of contacts **65** are spaced from one another and are arranged around the periphery of the housing **53** at the same level as the spring biased contact **61**. Each contact **65** is electrically connected to a post **67** which extends outside of the housing **53**. The number of contacts **65** is equal to the number of cylinders in the engine **21**. One of the wires **43**, which actuate the valves **39**, is secured to each of the posts **67**.

In operation, as the shaft **55** rotates in synchronism with the engine **21**, the insulating element **57** rotates and electricity is ultimately delivered to successive pairs of the contacts **65** and wires **43** through the spring loaded contact **61** and the flexible contact **59**. In this way, each of the electrical valves **39** is activated and opened in the proper timed sequence to admit compressed gas to each of the cylinders **20** to drive the pistons **22** on a downward stroke.

The embodiment illustrated in **Fig.2** and **Fig.3** is effective in causing each of the valves **39** to remain open for a long enough period of time to admit sufficient compressed gas to each of the cylinders **20** of the engine **21** to drive the engine **21**. The length of each of the contacts **65** around the periphery of the housing **53** is sufficient to permit the speed of the engine to be increased when desired by the operator by moving the throttle linkage **35** which actuates the linkage **33** to further open the regulating valve **31** to admit more compressed gas from the tank **23** to the distributor **33**. However, it has been found that the amount of air admitted by the valves **39** when using the first embodiment of the valve actuator **41** (**Fig.2** and **Fig.3**) is substantially more than required to operate the engine **21** at an idling speed. Therefore, it may be desirable to provide a valve actuator **41** which is capable of varying the duration of each engine cycle over which the solenoid valves **39** are actuated, i.e., remain open to admit compressed gas, as the speed of the engine **21** is varied.

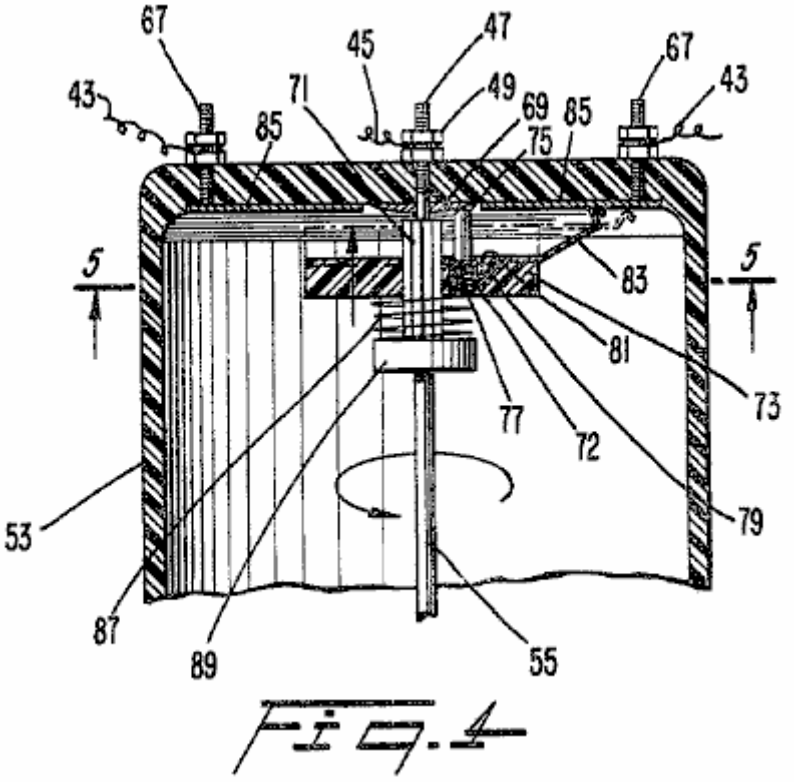

Fig. 4

A second embodiment of a valve actuator **41** which is capable of varying the duration of each engine cycle over which each of the valves **39** remains open to admit compressed gas to the cylinders **20** dependent upon the speed of the engine **21** will be described with reference to **Fig.4** and **Fig.5** wherein members corresponding to those of **Fig.2** and **Fig.3** bear like reference numbers. The wire **45** from the electricity source is attached to the post **47** by the nut **49**. The post **47** has a annular contact ring **69** electrically connected to an end of the post **47** and arranged within the housing **53**. The shaft **55** rotates at one half the speed of the engine as in the embodiment of **Fig.2** and **Fig.3**.

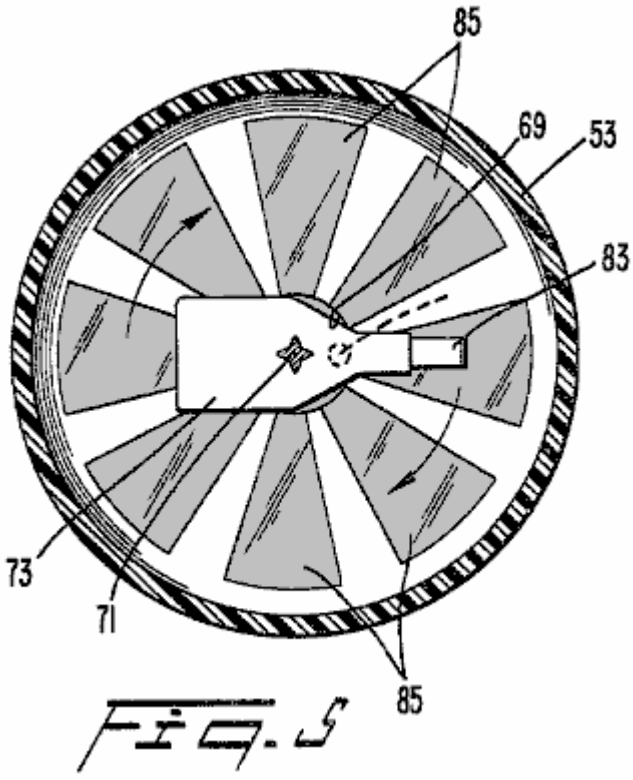

Fig. 5

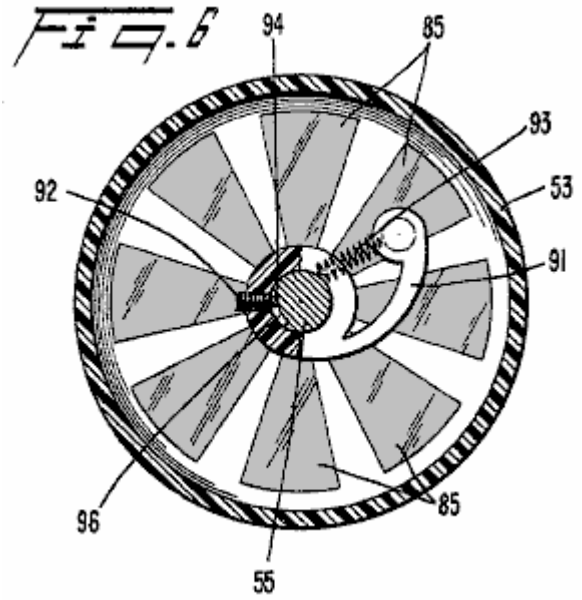
At an upper end of the shaft **55**, a splined section **71** receives a sliding insulating member **73**. The splined section **71** of the shaft **55** holds the insulating member **73** securely as it rotates with shaft **55** but permits the insulating member **73** to slide axially along the length of the splined section **71**. Near the shaft **55**, a conductive sleeve **72** is arranged in a bore **81** in an upper surface of the insulating element **73** generally parallel to the splined section **71**.

A contact **75**, biased towards the annular contact ring **69** by a spring **77**, is arranged within the conductive sleeve **72** and in contact with it. The conductive sleeve **72** also contacts a conductor **79** at a base of the bore **81**.

The conductor **79** extends to the upper surface of the insulating element **73** near an outer periphery of the insulating element **73** where the conductor **79** is electrically connected to a flexible contact **83**. The flexible contact **83** connects, one after the other, with a series of radial contacts **85** which are positioned on an upper inside surface of the housing **53**. A weak spring **87** arranged around the splined section **71** engages a stop member **89** secured on the shaft **55** and the insulating element **73** to slightly bias the insulating element **73** towards the upper inside surface of the housing **53** to ensure contact between the flexible contact **83** and the upper inside surface of the housing **53**. As best seen in **Fig.5**, the radial contacts **85** on the upper inside surface of the housing **53** are arranged generally in the form of radial spokes extending from the centre of the housing **53** with the number of contacts being equal to the number of cylinders **20** in the engine **21**. The number of degrees covered by each of the radial contacts **85** gradually increases as the distance from the centre of the upper inside surface of the housing **53** increases.

In operation of the device of **Fig.4** and **Fig.5**, as the shaft **55** rotates, electricity flows along a path through the wire **45** down through post **47** to the annular contact member **69** which is in constant contact with the spring biased contact **75**. The electrical current passes through the conductive sleeve **72** to the conductor **79** and then to the flexible contact **83**. As the flexible contact **83** rotates along with the insulating member **73** and the shaft **55**, the tip of the flexible contact **83** successively engages each of the radial contacts **85** on the upper inside of the housing **53**. As the speed of the shaft **55** increases, the insulating member **73** and the flexible contact **83** attached to it, move upwards along the splined section **71** of the shaft **55** due to the radial component of the splines in the direction of rotation under the influence of centrifugal force. As the insulating member **73** moves upwards, the flexible contact **83** is bent so that the tip of the contact **83** extends further outwards radially from the centre of the housing **53** (as seen in phantom lines in **Fig.4**). In other words, the effective length of the flexible contact **83** increases as the speed of the engine **21** increases.

As the flexible contact **83** is bent and the tip of the contact **83** moves outwards, the tip remains in contact with each of the radial contacts **85** for a longer period of each engine cycle due to the increased angular width of the radial contacts with increasing distance from the centre of the housing **53**. In this way, the length of time over which each of the valves **39** remains open is increased as the speed of the engine is increased. Thus, a larger quantity of compressed gas or air is injected into the cylinders as the speed increases. Conversely, as the speed decreases and the insulating member **73** moves downwards along the splined section **71**, a minimum quantity of air is injected into the cylinder due to the shorter length of the individual radial contact **85** which is in contact with the flexible contact **83**. In this way, the amount of compressed gas that is used during idling of the engine **21** is at a minimum whereas the amount of compressed gas which is required to increase the speed of the engine **21** to a level suitable to drive a vehicle on a highway is readily available.



Shown in **Fig.6** and **Fig.7**, is a third embodiment of a valve actuator **41** according to the present invention. This embodiment includes a curved insulating element **91** having it's first end able to pivot, being secured by any suitable device such as screw **92** to the shaft **55** for co-rotation with the shaft **55**. The screw **92** is screwed into a tapped hole in the insulating element **91** so that a tab **94** at an end of the screw **92** engages a groove **96** provided in the shaft **55**. In this way, the insulating element **91** rotates positively with the shaft **55**. However, as the shaft **55**

rotates faster, the other end **98** of the insulating element **91** is permitted to pivot outwards under the influence of centrifugal force because of the groove **96** provided in the shaft **55**. A spring **93**, connected between the second end **98** of the element **91** and the shaft **55** urges the second end of the element **91** towards the centre of the housing **53**.

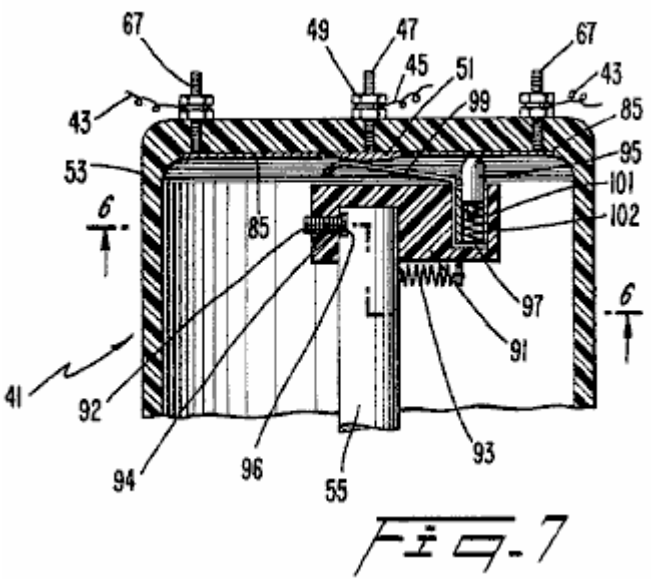


Fig. 7

A contact **99** similar to the contact **59** (Fig.2) is arranged so that one end of the contact piece **99** is in constant contact with the conducting plate **51** located centrally within the housing **53**. The other end of the contact **99** engages a conductive sleeve **101** arranged in bore **102**. A contact element **95** is arranged in the conductive sleeve **101** in constant contact with the sleeve **101**. The bore **102** is arranged generally parallel to the shaft **55** near the second end of the curved insulating element **91**. The contact **95** is biased by a spring **97** towards the upper inside surface of the housing **53** for selective contact with each of the plurality of radial contacts **85** which increase in arc length towards the outer peripheral surface of the housing **53** (**Fig.6**).

When the device shown in **Fig.6** and **Fig.7** is operating, as the shaft **55** rotates the curved insulating element **91** rotates with the shaft **55** and the second end **98** of the insulating element **91** tends to pivot about the shaft **55** due to centrifugal force. Thus, as the effective length of the contact **95** increases, i.e., as the curved insulating element **91** pivots further outwards, the number of degrees of rotation over which the contact **95** is in contact with each of the radial contacts **85** on the upper inside surface of the housing **53** increases thereby allowing each of the valves **39** to remain open for a longer period of each engine cycle, which in turn, allows more compressed gas enter the respective cylinder **20** to further increase the speed of the engine **21**.

With reference to **Fig.1**, a mechanical advance linkage **104** which is connected to the throttle linkage **35**, advances the initiation of the opening of each valve **39** such that compressed gas is injected into the respective cylinder further before the piston **22** in the respective cylinder **20** reaches a Top Dead Centre position as the speed of the engine is increased by moving the throttle linkage **35**. The advance linkage **104** is similar to a conventional standard mechanical advance employed on an internal combustion engine. In other words, the linkage **104** varies the relationship between the angular positions of a point on the shaft **55** and a point on the housing **53** containing the contacts. Alternatively, a conventional vacuum advance could also be employed. By advancing the timing of the opening of the valves **39**, the speed of the engine can more easily be increased.

The operation of the engine cycle according to the present invention will now be described. The compressed gas injected into each cylinder of the engine **21** drives the respective piston **22** downwards to rotate a conventional crankshaft (not shown). The movement of the piston downwards causes the compressed gas to expand rapidly and cool. As the piston **22** begins to move upwards in the cylinder **20** a suitable exhaust valve (not shown), arranged to close an exhaust passageway, is opened by any suitable apparatus. The expanded gas is then expelled through the exhaust passageway. As the piston **22** begins to move downwards again, a suitable intake valve opens to admit ambient air to the cylinder. The intake valve closes and the ambient air is compressed on the subsequent upward movement of the piston until the piston reaches approximately the Top Dead Centre position at which time the compressed gas is again injected into the cylinder **20** to drive the piston **22** downwards and the cycle begins again.

In the case of adapting a conventional internal combustion engine for operation on compressed gas, a plurality of plates **103** are arranged, preferably over an end of the exhaust passageways, in order to reduce the outlet size of the exhaust passageways of the conventional internal combustion engine. In the illustrated embodiment, a single

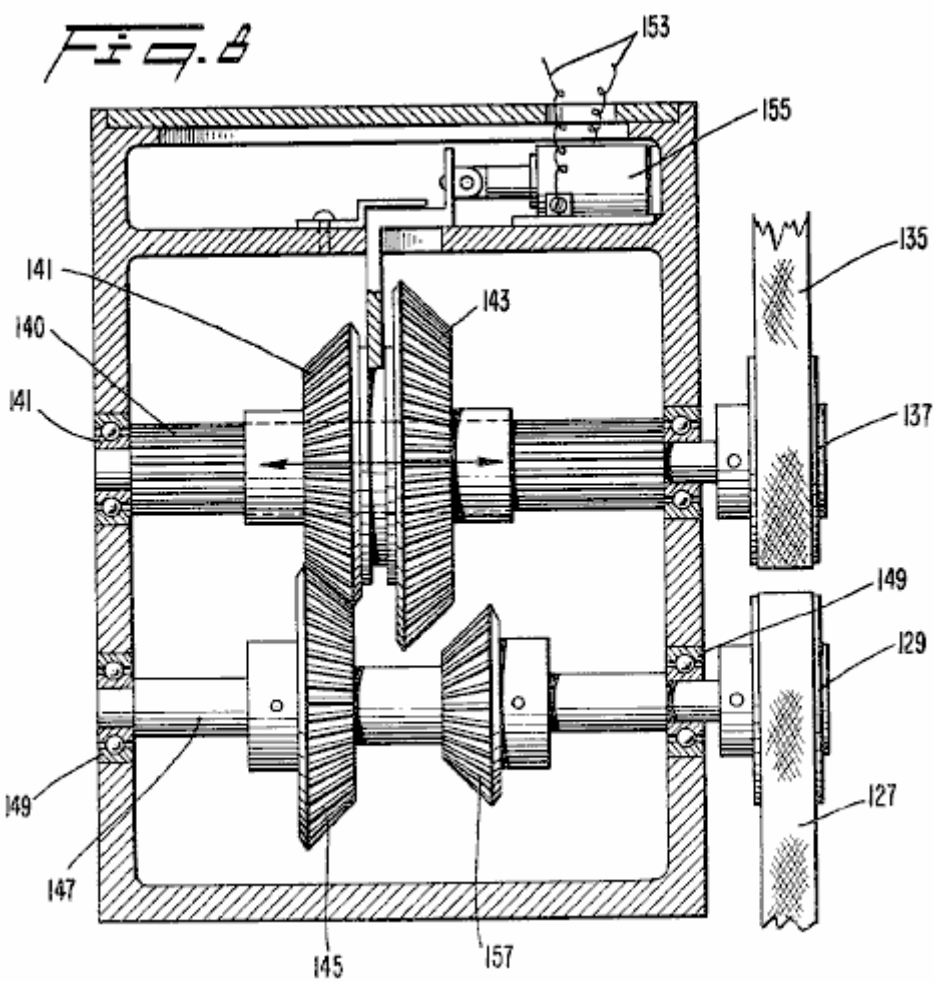
plate having an opening in the centre is bolted to the outside exhaust passageway on each bank of the V-8 engine, while another single plate having two openings in it, is arranged with one opening over each of the interior exhaust passageways on each bank of the V-8 engine. A line **105** is suitably attached to each of the adaptor plates to carry the exhaust to an appropriate location. In a preferred embodiment, the exhaust lines **105** are made from 1.5" plastic tubing.

In a preferred embodiment, the exhaust lines **105** of one bank of the V-8 engine are collected in a line **107** and fed to an inlet of a compressor **109**. The pressure of the exhaust gas emanating from the engine **21** according to the present invention is approximately 25 p.s.i. In this way, the compressor **109** does not have to pull the exhaust into the compressor since the gas exhausted from the engine **21** is at a positive pressure. The positive pressure of the incoming fluid increases the efficiency and reduces wear on the compressor **109**. The exhaust gas is compressed in the compressor **109** and returned through a line **111** and a check valve **113** to the compressed gas storage tank **23**. The check valve **113** prevents the flow of compressed gas stored in the tank **23** back towards the compressor **109**.

A suitable pressure sensor **115** is arranged at an upper end of the tank **23** and sends a signal along a line **117** when the pressure exceeds a predetermined level and when the pressure drops below a predetermined level. The line **117** controls an electrically activated clutch **119** positioned at the front end of the compressor **109**. The clutch **119** is operated to engage and disengage the compressor **109** from a drive pulley **121**. Also, the signal carried by the line **117** activates a suitable valve **123** arranged on compressor housing **125** to exhaust the air entering the compressor housing **125** from the line **107** when the clutch **119** has disengaged the compressor **109** from the drive pulley **121**.

In a preferred embodiment, when the pressure is the tank **23** reaches approximately 600 p.s.i., the clutch **119** is disengaged and the compressor **109** is deactivated and the valve **123** is opened to exhaust the expanded gas delivered to the compressor **109** from the line **107** to the atmosphere. When the pressure within the tank **23** drops below approximately 500 p.s.i., the sensor **115** sends a signal to engage the clutch **119** and close the valve **123**, thereby operating the compressor **109** for supplying the tank **23** with compressed gas.

The pulley **121** which drives the compressor **109** through the clutch **119** is driven by a belt **127** which is driven by a pulley **129** which operates through a gear box **131**. With reference to **Fig.1** and **Fig.8**, a second pulley **133** on the gear box is driven by a belt **135** from a pulley **137** arranged on a drive shaft **139** of the engine **21**. The pulley **137** drives a splined shaft **140** which has a first gear **141** and a second larger gear **143** placed on it, which rotates with the splined shaft **140**. The splined shaft **140** permits axial movement of the gears **141** and **143** along the shaft **140**.



In normal operation (as seen in **Fig.8**), the first gear **141** engages a third gear **145** arranged on a shaft **147** which drives the pulley **129**. The shafts **140** and **147** are arranged in suitable bearings **149** positioned at each end of it. When the speed of the engine **21** drops below a predetermined level, a suitable sensor **151** responsive to the speed of the drive shaft **139** of the engine **21** generates a signal which is transmitted through a line **153** to a solenoid actuator **155** arranged within the gear box **131**. The solenoid actuator **155** moves the first and second gears **141**, **143** axially along the splined shaft **140** to the right as seen in **Fig.8** so that the second, larger gear **143** engages a fourth smaller gear **157** which is arranged on the shaft **147**. The ratio of the second gear **143** to the fourth gear **157** is preferably approximately 3 to 1.

In this way, when the speed of the engine **21** drops below the predetermined level as sensed by the sensor **151** (which predetermined level is insufficient to drive the compressor **109** at a speed sufficient to generate the 500-600 pounds of pressure which is preferably in the tank **23**), the solenoid actuator **155** is energised to slide the gears **143**, **141** axially along the splined shaft **140** so that the second, larger gear **143** engages the fourth, smaller gear **157** to drive the pulley **129** and hence the compressor **109** at a higher rate, to generate the desired pressure. When the speed of the engine increases above the predetermined level, which, in a preferred embodiment is approximately 1500 rpm, the solenoid actuator **155** is deactivated by the sensor **151** thereby moving the gears **143** and **141** to the left as seen in **Fig.8** so that the first gear **141**, engages again with the third gear **145** to effectuate a 1 to 1 ratio between the output shaft **139** of the engine **21** and the pulley **129**.

The other bank of the V-8 engine has its exhaust ports arranged with adapter plates **103** similar to those on the first bank. However, the exhaust from this bank of the engine **21** is not collected and circulated through the compressor **109**. In a preferred embodiment, a portion of the exhaust is collected in a line **159** and fed to an enlarged chamber **161**. A second fluid is fed through a line **163** into the chamber **161** to be cooled by the cool exhaust emanating from the engine **21** in the line **159**. The second fluid in the line **163** may be either transmission fluid contained in a transmission associated with the engine **21** or a portion of the oil used to lubricate the engine **21**. A second portion of the exhaust from the second bank of the V-8 engine is removed from the line **159** in a line **165** and used as a working fluid in an air conditioning system or for any other suitable use.

It should be noted that the particular arrangement utilised for collecting and distributing the gas exhausted from the engine **21** would be determined by the use for which the engine is employed. In other words, it may be

advantageous to rearrange the exhaust tubing such that a larger or smaller percentage of the exhaust is routed through the compressor **109**. It should also be noted that since the exhaust lines **105** are plastic tubing, a rearrangement of the lines for a different purpose is both simple and inexpensive.

In operation of the engine of the present invention, the engine **21** is started by energising the solenoid valve **29** and any suitable starting device (not shown), e.g., a conventional electric starter as used on an internal combustion engine. Compressed gas from the full tank **23** flows through the line **25** and a variable amount of the compressed gas is admitted to the distributor **33** by controlling the regulator valve **31** through the linkage **33** and the operator actuated throttle linkage **35**. The compressed gas is distributed to each of the lines **37** which lead to the individual cylinders **20**. The compressed gas is admitted to each of the cylinders **20** in timed relationship to the position of the pistons within the cylinders by opening the valves **39** with the valve actuator **41**.

When it is desired to increase the speed of the engine, the operator moves the throttle linkage **35** which simultaneously admits a larger quantity of compressed gas to the distributor **33** from the tank **23** by further opening the regulator valve **31**. The timing of the valve actuator **41** is also advanced through the linkage **104**. Still further, as the speed of the engine **21** increases, the effective length of the rotating contact **83** (**Fig.4**) or **95** (**Fig.6**) increases thereby electrically contacting a wider portion of one of the stationary radial contacts **85** to cause each of the valves **39** to remain open for a longer period of each engine cycle to admit a larger quantity of compressed gas to each of the cylinders **20**.

As can be seen, the combination of the regulating valve **31**, the mechanical advance **104**, and the valve actuator **41**, combine to produce a compressed gas engine which is quickly and efficiently adaptable to various operating speeds. However, all three of the controls need not be employed simultaneously. For example, the mechanical advance **104** could be utilised without the benefit of one of the varying valve actuators **41** but the high speed operation of the engine may not be as efficient. By increasing the duration of each engine cycle over which each of the valves **39** remains open to admit compressed gas to each of the cylinders **20** as the speed increases, conservation of compressed gas during low speed operation and efficient high speed operation are both possible.

After the compressed gas admitted to the cylinder **20** has forced the piston **22** downwards within the cylinder to drive the shaft **139** of the engine, the piston **22** moves upwards within the cylinder **20** and forces the expanded gas out through a suitable exhaust valve (not shown) through the adapter plate **103** (if employed) and into the exhaust line **105**. The cool exhaust can then be collected in any suitable arrangement to be compressed and returned to the tank **23** or used for any desired purpose including use as a working fluid in an air conditioning system or as a coolant for oil.

When using the apparatus and method of the present invention to adapt a ordinary internal combustion engine for operation with compressed gas it can be seen that considerable savings in weight are achieved. For example, the ordinary cooling system including a radiator, fan, hoses, etc. can be eliminated since the compressed gas is cooled as it expands in the cylinder. In addition, there are no explosions within the cylinder to generate heat. Further reductions in weight are obtained by employing plastic tubing for the lines which carry the compressed gas between the distributor and the cylinders and for the exhaust lines. Once again, heavy tubing is not required since there is little or no heat generated by the engine of the present invention. In addition, the noise generated by an engine according to the present invention is considerably less than that generated by an ordinary internal combustion engine since there are no explosions taking place within the cylinders.

The principles of preferred embodiments of the present invention have been described in the foregoing specification. However, the invention which is intended to be protected is not to be construed as limited to the particular embodiments disclosed. The embodiments are to be regarded as illustrative rather than restrictive. Variations and changes may be made by others without departing from the spirit of the invention. Accordingly, it is expressly intended that all such variations and changes which fall within the spirit and the scope of the present invention as defined in the appended claims be embraced thereby.

Eber Van Valkinburg's Compressed Fluid Engine

Patent US 3,744,252 10th July 1973 Inventor: Eber Van Valkinburg

CLOSED MOTIVE POWER SYSTEM UTILISING COMPRESSED FLUIDS

ABSTRACT

Stored energy in a compressed elastic fluid is utilised in a controlled manner to pressurise an inelastic fluid and to maintain such pressurisation. The pressurised inelastic fluid is throttled to the impeller of a prime mover. Only a portion of the output energy from the prime mover is utilised to circulate the inelastic fluid so as to maintain a nearly constant volumetric balance in the system.

DESCRIPTION

The objective of the invention is to provide a closed-loop power system which utilises the expansive energy of a compressed elastic fluid, such as air, to pressurise and maintain pressurised throughout the operational cycle of the system a second non-elastic and non-compressible fluid, such as oil. The pressurised non-elastic fluid is released in a controlled manner by a throttle to the rotary impeller of a turbine or the like, having an output shaft. This shaft is coupled to a pump for the non-elastic fluid which automatically maintains the necessary circulation needed for the operation of the prime mover, and maintains a near volumetric balance in the system between the two fluids which are separated by self-adjusting free piston devices. The pump for the non-elastic fluid includes an automatic by-pass for the non-elastic fluid which eliminates the possibility of starving the pump which depends on the discharge of the non-elastic fluid at low pressure from the exhaust of the turbine. Other features and advantages of the invention will become apparent during the course of the following detailed description.

BRIEF DESCRIPTION OF DRAWING FIGURES

Fig.1 is a partly schematic cross-sectional view of a closed motive power system embodying the invention.

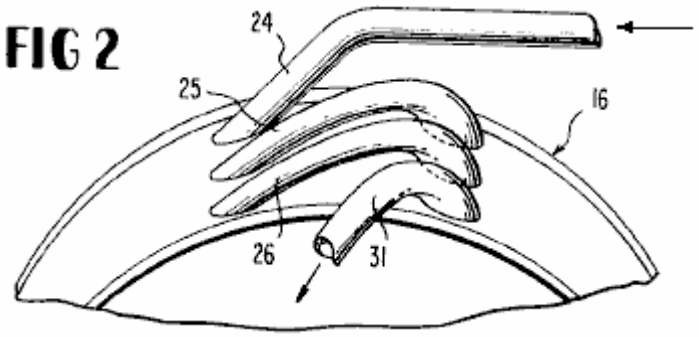


Fig.2 is a fragmentary perspective view of a rotary prime mover utilised in the system.

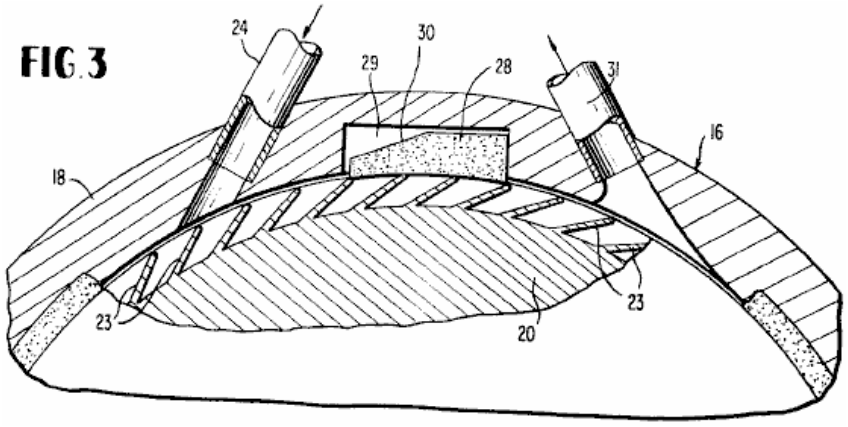

Fig.3 is an enlarged fragmentary vertical section through the prime mover taken at right angles to its rotational axis.

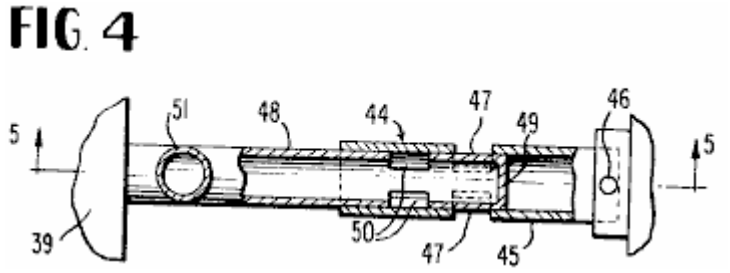

Fig.4 is an enlarged fragmentary vertical section taken on line **4--4** of **Fig.1**.

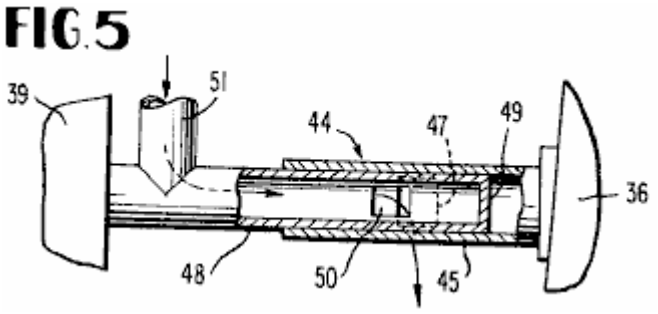

Fig.5 is a similar section taken on line **5--5** of **Fig.4**.

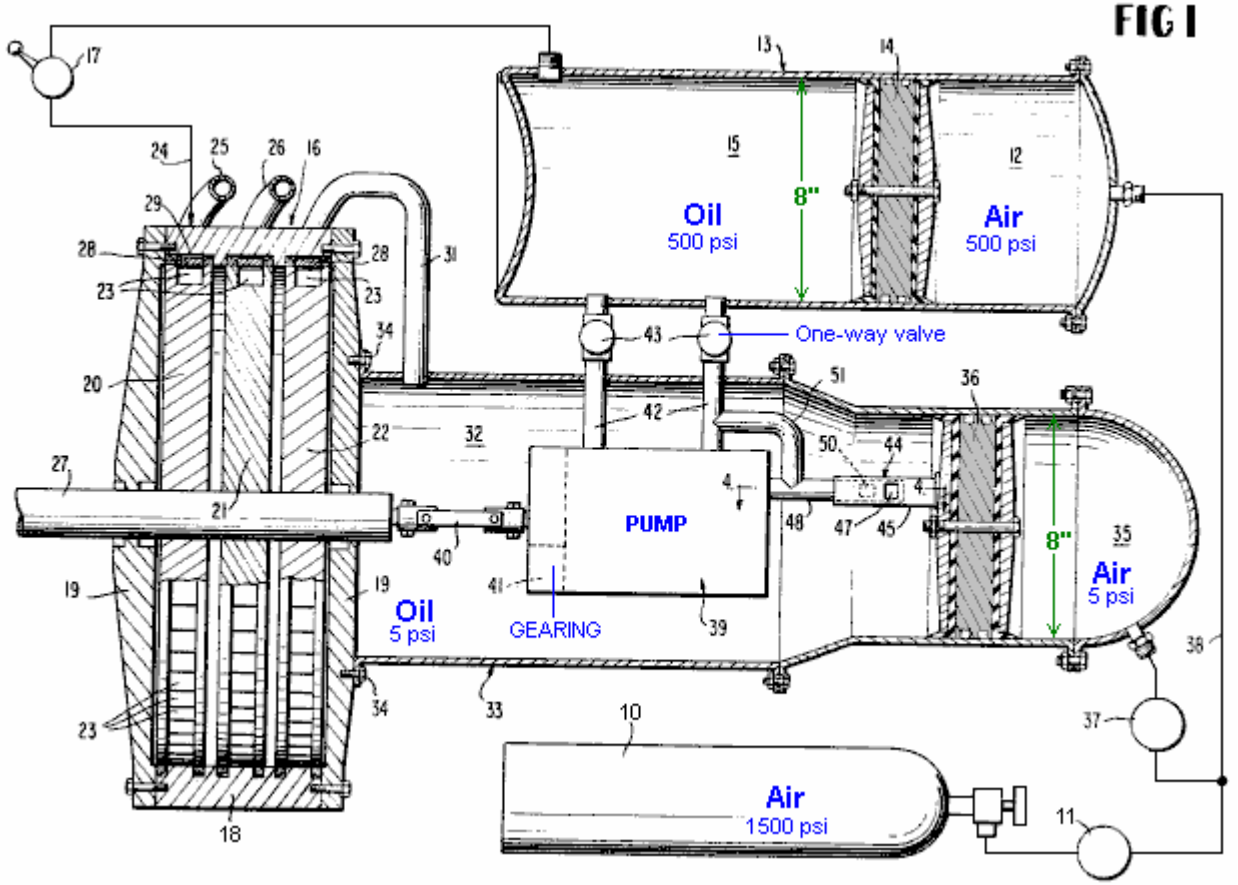
DETAILED DESCRIPTION

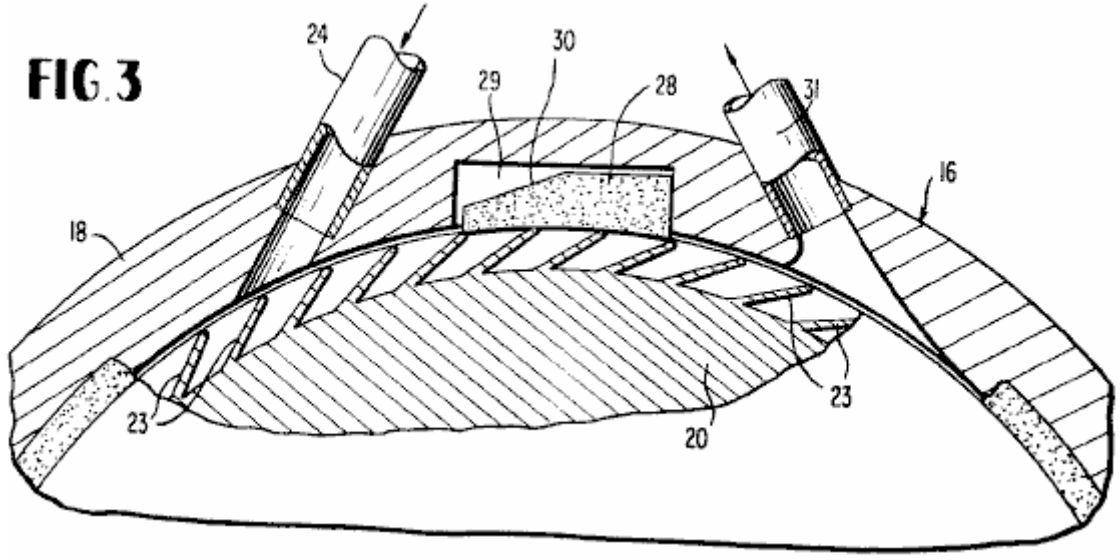


Referring to the drawings in detail, in which the same numbers refer to the same parts in each drawing, the numeral **10** designates a supply bottle or tank for a compressed elastic fluid, such as air. Preferably, the air in the bottle **10** is compressed to approximately 1,500 p.s.i. The compressed air from the bottle **10** is delivered through a suitable pressure regulating valve **11** to the chamber **12** of a high pressure tank **13** on one side of a free piston **14** in the bore of such tank. The free piston **14** separates the chamber **12** for compressed air from a second chamber **15** for an inelastic fluid, such as oil, on the opposite side of the free piston. The free piston **14** can move axially within the bore of the cylindrical tank **13** and is constantly self-adjusting there to maintain a proper volumetric balance between the two separated fluids of the system. The free piston has the ability to maintain the two fluids, air and oil, completely separated during the operation of the system.

The regulator valve **11** delivers compressed air to the chamber **12** under a pressure of approximately 500 p.s.i. The working inelastic fluid, oil, which fills the chamber **15** of high pressure tank **13** is maintained under 500 p.s.i. pressure by the expansive force of the elastic compressed air in the chamber **12** on the free piston **14**. The oil in the chamber **15** is delivered to a prime mover **16**, such as an oil turbine, through a suitable supply regulating or throttle valve **17** which controls the volume of pressurised oil delivered to the prime mover.

The turbine **16** embodies a stator consisting of a casing ring **18** and end cover plates **19** joined to it in a fluid- tight manner. It further embodies a single or plural stage impeller or rotor having bladed wheels **20**, **21** and **22** in the illustrated embodiment. The peripheral blades **23** of these turbine wheels receive the motive fluid from the pressurised chamber **15** through serially connected nozzles **24**, **25** and **26**, connected generally tangentially through the stator ring **18**, as shown in **Fig.3**. The first nozzle **24** shown schematically in **Fig.1** is connected directly with the outlet of the throttle valve **17**. The successive nozzles **25** and **26** deliver the pressurised working fluid serially to the blades **23** of the turbine wheels **21** and **22**, all of the turbine wheels being suitably coupled to a central axial output or working shaft **27** of the turbine **16**.

FIG. 3



Back-pressure sealing blocks **28**, made of fibre, are contained within recesses **29** of casing ring **18** to prevent co-mingling of the working fluid and exhaust at each stage of the turbine. A back-pressure sealing block **28** is actually only required in the third stage between inlet **26** and exhaust **31**, because of the pressure distribution, but such a block can be included in each stage as shown in **Fig.1**. The top surface, including a sloping face portion **30** on each block **28**, reacts with the pressurised fluid to keep the fibre block sealed against the adjacent, bladed turbine wheel; and the longer the slope on the block to increase it's top surface area, the greater will be the sealing pressure pushing it against the periphery of the wheel.

Leading from the final stage of the turbine **16** is a low-pressure working fluid exhaust nozzle **31** which delivers the working fluid, oil, into an oil supply chamber or reservoir **32** of a low pressure tank **33** which may be bolted to the adjacent end cover plate **19** of the turbine, as indicated at **34**. The oil entering the reservoir chamber **32** from the exhaust stage of the turbine is at a pressure of about 3-5 p.s.i. In a second chamber **35** of the low pressure tank **33** separated from the chamber **32** by an automatically moving or self-adjusting free piston **36**, compressed air at a balancing pressure of from 3-5 p.s.i. is maintained by a second pressure regulating valve **37**. The pressure regulating valve **37** is connected with the compressed air supply line **38** which extends from the regulating valve **11** to the high pressure chamber **12** for compressed air.

Within the chamber **32** is a gear pump **39** or the like having its input shaft connected by a coupling **40** with the turbine shaft **27**. Suitable reduction gearing **41** for the pump may be provided internally, as shown, or in any other conventional manner, to gear down the rotational speed derived from the turbine shaft. The pump **39** is supplied with the oil in the filled chamber **32** delivered by the exhaust nozzle or conduit **31** from the turbine. The pump, as illustrated, has twin outlet or delivery conduits **42** each having a back-pressure check valve **43** connected therein and each delivering a like volume of pressurised oil back to the high pressure chamber **15** at a pressure of about 500 p.s.i. The pump **39** also has twin fluid inlets. The pump employed is preferably of the type known on the market as "Hydreco Tandem Gear Pump," Model No. 151515, L12BL, or equivalent. In some models, other types of pumps could be employed including pumps having a single inlet and outlet. The illustrated pump will operate clockwise or counter-clockwise and will deliver 14.1 g.p.m. at 1,800 r.p.m. and 1,500 p.s.i. Therefore, in the present application of the pump **39**, it will be operating at considerably less than capacity and will be under no undue stress.

FIG. 4

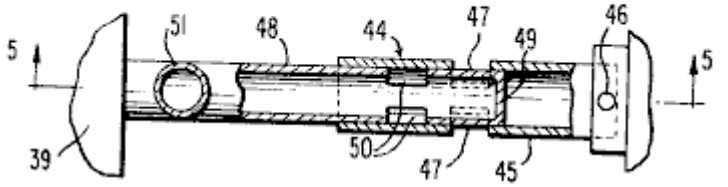


FIG.5

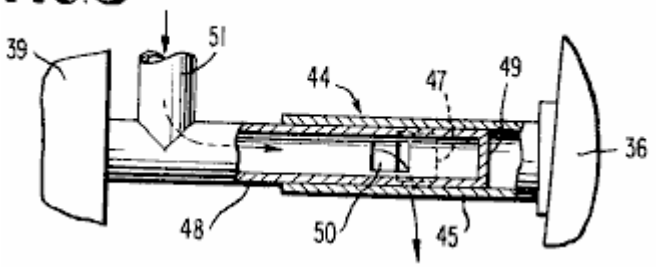

Since the pump depends for its supply of fluid on the delivery of oil at low pressure from the turbine **16** into the chamber **32**, an automatically operating by-pass sleeve valve device **44** for oil is provided as indicated in **Fig.1**, **Fig.4** and **Fig.5**. This device comprises an exterior sleeve or tube **45** having one end directly rigidly secured as at **46** to the movable free piston **36**. This sleeve **45** is provided with slots **47** intermediate its ends. A co-acting interior sleeve **48** engages telescopically and slidably within the sleeve **45** and has a closed end wall **49** and ports or slots **50** intermediate its ends, as shown. The sleeve **48** communicates with one of the delivery conduits **42** by way of an elbow **51**, and the sleeve **48** is also connected with the adjacent end of the pump **39**, as shown.

As long as the chamber **32** is filled with low pressure oil sufficient to balance the low air pressure in the chamber **35** on the opposite side of free piston **36**, such piston will be positioned as shown in **Fig.1** and **Fig.4** so that the slots **47** and **50** of the two sleeves **45** and **48** are out of registration and therefore no flow path exists through them. Under such circumstances, the oil from the chamber **32** will enter the pump and will be delivered by the two conduits **42** at the required pressure to the chamber **15**. Should the supply of oil from the turbine **16** to the chamber **32** diminish so that pump **39** might not be adequately supplied, then the resulting drop in pressure in the chamber **32** will cause the free piston **36** to move to the left in **Fig.1** and bring the slots **47** into registration or partial registration with the slots **50**, as depicted in **Fig.5**. This will instantly establish a by-pass for oil from one conduit **42** back through the elbow **51** and tubes **48** and **45** and their registering slots to the oil chamber **32** to maintain this chamber filled and properly pressurised at all times. The by-pass arrangement is completely automatic and responds to a diminished supply of oil from the turbine into the chamber **32**, so long as the required compressed air pressure of 3-5 p.s.i. is maintained in the chamber **35**.

Briefly, in summary, the system operates as follows. The pressurised inelastic and non-compressible fluid, oil, from the chamber **15** is throttled into the turbine **16** by utilising the throttle valve **17** in a control station. The resulting rotation of the shaft **27** produces the required mechanical energy or work to power a given instrumentality, such as a propeller. A relatively small component of this work energy is utilised through the coupling **40** to drive the pump **39** which maintains the necessary volumetric flow of oil from the turbine back into the high pressure chamber **15**, with the automatic by-pass **44** coming into operation whenever needed.

The ultimate source of energy for the closed power system is the compressed elastic fluid, air, in the tank or bottle **10** which through the regulating valves **11** and **37** maintains a constant air pressure in the required degree in each of the chambers **12** and **35**. As described, the air pressure in the high pressure chamber **12** will be approximately 500 p.s.i. and in the low pressure chamber **35** will be approximately 3-5 p.s.i.

It may be observed in **Fig.1** that the tank **33** is enlarged relative to the tank **13** to compensate for the space occupied by the pump and associated components. The usable volumes of the two tanks are approximately equal.

In an operative embodiment of the invention, the two free pistons **14** and **36** and the tank bores receiving them are 8 inches in diameter. The approximate diameters of the bladed turbine wheels are 18 inches. The pump **39** is approximately 10 inches long and 5 inches in diameter. The tank **13** is about 21 inches long between its crowned end walls. The tank **33** is 10 inches in diameter adjacent to the pump **39**.

The terms and expressions which have been employed herein are used as terms of description and not of limitation, and there is no intention, in the use of such terms and expressions, of excluding any equivalents of the features shown and described or portions thereof but it is recognised that various modifications are possible within the scope of the invention claimed.

Josef Papp's Inert Gas Engine

US Patent 4,428,193 **31st January 1984** **Inventor: Josef Papp**

INERT GAS FUEL, FUEL PREPARATION APPARATUS AND SYSTEM FOR EXTRACTING USEFUL WORK FROM THE FUEL

ABSTRACT

An inert gas fuel consisting essentially of a precise, homogeneous mixture of helium, neon, argon, krypton and xenon. Apparatus for preparing the fuel includes a mixing chamber, tubing to allow movement of each inert gas into and through the various stages of the apparatus, a plurality of electric coils for producing magnetic fields, an ion gauge, ionises, cathode ray tubes, filters, a polarise and a high frequency generator. An engine for extracting useful work from the fuel has at least two closed cylinders for fuel, each cylinder being defined by a head and a piston. A plurality of electrodes extend into each chamber, some containing low level radioactive material. The head has a generally concave depression facing a generally semi-toroidal depression in the surface of the piston. The piston is axially movable with respect to the head from a first position to a second position and back, which linear motion is converted to rotary motion by a crankshaft. The engine's electrical system includes coils and condensers which circle each cylinder, an electric generator, and circuitry for controlling the flow of current within the system.

BACKGROUND OF THE INVENTION

This invention relates to closed reciprocating engines, i.e., ones which do not require an air supply and do not emit exhaust gases, and more particularly to such engines which use inert gases as fuel. It also concerns such inert gas fuels and apparatus for preparing same.

Currently available internal combustion engines suffer from several disadvantages. They are inefficient in their utilisation of the energy present in their fuels. The fuel itself is generally a petroleum derivative with an ever-increasing price and sometimes limited availability. The burning of such fuel normally results in pollutants which are emitted into the atmosphere. These engines require oxygen and, therefore, are particularly unsuitable in environments, such as underwater or outer space, in which gaseous oxygen is relatively unavailable. Present internal combustion engines are, furthermore, relatively complex with a great number of moving parts. Larger units, such as fossil-fuel electric power plants, escape some of the disadvantages of the present internal combustion engine, but not, inter alia, those of pollution, price of fuel and availability of fuel.

Several alternative energy sources have been proposed, such as the sun (through direct solar power devices), nuclear fission and nuclear fusion. Due to the lack of public acceptance, cost, other pollutants, technical problems, and/or lack of development, these sources have not wholly solved the problem.
Moreover, the preparation of fuel for nuclear fission and nuclear fusion reactors has heretofore been a complicated process requiring expensive apparatus.

SUMMARY OF THE INVENTION

Among the several objects of the present invention may be noted the provision of an engine which is efficient; the provision of an engine which does not require frequent refuelling; the provision of an engine which develops no pollutants in operation; the provision of an engine which is particularly suited for use in environments devoid of free oxygen; the provision of an engine which requires no oxygen in operation; the provision of an engine having a relatively small number of moving parts; the provision of an engine of a relatively simple construction; the provision of an engine which can be used in light and heavy-duty applications; the provision of an engine which is relatively inexpensive to make and operate; the provision of a fuel which uses widely available components; the provision of a fuel which is relatively inexpensive; the provision of a fuel which is not a petroleum derivative; the provision of relatively simple and inexpensive apparatus for preparing inert gases for use as a fuel; the provision of such apparatus which mixes inert gases in precise, predetermined ratios; and the provision of such apparatus which eliminates contaminants from the inert gas mixture. Other objects and features will be in part apparent and in part pointed out hereinafter.

Briefly, in one aspect the engine of the present invention includes a head having a generally concave depression in it, the head defining one end of a chamber, a piston having a generally semi-toroidal depression in its upper surface, the piston defining the other end of the chamber, and a plurality of electrodes extending into the chamber for exciting and igniting the working fluid. The piston can move along its axis towards and away from the head, causing the volume of the chamber to alter, depending on the position of the piston relative to the head.

In another aspect, the engine of the present invention includes a head which defines one end of the chamber, a piston which defines the other end of the chamber, a plurality of magnetic coils wound around the chamber for generating magnetic fields inside the chamber, and at least four electrodes extending into the chamber for exciting and igniting the working fluid. The magnetic coils are generally coaxial with the chamber. The electrodes are generally equidistantly spaced from the axis of the chamber and are each normally positioned 90 degrees from the adjacent electrodes. Lines between opposed pairs of electrodes intersect generally on the axis of the chamber to define a focal point.

In a further aspect, the engine of the present invention includes a head which defines one end of a chamber, a piston which defines the other end of the chamber, at least two electric coils wound around the chamber for generating magnetic fields inside the chamber, and a plurality of electrodes extending into the chamber for exciting and igniting the working fluid. The electric coils are generally coaxial with the chamber. And the working fluid includes a mixture of inert gases.

The apparatus of the present invention for preparing a mixture of inert gases for use as a fuel includes a chamber, electric coils for generating predetermined magnetic fields inside the chamber, tubing adapted to be connected to sources of preselected inert gases for flow of the gases from the sources to the chamber, and ionisers for ionising the gases.

The fuel of the present invention includes a mixture of inert gases including approximately 36% helium, approximately 26% neon, approximately 17% argon, approximately 13% krypton, and approximately 8% xenon by volume.

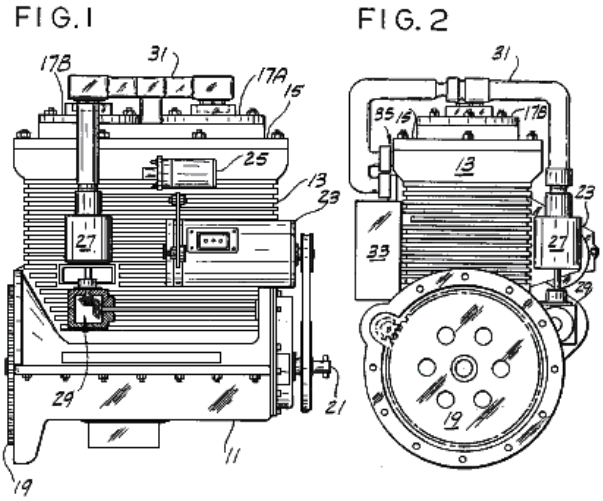
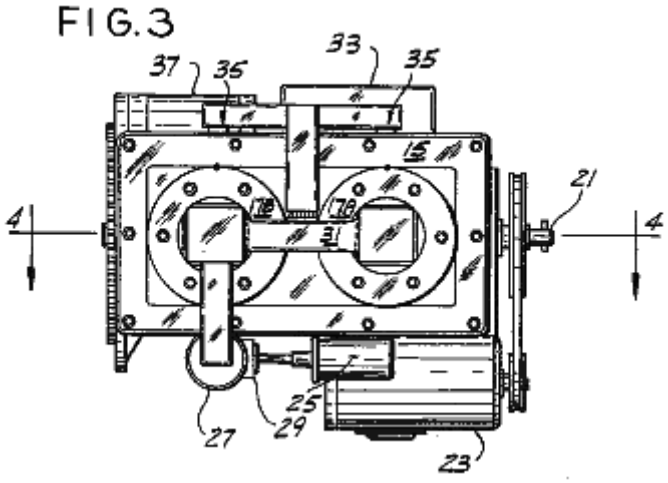
DESCRIPTION OF A PREFERRED EMBODIMENT

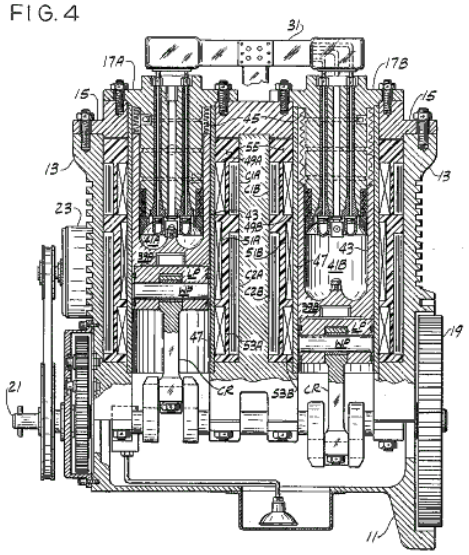


Referring to the drawings, there is shown in **Fig.1** a two-cylinder engine **11** comprising a block **13** preferably of a nonmagnetic material such as aluminium, a nonmagnetic head **15**, and a pair of cylinder heads **17A** and **17B** of a magnetisable material such as 0.1-0.3% carbon steel. Also shown in **Fig.1** is a flywheel **19** attached to a crankshaft **21**, a generator **23**, a high-voltage coil **25**, a distributor **27** attached by a gear arrangement shown in part at **29** to the crankshaft, and an electrical cable **31** which is connected to the distributor and to both cylinders. Cable **31** (see **Fig.2**) is also electrically connected to a switching unit **33** which preferably comprises a plurality of silicon controlled rectifiers (SCRs) or transistors. Also shown in **Fig.2** is a second electrical connection of the cable to the cylinders, which connection is indicated generally at **35**. Turning to **Fig.3**, there is shown a starter motor **37** as well as a clearer view of the connections **35** to each cylinder.



A cross section of the engine is shown in **Fig.4**. The cylinder heads have associated with them, pistons marked **39A** and **39B**, respectively, the heads and pistons define opposite ends of a pair of chambers or cylinders **41A** and **41B** respectively. The pistons are made of a magnetisable material. Although only two chambers are shown, the engine can include any number. It is preferred, however, for reasons set forth below, that there be an even number of cylinders. Pistons **39A** and **39B** move axially with respect to their corresponding heads from a first position (the position of piston **39A** in **Fig.4**) to a second position (the position of piston **39B**) and back, each piston being suitably connected to crankshaft **21**. As shown in **Fig.4**, this suitable connection can include a connecting rod **CR**, a wrist pin **WP**, and a lower piston portion or power piston **LP**. The connecting rods and/or power pistons must be of non-magnetisable material. When a split piston is used, pistons **39A** and **39B** are suitably connected to lower piston portions **LP** by bolting, spring-loaded press fitting, or the like. Pistons **39A** and **39B** are attached 180 degrees apart from each other with respect to the crankshaft so that when one piston is at top dead centre (TDC) the other will be at bottom dead centre (BDC) and vice versa. Additional pairs of cylinders may be added as desired but the pistons of each pair should be attached to the crankshaft 180 degrees from each other. Of course, the relative position of each piston with respect to its respective head determines the volume of its chamber.

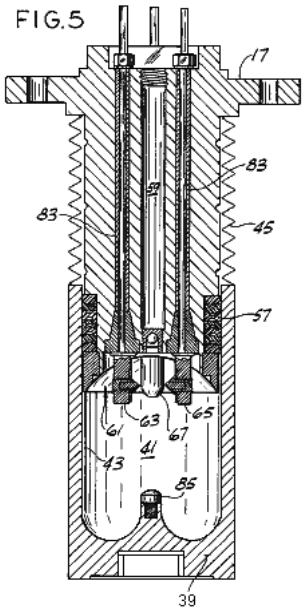
FIG. 4



Integral with the piston bodies are walls **43** which form the walls of the chambers. Preferably, a set of air-tight bellows **45**, of similar construction to that sold under the designation ME 197-0009-001 by the Belfab Company of Daytona Beach, Fla., are suitably secured between walls **43** and cylinder heads **17A** and **17B** respectively to form an airtight seal between each piston and its cylinder head. While walls **43** and piston **39** can be made of one magnetisable piece, a preferable and more efficient construction has walls **43** separate from piston **39** and made of a non-magnetisable material. The length of time that a given engine will run is a function of the efficacy of its sealing system. Means, such as bellows **45**, for hermetically sealing the cylinders will optimise said length of time. Such a hermetic seal should be secured between walls **43** and cylinder heads **17** to form an airtight seal between them. This seal could be the airtight bellows system shown or some other sealing system such as an oil sealing system.

Cylinder bodies **47** (see **Fig.4**), made of nonmagnetic material such as stainless steel, extend from the point of attachment of each bellows to its cylinder head to the base of the corresponding pistons, forming sleeves for each piston in which each piston moves. Three sets of electric coils **49A, 49B, 51A, 51B**, and **53A, 53B**, are wound around sleeves **47**, and hence around chambers **41A** and **41B**, respectively, for generating magnetic fields in the chambers, those coils being generally coaxial with their respective chambers. Each of these coils has an inductance of approximately 100 mH. It is preferred that 14-19 gauge wire be used to wind these coils and that the coils be coated with a suitable coating, such as #9615 hardener from Furane Plastics, Inc., of Los Angeles, California, or the coating sold by the Epoxylite Corp. of South El Monte, California under the trade designation Epoxylite 8683. Each chamber is also surrounded by a pair of capacitors, **C1A**, **C1B** and **C2A, C2B** wound around it, capacitors **C1A**, **C1B** having a capacitance of approximately 1.3 microfarads and capacitors **C2A, C2B** having a capacitance of approximately 2.2 microfarads. The coils and capacitors are potted in hardened epoxy of fibreglass material **55**. The epoxy resin and hardener sold under the designations EPI Bond 121 and #9615 hardener by Furane Plastics, supra, are satisfactory, but other epoxy material which will remain stable at temperatures up to 200 degrees F would probably also be acceptable. It is preferred that a small amount of graphite such as that sold under the trade designation Asbury 225 by Asbury Graphite, Inc. of Rodeo, Calif., be included in the epoxy potting to prevent nuclear particles formed in the chamber from escaping from the apparatus. Ten to 15% graphite to epoxy by weight is more than enough.

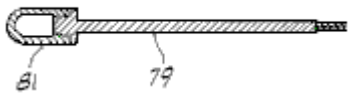
FIG.5



A typical cylinder is shown in section in **Fig.5**, showing the piston in its fully extended position with respect to the head and showing many details on a somewhat larger scale than that of **Fig.4**. A set of seals **57**, made of a material such as that sold under the trade designation Teflon by the DuPont Company of Delaware, is positioned between the cylinder head and wall **43** to prevent escape of the working fluid from chamber **41**. A filler tube **59** with a ball valve at its lower end is used in filling the chamber with the working fluid but is closed during operation of the engine.

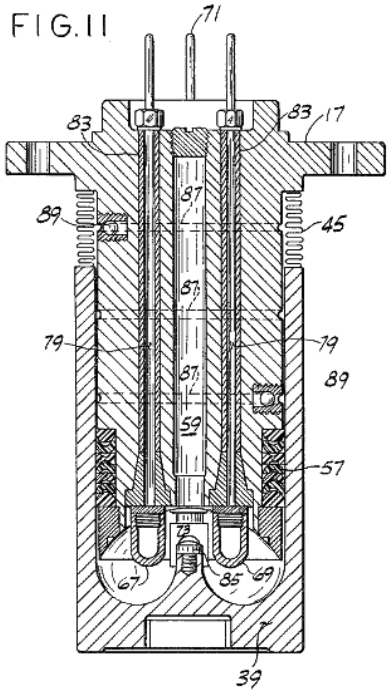
The cylinder head has a generally concave depression therein, indicated at **61**, which defines the top end of the chamber. A plurality of electrodes for exciting and igniting the working fluid extend through the cylinder head into the chamber. Two of those electrodes, shown in section in **Fig.5** and labelled **63** and **65**, have tungsten points **75**, while the other two, labelled **67** and **69** (see **Fig.6** for electrode **69**) are containers called, respectively, the anode and the cathode. The electrodes are generally equidistantly spaced from the axes of their chambers and are generally coplanar to each other, their mutual plane being perpendicular to the axes of their chambers. Each electrode is positioned 90 degrees from adjacent electrodes in this embodiment and are generally positioned so that a line from the anode to the cathode and a line between the other two electrodes intersect at a focal point generally on the axis of the chamber. The radial distance of each electrode from the focal point is fixed for a reason discussed below. The general construction of electrodes **63** and **65** is shown in **Fig.6** to **Fig.9**. These electrodes include a conductive rod **71** (see **Fig.7**) preferably of brass or copper; a conductive, generally rectangular plate **73** (see **Fig.6**, **Fig.8** and **Fig.9**); and tungsten point **75** mounted in a conductive base **77** generally at right angles to the plate (see **Fig.8** and **Fig.9**).

FIG.10



The construction of the anode and cathode is shown in **Fig.10**. Each includes a conductive rod **79** and a container **81**. The cathode container is substantially pure aluminium. If desired, aluminium alloys with, e.g., less than 5% copper, 1% manganese and 2% magnesium may be used. In one embodiment, the cathode container contains approximately four grams of thorium-232 and is filled with argon. In this same embodiment the anode container is copper or brass and contains approximately two grams of rubidium-37 and approximately three grams of phosphorus-15 hermetically sealed in mineral oil. In a second embodiment, the cathode is still aluminium, but it contains at least two grams of rubidium-37 in addition to the approximately four grams of thorium-232 in either argon or mineral oil. In this second embodiment, the anode is also aluminium and contains at least 4 grams of phosphorus-15 and at least 2 grams of thorium-232 in argon or mineral oil. Alternatively, mesothorium may be used for the thorium, strontium-38 may be used for the rubidium, and sulphur-16 may be used for the phosphorus. Rods **71** and **79** extend through cylinder head **17** to the exterior where electrical connections are made to the electrodes. Each rod is surrounded by one of four insulating sleeves **83**, the lower portion of each of which being flared outwards to seat firmly in the cylinder head.

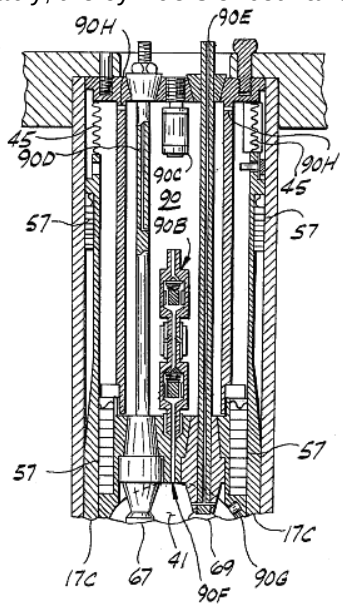
FIG.11



The piston has a generally semi-toroidal depression in its upper surface (see **Fig.4**, **Fig.5** and **Fig.11**) and carries a conductive discharge point **85** of copper, brass or bronze generally along the axis of the chamber. When the piston is generally extended, the discharge point is a substantial distance from the electrodes. But when the piston is in its upper position (see **Fig.11**), the discharge point is positioned generally between all four electrodes and close to them, there being gaps between the electrodes and the discharge point. When the piston is in this upper position, the electrodes extend somewhat into the semi-toroidal depression in the piston's upper surface and the chamber is generally toroidal in shape. The volume of the chamber shown in **Fig.11** can be from approximately 6.0 cubic inches (100 cc) or larger. Given the present state of the art, 1500 cubic inches (25,000 cc) appears to be the upper limit. A plurality of ports **87** and one-way valves **89** return working fluid which escapes from the chamber back into it, so long as a sealing system such as bellows **45** is used.

An alternative cylinder head/piston arrangement is shown in **Fig.12**. The main difference between this arrangement and that of **Fig.5** is that the chamber walls, here labelled **43'** are integrally formed with the head. As a result seals **57** are carried by the piston rather than by the head, the attachment of bellows **45** is somewhat different, and the fluid-returning valves and ports are part of the piston rather than of the head. Otherwise these arrangements are substantially the same. Preferably, the cylinders of both arrangements are hermetically sealed.

FIG.12A



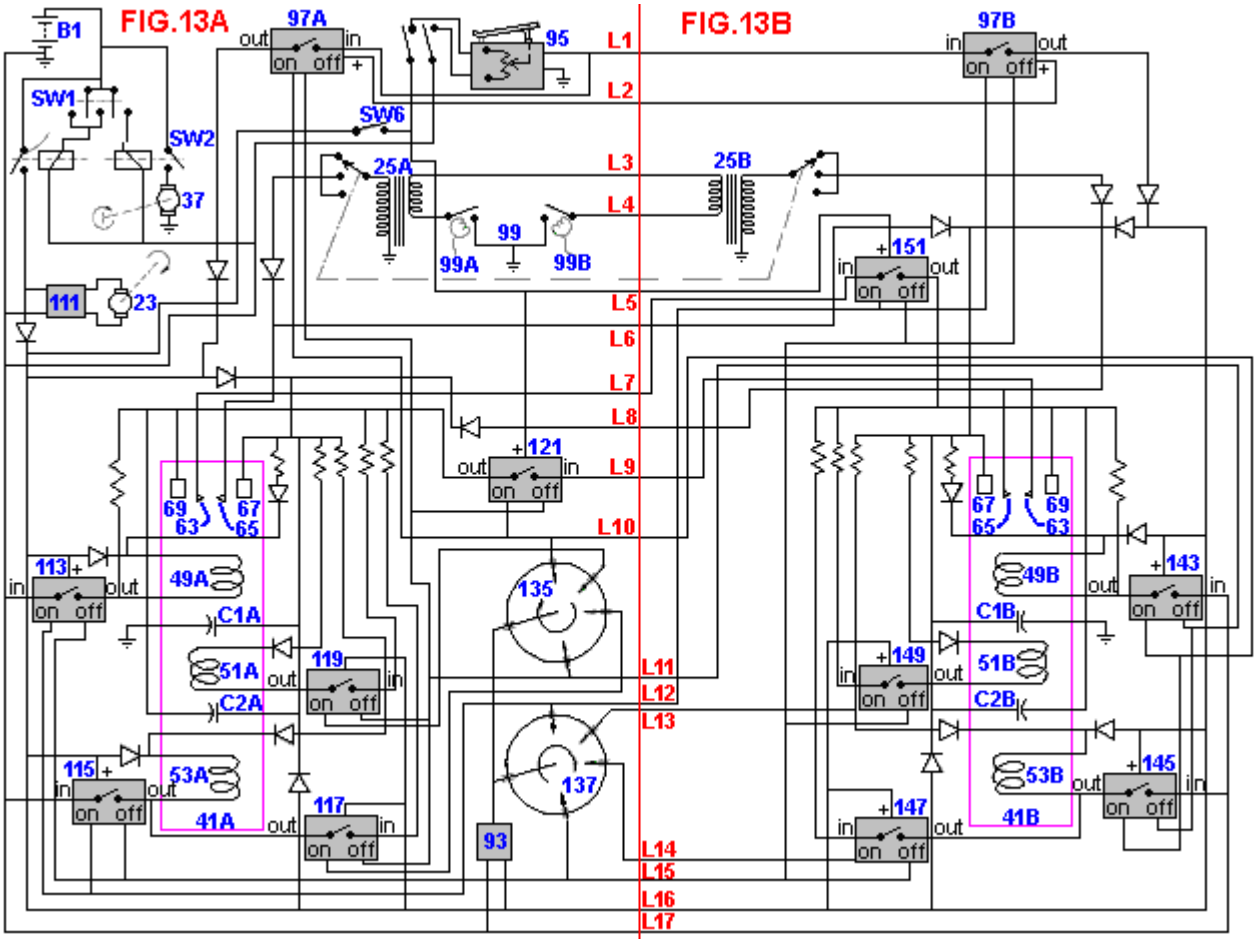
An additional embodiment of a cylinder head/piston arrangement used in the present invention is shown in **Fig.12A**. In this arrangement, a tapered sleeve **17C** mates between cylinder head **17** and piston **39**, a plurality of seals **57** are provided, and electrodes **67** and **69** have a somewhat different shape. Also, in this embodiment, a chamber **90** is provided in cylinder head **17** for storing additional working fluid, i.e., the purpose of chamber **90** is to extend the operating time between refuelling by circulating the working fluid, viz. the mixture of inert gases

described, between cylinder **41** and chamber **90** as needed so that the reactions in cylinder 41 are not adversely affected. To accomplish this, this embodiment further includes a two-way circulation valve **90B**, a relief valve **90C**, and duct or passageway **90D** for evacuating and filling chamber **90**, a duct or passageway **90E** for evacuating and filling cylinder **41**, a passageway **90F** between chamber **90** and cylinder **41** in which two-way valve **90B** is disposed, a sensor **90G** and a plurality of small pressure relief holes **90H**. Relief holes **90H** serve to relieve the pressure on bellows **45** as the piston moves from BDC to TDC.

In larger engines holes **90H** should be replaced with one way valves. Two-way valve **90B** is either controlled by sensor **90G** or is manually operated, as desired, to allow the circulation of gases between chamber **90** and cylinder **41**. The sensor itself detects a condition requiring the opening or closing of valve **90B** and signals that condition to the valve. For example, sensor **90G** can measure pressure in cylinder **41** while the piston is at top dead centre. A predetermined cylinder pressure can cause a spring to compress, causing the valve to open or close as appropriate. A subsequent change in the cylinder pressure would then cause another change in the valve. Another sensor (not shown) could measure the physical location of the piston by a physical trip switch or an electric eye, or it could measure angular distance from top dead centre on the distributor or the crankshaft. The sensor must keep the gas pressure in chamber **90** at one atmosphere, plus or minus 5%, and at top dead centre, cylinder **41** should also be at that pressure. If gas is lost from the system, it is more important to maintain the proper pressure in cylinder **41**. Alternatively, a small passage between cylinder **41** and chamber **90** could function in a passive manner to satisfactorily accomplish the same result. From the above, it can be seen that this embodiment utilises the hollowed out centre of the cylinder head for storing additional working fluid, which fluid is circulated between chamber **90** and cylinder **41** through a valve system comprising valve **90B** and sensor **90G** with the moving piston causing the gases to circulate.

The electrical circuitry for engine **11** includes (see **Fig.13A**) a 24 V battery **B1**, an ignition switch **SW1**, a starter switch **SW2**, starter motor **37**, a main circuit switch **SW4**, a step-down transformer **93** (e.g., a 24 V to 3.5 V transformer), a switch **SW6** for supplying power to ignition coil **25** (shown in **Fig.13A** and **Fig.13B** as two separate ignition coils **25A** and **25B**), and various decoupling diodes.

The circuitry of **Fig.13A** also includes a high frequency voltage source or oscillator **95** for supplying rapidly varying voltage through two electronic current regulators **97A, 97B** (see **Fig.13B** for regulator **97B**) to the anode and cathode electrodes of each cylinder, and a high-voltage distributor **99** for distributing 40,000 volt pulses to the cylinders. Distributor **99** has two wipers **99A** and **99B** and supplies three pulses to each cylinder per cycle. Wipers **99A** and **99B** are 180 degrees out of phase with each other and each operates to supply pulses to its respective cylinder from TDC to 120 degrees thereafter. More pulses are desirable and therefore a better distributor arrangement (shown in **Fig.14**) may be used. The arrangement shown in **Fig.14** includes two ignition coils **101**, **103**, a simple distributor **105** and a pair of magnetic ignition circuits **107** and **109**, described below. Of course many other ignition systems could also be developed. For example, a single circuit might be used in place of circuits **107**, **109**, additional induction coils might be added to the ignition coils to assist in starting or a resistor could be added to the ignition coils to ensure a constant 40,000 volt output regardless of engine rpm. Also, a solid-state distributor could be used instead of the mechanical distributor labelled **99**.



Referring back to **Fig.13A**, for engines of more than 1000 hp a high frequency source **95** could be used to control engine RPM. The output frequency is controlled by a foot pedal similar to an accelerator pedal in a conventional vehicle. The output frequency varies through a range of from approximately 2.057 MHz to approximately 27.120 MHz with an output current of approximately 8.4 amps. The speed of engine **11** is controlled by the output frequency of source **95**. The high frequency current, as described below, is directed to each cylinder in turn by circuitry described below. For engines producing from 300 to 1000 hp (not shown), a high frequency source having a constant output of 27.120 MHz with a constant current of 3.4 amps which is continually supplied to all cylinders could be used. In this case an autotransformer, such as that sold under the trade designation Variac by the General Radio Company, controlled by a foot pedal varies the voltage to each cylinder from 5 to 24 volts DC at 4.5 amps, using power from the batteries or the alternator. The DC current from the Variac is switched from cylinder to cylinder by two small electronic switching units which in turn are controlled by larger electronic switching units. For the smallest engines (not shown), a high frequency generator could supply a constant output of 27.120 MHz with a constant current of 4.2 amps to the cylinders during starting only. Speed control would be achieved by a Variac as described above which controls the DC voltage supplied to the cylinders in turn within a range of from 5 to 24 volts at a current of 5.2 amps. In this case, once the engine is running, the full voltage needed to ignite the (smaller) quantity of gases is obtained from the electrodes in the other cylinder of the pair.

The circuitry of **Fig.13A** also includes the generator, a voltage regulator and relay **111**, five electronic switching units **113, 115, 117, 119** and **121**, electrodes **63** and **65** associated with chamber **41A** (hereinafter chamber **41A** is sometimes referred to as the "**A**" cylinder and chamber **41B** is sometimes referred to as the "**B**" cylinder), anode **67**, cathode **69**, magnetic coils **49A, 51A** and **53A**, capacitors **C1A** and **C2A**, and various decoupling diodes. The electronic switching units can take a variety of forms. For example, one simple form (see **Fig.15**) includes a pair of SCRs **123** and **125**. The switching unit is connected at terminal IN to the corresponding line on the input side and at terminal OUT to the corresponding line on the output side. When a voltage of 3.5 volts is supplied from the battery through a distributor, for example, to the ON terminal, SCR **125** conducts, thereby completing a circuit through the switching unit. Conversely, when 3.5 volts is applied to the OFF terminal, SCR **123** conducts and the circuit is broken. Likewise, the circuit for regulators **97A** and **97B** (see **Fig.16**) includes two SCRs **127** and **129** and a PNP transistor **131**. In this circuit when SCR **127** is gated on, it forces transistor **131** into conduction, thereby completing the circuit through the regulator. When SCR **129** is gated on, the circuit through transistor **131** is broken. A number of other configurations may be used in place of those of **Fig.15** and **Fig.16** and not all would use SCRs. For example, one triode could be used to replace two main SCRs, or transistors could be used instead of SCRs.

A pair of low-voltage distributors **135** and **137** are also shown in **Fig.13A**. Distributors **135** and **137** provide gating pulses for the electronic switching units of **Fig.13A** and **Fig.13B**. Of course, solid-state distributors could also replace mechanical distributors **135** and **137**.

In addition, the engine circuitry includes (see **Fig.13B**) five electronic switching units **143, 145, 147, 149** and **151** corresponding to units **113, 115, 117, 119** and **121** of **Fig.13A**, electrodes **63** and **65** of the "**B**" cylinder, anode **67**, cathode **69**, electric coils **49B, 51B** and **53B**, capacitors **C1B** and **C2B**, and various decoupling diodes. The circuitry of **Fig.13B** is generally the same as the corresponding portions of **Fig.13A**, so the description of one for the most part applies to both. Of course, if more than two cylinders are used, each pair of cylinders would have associated with them, circuitry such as that shown in **Fig.13A** and **Fig.13B**. The circuitry of **Fig.13A** is connected to that of **Fig.13B** by the lines **L1-L17**.

The working fluid and the fuel for the engine are one and the same and consist of a mixture of inert gases, which mixture consists essentially of helium, neon, argon, krypton and xenon. It is preferred that the mixture contain 35.6% helium, 26.3% neon, 16.9% argon, 12.7% krypton, and 8.5% xenon by volume, it having been calculated that this particular mixture gives the maximum operation time without refuelling. Generally, the initial mixture may contain, by volume, approximately 36% helium, approximately 26% neon, approximately 17% argon, approximately 13% krypton, and approximately 8% xenon. This mixture results from a calculation that equalises the total charge for each of the gases used after compensating for the fact that one inert gas, viz. radon, is not used. The foregoing is confirmed by a spectroscopic flashing, described below, that occurs during the mixing process. If one of the gases in the mixture has less than the prescribed percentage, it will become over-excited. Similarly, if one of the gases has more than the prescribed percentage, that gas will be under-excited. These percentages do not vary with the size of the cylinder.

Operation of the engine is as follows: At room temperature, each cylinder is filled with a one atmosphere charge of the fuel mixture of approximately 6 cubic inches (100 cc) /cylinder (in the case of the smallest engine) by means of filler tube **59**. The filler tubes are then plugged and the cylinders are installed in the engine as shown in **Fig.4**, one piston being in the fully extended position and the other being in the fully retracted position. To start the engine, the ignition and starter switches are closed, as is switch **SW6**. This causes the starter motor to crank the engine, which in turn causes the wiper arms of the distributors to rotate. The starting process begins, for example, when the pistons are in the positions shown in **Fig.4**. Ignition coil **25** and distributor **99** (see **Fig.13A**) generate a 40,000 volt pulse which is supplied to electrode **65** of chamber **41A**. Therefore, a momentary high potential exists between electrodes **63** and **65** and the plates on each. The discharge point on piston **39A** is adjacent these electrodes at this time and sparks occur between one or more of the electrodes and the discharge point to partially excite, e.g. ionise, the gaseous fuel mixture.

The gaseous fuel mixture in cylinder **41A** is further excited by magnetic fields set up in the chamber by coil **49A**. This coil is connected to the output side of electronic switching unit **121** and, through switching unit **113**, to the battery and the generator. At this time, i.e., between approximately 5 degrees before TDC and TDC, distributor **135** is supplying a gating signal to unit **121**. Any current present on the input side of unit **121**, therefore, passes through unit **121** to energise coil **49A**. Moreover, high frequency current from oscillator **95** is supplied via regulator **97A** to coil **49A**. This current passes through regulator and relay **97A** because the gating signal supplied from distributor **135** to unit **121** is also supplied to relay **97A**. The current from switching unit **121** and from oscillator **95** also is supplied to the anode and the cathode. It is calculated that this causes radioactive rays (x-rays) to flow between the anode and the cathode, thereby further exciting the gaseous mixture.

As the starter motor continues cranking, piston **39A** begins moving downward, piston **39B** begins moving upward, and the wiper arms of the distributors rotate. (Needless to say, a solid-state distributor would not rotate. The distributor could utilise photo cells, either light or reflected light, rather than contact points). After 45 degrees of rotation, distributor **135** supplies a gating pulse to electronic switching unit **119**, thereby completing a circuit through unit **119**. The input to unit **119** is connected to the same lines that supply current to coil **49A**. The completion of the circuit through unit **119**, therefore, causes coil **51A** to be energised in the same manner as coil **49A**. After an additional 45 degrees of rotation, distributor **135** gates on electronic switching unit **117** which completes a circuit to the same lines. The output terminal of unit **117** is connected to coil **53A**, and so this coil is energised when unit **117** is gated on. All three coils of the "**A**" cylinder remain energised and, therefore, generating magnetic fields in chamber **41A** until piston **39A** reaches BDC.

As piston **39A** moves from TDC to BDC, two additional 40,000 volt pulses (for a total of three) are supplied from distributor **99** to the "**A**" cylinder. These pulses are spaced approximately 60 degrees apart. If more pulses are desired, the apparatus shown in **Fig.14** may be used. In that case, the solenoids indicated generally at **107A, 107B** and **109A, 109B** are energised to create a number of rapid, high-voltage pulses which are supplied as indicated in **Fig.14** to the cylinders, distributor **105** operating to supply pulses to only one of the pair of cylinders at a time.

As piston **39A** reaches BDC, distributor **135** sends a pulse to the OFF terminals of electronic switching units **121, 117** and **119**, respectively, causing all three coils **49A, 51A** and **53A** to be de-energised. At about the same time, i.e., between approximately 5 degrees before TDC and TDC for piston **39B**, distributor **137** supplies a gating pulse to the ON terminals of electronic switching units **113** and **115**. The power inputs to units **113** and **115** come from the generator through regulator **111** and from the battery, and the outputs are directly connected to coils **49A** and **53A**. Therefore, when units **113** and **115** are gated on, coils **49A** and **53A** are reenergised. But in this part of the cycle, the coils are energised with the opposite polarity, causing a reversal in the magnetic field in chamber **41A**. Note that coil **51A** is not energised at all during this portion of the cycle. Capacitors **C1A** and **C2A** are also charged during the BDC to TDC portion of the cycle. (During the TDC to BDC portion of the cycle, these capacitors are charged and/or discharged by the same currents as are supplied to the anode and cathode since they are directly connected to them).

As piston **39A** moves upwards, electrodes **63** and **65** serve as pick-up points in order to conduct some of the current out of chamber **41A**, this current being generated by the excited gases in the chamber. This current is transferred via line **L7** to electronic switching unit **151**. The same gating pulse which gated on units **113** and **115** was also supplied from distributor **137** via line **L12** to gate on switching unit **151**, so the current from the electrodes of chamber **41A** passes through unit **151** to the anode, cathode and capacitors of chamber **41B**, as well as through switching units **147** and **149** to coils **49B, 51B** and **53B**. Thus it can be seen that electricity generated in one cylinder during a portion of the cycle is transferred to the other cylinder to assist in the excitation of the gaseous mixture in the latter. Note that this electricity is regulated to maintain a constant in-engine current. It should be noted, that twenty four volts from the generator is always present on electrodes **63** and **65** during operation to provide for pre-excitement of the gases.

From the above it can be seen that distributors **135** and **137** in conjunction with electronic switching units **113, 115, 117, 119, 121, 143, 145, 147, 149** and **151** constitute the means for individually energising coils **49A**, **49B, 51A, 51B, 53A** and **53B**. More particularly, they constitute the means to energise all the coils of a given cylinder from the other cylinder when the first cylinder's piston is moving from TDC to BDC and operate to energise only two (i.e., less than all) of the coils from the alternator when that piston is moving from BDC to TDC. Additionally, these components constitute the means for energising the coils with a given polarity when the piston of that cylinder is moving from TDC to BDC and for energising the first and third coils with the opposite polarity when that piston is moving from BDC to TDC.

As can also be seen, switching units **121** and **151** together with distributors **135** and **137** constitute the means for closing a circuit for flow of current from chamber **41A** to chamber **41B** during the BDC to TDC portion of the cycle of chamber **41A** and for closing a circuit for flow of current from chamber **41B** to chamber **41A** during the TDC to BDC portion of the cycle of chamber **41A**. Oscillator **95** constitutes the means for supplying a time varying electrical voltage to the electrodes of each cylinder, and oscillator **95**, distributors **135** and **137**, and regulators **97A** and **97B** together constitute the means for supplying the time varying voltage during a predetermined portion of the cycle of each piston. Moreover, distributor **99** together with ignition coils **25A** and **25B** constitute the means for supplying high-voltage pulses to the cylinders at predetermined times during the cycle of each piston.

The cycle of piston **39B** is exactly the same as that of piston **39A** except for the 180 degree phase difference. For each cylinder, it is calculated that the excitation as described above causes the gases to separate into layers, the lowest atomic weight gas in the mixture, namely helium, being disposed generally in the centre of each chamber, neon forming the next layer, and so on until we reach xenon which is in physical contact with the chamber walls. The input current (power) to do this is the calculated potential of the gas mixture. Since helium is located in the centre of the chamber, the focal point of the electrode discharges and the discharges between the anode and cathode is in the helium layer when the piston is near TDC. As the piston moves slightly below TDC, the electrons from electrodes **63** and **65** will no longer strike the tip of the piston, but rather will intersect in the centre of the cylinder (this is called "focal point electron and particle collision") as will the alpha, beta and gamma rays from the anode and cathode. Of course, the helium is in this exact spot and is heavily ionised at that time. Thus the electrodes together with the source of electrical power connected thereto constitute the means for ionising the inert gas.

It is calculated that as a result of all the aforementioned interactions, an ignition discharge occurs in which the helium splits into hydrogen in a volume not larger than 2 or 3 x 10^{-6} cubic millimetres at a temperature of approximately 100,000,000 degrees F. Of course this temperature is confined to a very small space and the layering of the gases insulates the cylinder walls from it. Such heat excites the adjacent helium so that a plasma occurs. Consequently, there is a minute fusion reaction in the helium consisting of the energy conversion of a single helium atom, which releases sufficient energy to drive the piston in that chamber toward BDC with a force similar in magnitude to that generated in a cylinder of a conventional internal combustion engine. Electrodes **63** and **65** extend into the argon layer while each piston is in its BDC to TDC stroke so as to pick up some of the

current flowing in that layer. It may take a cycle or two for the gases in the cylinders to become sufficiently excited for ignition to occur.

Once ignition does occur, the electrical operation of the engine continues as before, without the operation of the starter motor. Distributor **99** supplies three pulses per cycle (or more if the magnetic ignition system of **Fig.14** is used) to each cylinder; and distributors **135** and **137** continue to supply "on" and "off" gating pulses to the electronic switching units. The rpm of the engine is, as explained above, governed by the frequency of the current from oscillator **95** (or in the case of smaller horsepower units, by the DC voltage supplied to the cylinders from the Variac).

Because of the minute amount of fuel consumed in each cycle, it is calculated that a cylinder can run at 1200 rpm approximately 1000 hours, if not more, on a single charge of gas. Note that even at 1200 rpm, there will be intense heat occurring only 0.002% of the time. This means that input power need be applied only sporadically. This power can be supplied to a cylinder from the other cylinder of its pair by means of electronic switching units which, in the case of SCRs, are themselves triggered by low voltage (e.g. 3.5 V) current. Thus, since electrical power generated in one cylinder is used to excite the gases in the other cylinder of a pair, it is practical that the cylinders be paired as discussed above. Capacitors are, of course, used to store such energy for use during the proper portion of the cycle of each cylinder.

From the above, it should be appreciated that the engine of this invention has several advantages over presently proposed fusion reactors, such as smaller size, lower energy requirements, etc. But what are the bases of these advantages? For one, presently proposed fusion reactors use hydrogen and its isotopes as a fuel instead of inert gases. Presumably this is because hydrogen requires less excitement power. While this is true, the input power that is required in order to make hydrogen reactors operate makes the excitation power almost insignificant. For example, to keep a hydrogen reactor from short circuiting, the hydrogen gas has to be separated from the reactor walls while it is in the plasma state. This separation is accomplished by the maintenance of a near vacuum in the reactor and by the concentration of the gas in the centre of the reactor (typically a toroid) by a continuous, intense magnetic field. Accordingly, separation requires a large amount of input energy.

In the present invention, on the other hand, the greater excitation energy of the fuel is more than compensated for by the fact that the input energy for operation can be minimised by manipulation of the unique characteristics of the inert gases. First, helium is the inert gas used for fusion in the present invention. The helium is primarily isolated from the walls of the container by the layering of the other inert gases, which layering is caused by the different excitation potential (because of the different atomic weights) of the different inert gases, said excitation being caused by the action of the electrodes, anode and cathode in a magnetic field. This excitation causes the gases each to be excited in inverse proportion to their atomic numbers, the lighter gases being excited correspondingly more. Helium, therefore, forms the central core with the other four gases forming layers, in order, around the helium. The helium is secondarily isolated from the walls of the container by a modest vacuum (in comparison to the vacuum in hydrogen reactors) which is caused partially by the "choking" effect of the coils and partially by the enlargement of the combustion chamber as the piston moves from TDC to BDC. (Unexcited, the gases are at one atmosphere at TDC). Second, argon, the middle gas of the five, is a good electrical conductor and becomes an excellent conductor when (as explained below) it is polarised during the mixing process. By placing the electrodes such that they are in the argon layer, electrical energy can be tapped from one cylinder for use in the other. During a piston's movement from BDC to TDC, the gases are caused to circulate in the cylinder by the change in the polarity of the coils, which occurs at BDC.

During such circulation, the gases remain layered, causing the argon atoms to be relatively close to each other, thereby optimising the conductivity of the argon. This conductivity optimisation is further enhanced by a mild choking effect that is due to the magnetic fields. The circulation of the highly conductive argon results in a continuous cutting of the magnetic lines of force so that the current flows through the electrodes. This production of electricity is similar to the rotating copper wire cutting the magnetic lines of force in a conventional generator except that the rotating copper wire is replaced by the rotating, highly conductive argon. The amount of electricity that can be produced in this manner is a function of how many magnetic field lines are available to be cut. If one of the coils, or all three of the coils or two adjacent coils were energised, there would be only one field with electricity produced at each end. By energising the top and the bottom coil, two separate fields are produced, with electricity produced at four points.

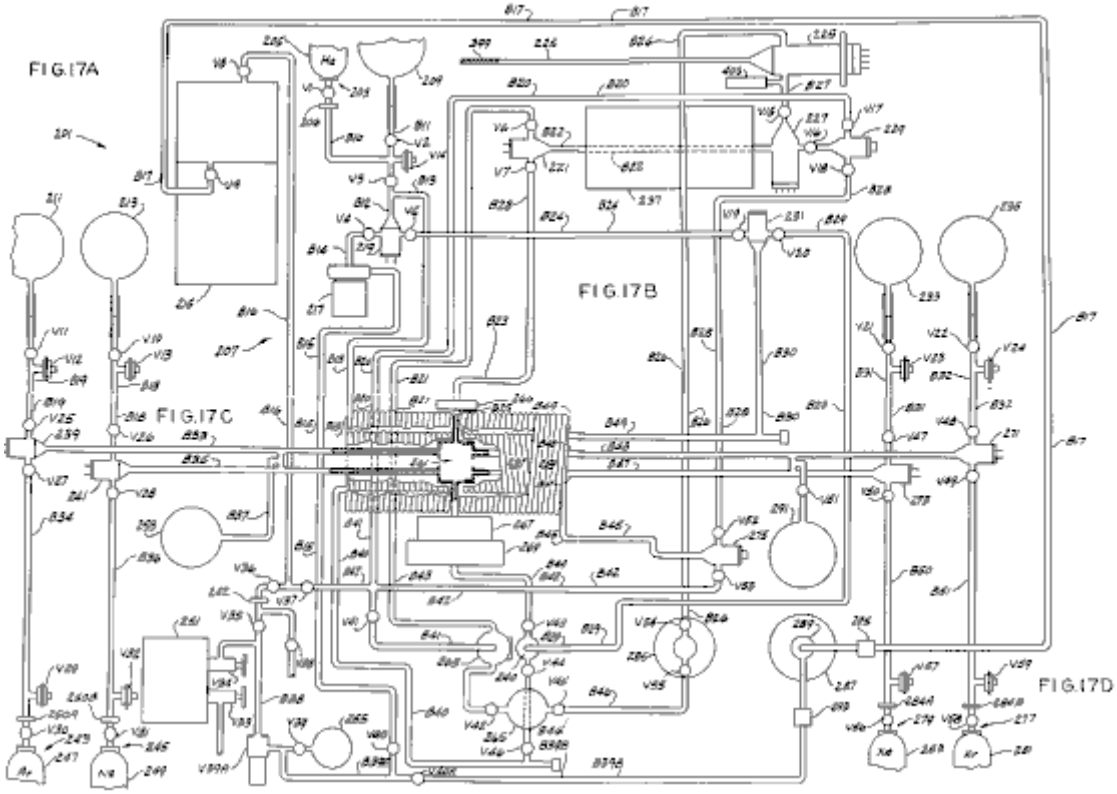
A five coil system, if there were sufficient space, would produce three fields with the top, bottom and middle coils energised. Six points for electricity production would result. The number of coils that can be installed on a given cylinder is a function of space limitations. The recombination of gas atoms during the BDC to TDC phase causes the radiation of electrical energy which also provides a minor portion of the electricity that the electrode picks up. Additional non-grounded electrodes in each cylinder would result in more electricity being tapped off. It should be noted that during the BDC to TDC phase, the anode and the cathode are also in the argon layer and, like the electrodes, they pick up electricity, which charges the capacitors around the cylinder. Third, inert gases remain a

mixture and do not combine because of the completeness of the electron shells. They are therefore well suited to a cycle whereby they are continually organised and reorganised. Fourth, as the helium atoms are consumed, the other gases have the capacity to absorb the charge of the consumed gas so that the total charge of the mixture remains the same.

The second basis of these advantages of the present engine over proposed fusion reactors concerns the fact that hydrogen reactors develop heat which generates steam to turn turbines in order to generate electrical power. This requires tremendous input energy on a continuous basis. The present invention operates on a closed cycle, utilising pistons and a crankshaft which does not require a continuous plasma but rather an infrequent, short duration (10^{-6} second) plasma that therefore requires much less input energy. In the present invention, a plasma lasting longer than 10^{-6} second is not necessary because sufficient pressure is generated in that time to turn the engine. A plasma of longer duration could damage the engine if the heat were sufficiently intense to be transmitted through the inert gas layers to the cylinder walls. A similar heat build-up in the engine can occur if the repetition rate is increased. Such an increase can be used to increase the horsepower per engine size but at the cost of adding a cooling system, using more expensive engine components, and increasing fuel consumption. Note that even though layers of inert gases insulate the cylinder walls, there might be some slight increase in the temperature of the gas layers after a number of cycles, i.e., after a number of ignitions.

Whereas hydrogen fusion reactors cannot directly produce power by driving a piston (because of the required vacuum), the present invention uses the layered inert gases to transmit the power from the plasma to each gas in turn until the power is applied to a piston, which can easily be translated into rotary motion. The layered gases also cushion the piston from the full force of the ignition. Moreover, the fields inside the cylinder undergoing expansion cause the gases to shrink, thereby taking up some of the pressure generated by the explosion and preventing rupturing of the cylinder walls.

Turning now to **Fig.17A** to **Fig.17D**, there is shown apparatus **201** for preparing the fuel mixture for engine **11**. For convenience apparatus **201** is called a mixer although it should be understood that the apparatus not only mixes the gases which form the fuel but also performs many other vital functions as well. The five constituent inert gases are introduced in precise, predetermined proportions. The mixer extracts, filters and neutralises the non-inert gases and other contaminants which may be found in the gas mixture. It also increases the potential capacity of gas atoms, discharges the krypton and xenon gases, polarises the argon gases, ionises the gases in a manner such that the ionisation is maintained until the gas has been utilised and otherwise prepares them for use as a fuel in engine **11**. In particular, the mixer makes the gases easier to excite during operation of the engine. Mixing does not mean an atomic or molecular combination or unification of gases because inert gases cannot chemically combine, in general, due to the completeness of the outer shell of electrons. During mixing, the various gases form a homogeneous mixture. The mixing of the five inert gases in apparatus **201** is somewhat analogous to preparing a five part liquid chemical mixture by titration. In such a mixture, the proportions of the different chemicals are accurately determined by visually observing the end point of each reaction during titration. In apparatus **201**, a visible, spectroscopic flash of light accompanies the desired end point of the introduction of each new gas as it reaches its proper, precalculated proportion. (Each gas has its own distinctive, characteristic, spectroscopic display). The ends points are theoretically calculated and are determined by pre-set voltages on each of a group of ionising heads in the apparatus, as described below.

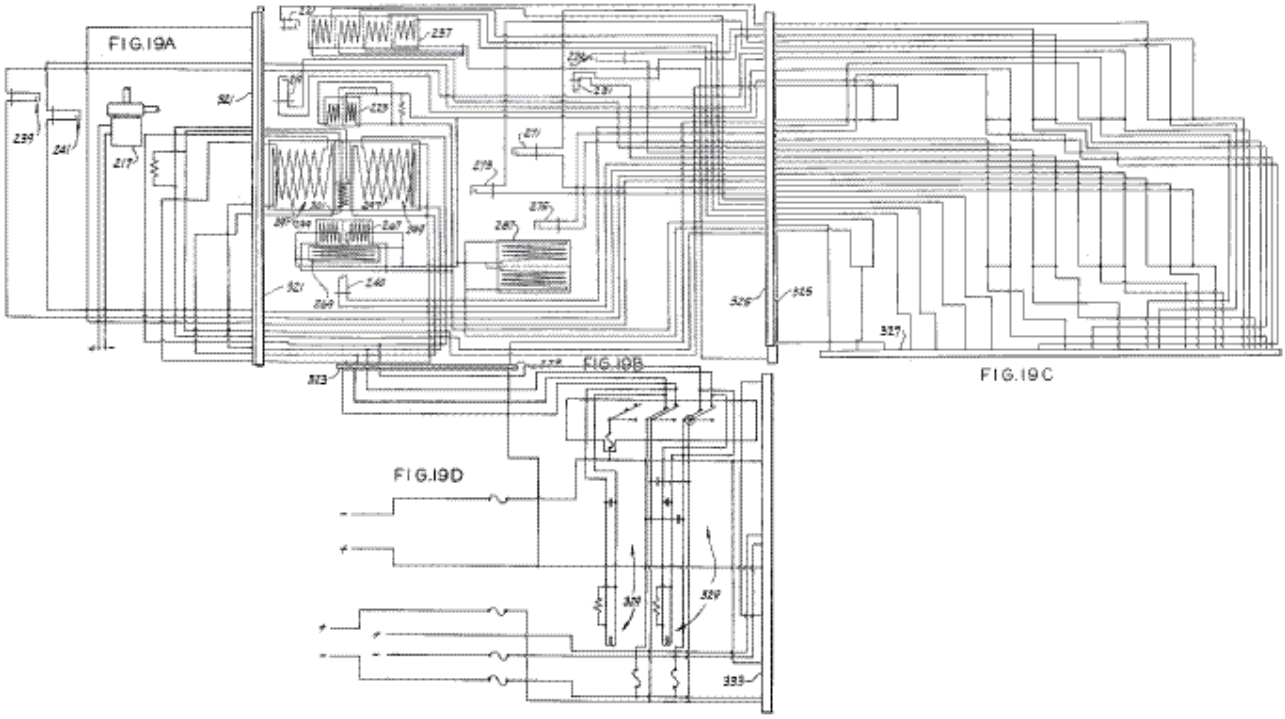


Mixer **201** includes (see **Fig.17A**) an intake port, indicated generally at **203**, which during operation is connected to a source **205** of helium gas, a gauge **206**, glass tubing **207** comprising a plurality of branches **B10-B25** for flow of the gases through the mixer, a plurality of valves **V1-V11** in the branches, which valves may be opened or closed as necessary, three gas reservoirs **209, 211** and **213** for storing small quantities of helium, argon and neon gas respectively, an ionising and filtering unit **215** for filtering undesired non-inert gases and contaminants out of the fuel mixture, for regulating the gas atom electron charge and to absorb the free flowing electrons, a gas flow circulation pump **217**, two ionising heads **219** and **221**, and three quality control and exhaust valves **V12-V14**. The mixer also comprises (see **Fig.17B**) a high frequency discharge tube **225**, a non-directed cathode ray tube **227**, two more ionising heads **229** and **231**, two additional gas reservoirs **233** and **235** for storing small quantities of xenon and krypton, a quadruple magnetic coil **237**, a group of valves **V15-V24**, valves **V23** and **V24** being quality control and exhaust valves, and a plurality of additional glass tubing branches **B26-B32**.

Turning to **Fig.17C**, mixer **201** also includes additional ionising heads **239, 240** and **241**, additional valves **V25-V46**, **V39A** and **V40A**, valves **V29** and **V32** being quality control and exhaust valves and valve **V39A** being a check valve, a vacuum and pressure gauge **242** between valves **V35** and **V36**, tubing branches **B34-B49** (branch **B39** consisting of two parts **B39A** and **B39B**), a pair of intake ports **243** and **245** which during operation are connected to sources **247** and **249** of argon and neon gas respectively, gauges **250A** and **250B**, a spark chamber **251**, a hydrogen and oxygen retention chamber **253** containing No. 650 steel dust in a silk filter, an ion gauge **255** (which can be an RG 75K type Ion Gauge from Glass Instruments, Inc. of Pasadena, Calif.) for removing excess inert gases from the mixture, inner and outer coils of glass tubing **257** and **259** surrounding a mixing chamber **261**, a focused x-ray tube **263** for subjecting the mixture flowing through it to 15-20 millirem alpha radiation and 120-125 millirem beta radiation, a directed cathode ray tube **265**, two twin parallel magnetic coils **266** and **267**, and a focusing magnetic coil **269**. It is important that coils **266** and **267** be immediately adjacent mixing chamber **261**. And (see **Fig.17D**) the mixer also comprises three more ionising heads **271**, **273** and **275**, two entry ports **277** and **279** which during operation are connected to sources **281** and **283** of krypton and xenon respectively, gauges **284A** and **284B**, a high frequency discharge tube **285**, a twin parallel magnetic coil **287** surrounding a polariser **289** for polarising the argon, said polarise containing fine steel particles which are polarised by coils **287** and which in turn polarise argon, a second hydrogen retention chamber **291**, a pair of tubing branches **B50** and **B51**, two filters **293** and **295** and a plurality of valves **V47-V59**, valves **V57** and **V59** being quality control and exhaust valves.

Inner and outer glass tubing coils **257** and **259** and mixing chamber **261** are shown in cross section in **Fig.18**. Intermediate glass coils **257** and **259** are two magnetic coils **297** and **299** having an inductance of approximately 130 mH. A yoke coil **301** is positioned in a semi-circle around mixing chamber **261**. Inside mixing chamber **261** are located a pair of screens **303** and **305**, insulators **307** and **309**, and a pair of spark gaps indicated generally at **311** and **313**. A high frequency amplitude modulated source provides 120 V AC, 60 Hz, 8.4 amp, 560 watt, 27,120 to 40,000 MHz plus or minus 160 KHz current via heavily insulated wires **315** and **317** to the chamber.

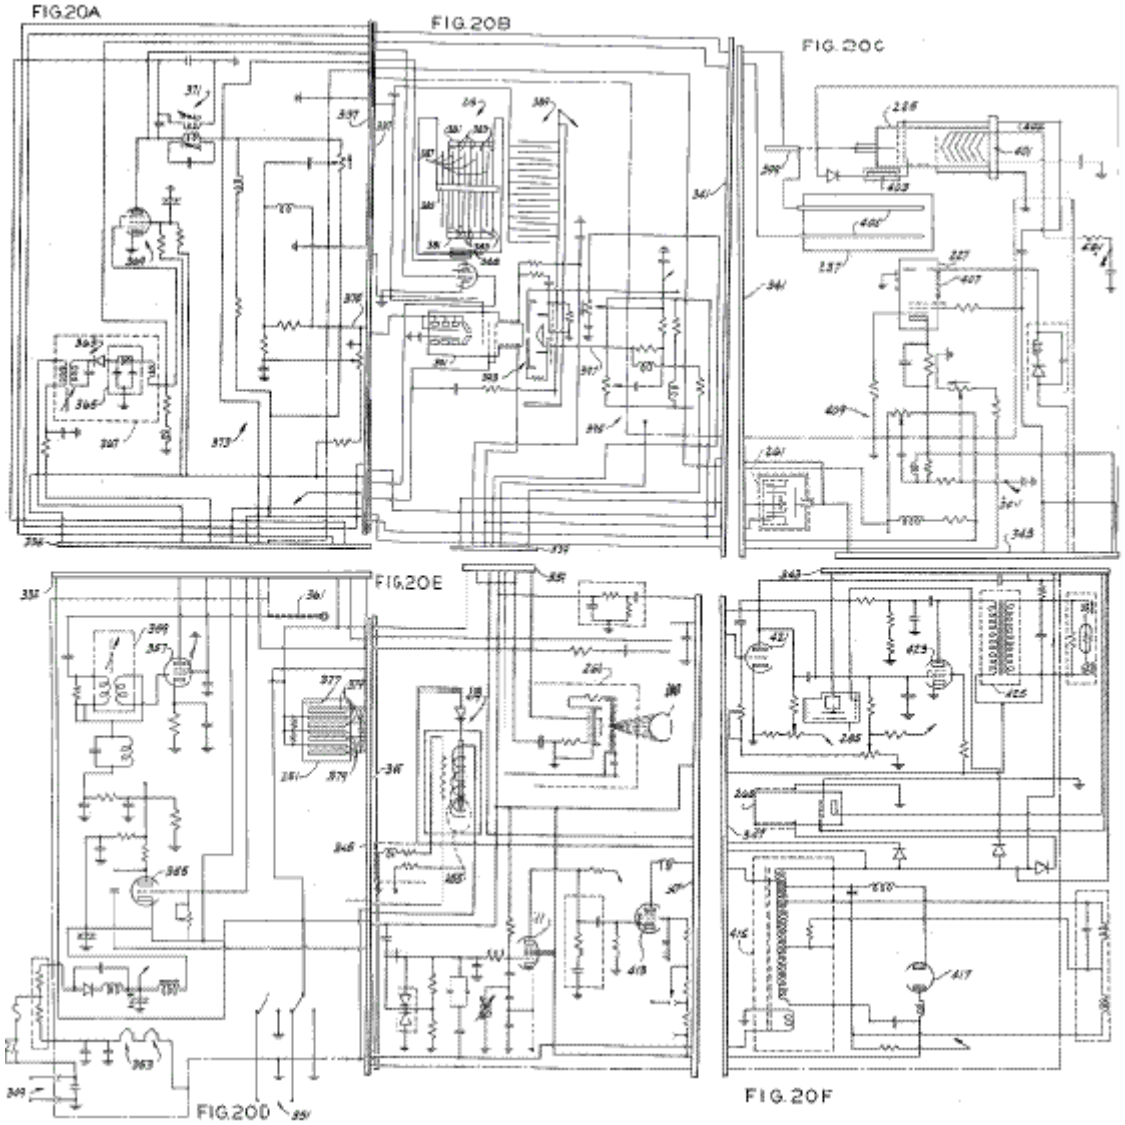
These wires are about twelve gauge, like those used as spark plug wires on internal combustion engines. Additionally 95 volt Direct Current is supplied via a smaller (e.g. sixteen to eighteen gauge) insulated wire **319**. As described below, the gases to be mixed and prepared flow through chamber **261** and are suitably treated therein by the action of the various fields present in the chamber.



The magnetic coils, ionisation heads, and pump **217**, along with the required electrical interconnections, are schematically shown in **Fig.19A** to **Fig.19E**. More particularly, heads **239** and **241** are shown in **Fig.19A**, as is pump **217**. Each ionising head has two electrodes with a gap between them to cause ionisation of gases flowing through the head, the electrodes being connected to a source of electrical power. Pump **217** is directly connected to a source of power (either AC or DC as required by the particular pump being used). The connections between the circuitry on **Fig.19A** and that on **Fig.19B** are shown as a plug **321**, it being understood that this plug represents a suitable one-to-one connection between the lines of **Fig.19A** and those of **Fig.19B**.

The remaining ionising heads and all the magnetic coils are shown in **Fig.19B**. For clarity, the coils are shown in an unconventional form. Quadruple coil **237** (shown at the top of **Fig.19B**) has one side of each winding connected in common but the other sides are connected to different lines. Coil **223** consists of two windings in parallel. Coils **297** and **299**, the ones around the mixing chamber, are shown overlapping, it being understood that coil **297** is actually interior of coil **299**. Yoke coil **301**, as shown, extends half-way from the bottom to the top of coils **297** and **299**. Twin parallel magnetic coils **267** are connected in parallel with each other, both sides of focusing coil **269** being connected to one node of coils **267**. Likewise coils **287** are connected in parallel. The connections between the lines of **Fig.19B** and those of **Fig.19C** and **Fig.19D** are shown as plugs **323** and **325**, although other suitable one-to-one connections could certainly be made. **Fig.19C** shows the interconnecting lines between **Fig.19B** and **Fig.19E**. A plug **327** or other suitable one-to-one connections connects the lines of **Fig.19C** and **Fig.19E**.

A plurality of power sources, like the above-mentioned Variacs, of suitable voltages and currents as well as a plurality of relays **329**, and plugs **331** are shown on **Fig.19D** and **Fig.19E**. The connections between these two Figures is shown as a plug **333**. It should be appreciated that the Variacs can be adjusted by the operator as necessary to supply the desired voltages to the aforementioned coils and ionising heads. It should also be realised that the desired relays can be closed or opened as needed by connecting or disconnecting the two parts of the corresponding plug **331**. That is, by use of plugs **331**, the operator can control the energising of the ionising heads and magnetic coils as desired. Plugs **331** are also an aid in checking to ensure that each component is in operating condition just prior to its use. Of course, the manipulation of the power sources and the relays need not be performed manually; it could be automated.



The remaining circuitry for the mixer is shown on **Fig.20A** to **Fig.20F**. For convenience, plugs **335**, **337**, **339, 341, 343, 345** and **347** are shown as connecting the circuitry shown in the various Figures, although other suitable one-to-one connections may be used. The chassis of the apparatus is shown on these Figures in phantom and is grounded. The power supply for the apparatus is shown in part on **Fig.20A** and **Fig.20D** and includes an input **349** (see **Fig.20D**) which is connected to 120 volt, 60 Hz power during operation and an input **351** which is connected to the aforementioned high frequency generator or some other suitable source of approximately 27,120 MHz current. The power supply includes a pair of tuners **353**, numerous RLC circuits, a triode **355**, a pentode **357** with a ZnS screen, a variable transformer **359**, an input control **361**, a second variable transformer **363** (see **Fig.20A**) which together with a filter **365** forms a 2.0 volts (peak-to-peak) power supply **367**, a pentode **369**, a variable transformer **371**, and a resistor network indicated generally at **373**. Exemplary voltages in the power supply during operation are as follows: The anode of triode **355** is at 145 V, the control grid at 135 V and the cathode at -25 V. The voltage at the top of the right-hand winding of transformer **359** is -5 V. The anode of pentode **357** is at 143 V, the top grid is grounded (as is the ZnS screen), the bottom grid is connected to transformer **359**, and the control electrode is at 143 V. The input to supply **367** is 143 volts AC while its output, as stated above, is 2 V (peak-to-peak). The anode of pentode **369** is at 60 V, the grids at -1.5 V, the control electrode at 130 V, and the cathode is substantially at ground. The output of resistor network **373**, labelled **375**, is at 45 V.

Also shown on **Fig.20D** is spark chamber **251**. Spark chamber **251** includes a small amount of thorium, indicated at **377**, and a plurality of parallel brass plates **379**. When the gases in the mixer reach the proper ionisation, the alpha particles emitted by the thorium shown up as flashes of light in the spark chamber.

Turning now to **Fig.20B**, ionising and filtering unit **215** includes a pair of conductive supports **381** for a plurality of conductors **383**, said supports and conductors being connected to a voltage source, an insulating support **385** for additional conductors **387**, and a ZnS screen **388** which emits light when impurities are removed from the gaseous fuel mixture. Unit **215** also includes a second set of interleaved conductors indicated generally at **389**, a

cold-cathode tube **391**, and an x-ray tube indicated generally at **393**. Also shown on **Fig.20B** is an RLC network **395** which has an output on a line **397** which is at 35 V, this voltage being supplied to the x-ray tube.

High frequency discharge tube **255** (see **Fig.20C**) has a conductive electrode **399** at one end to which high frequency current is applied to excite the gases in the mixer, and an electrode/heater arrangement **401** at the other, a voltage of 45 V being applied to an input **402** of the tube. It is desirable that a small quantity of mercury, indicated at **403**, be included in tube **225** to promote discharge of the helium gas. Magnetic coils **237** have disposed therein a pair of generally parallel conductors **405** to which a high frequency signal is applied. When gas flows through coils **237** and between parallel conductors **405**, therefore, it is subjected to the combination of a DC magnetic field from the coil and high frequency waves from the conductors, which conductors act as transmitting antennas. The resulting high frequency magnetic field causes the atoms to become unstable, which allows the engine to change a given atom's quantum level with much less input power than would normally be required. The volume of each gas atom will also be smaller. Also shown on **Fig.20C** is non-directed cathode ray tube **227**. The grids of tube **227** are at 145 V, the control electrode is at ground, while the anode is at 35 V to 80 V (peak-to-peak). The purpose of non-directed cathode ray tube **227** is to add photons to the gas mixture. To generate these photons, tube **227** has a two layer ZnS coating indicated generally at **407**. Chamber **261**, described above, is also shown schematically on **Fig.20C**, along with an RLC network **409**.

The power supply for the mixer (see the lower halves of **Fig.20E** and **Fig.20F**) also includes two pentodes **411** and **413**, a transformer **415**, and a diode tube **417**. The control electrode of pentode **411** is at 5 V to 40 V (peak-to-peak), the grids are at 145 V, the anode is at 100 V, and the cathode is at 8 V to 30 V (peak-to-peak). The control electrode of pentode **413** is at 115 V, while its grids and cathode are at -33 V. The anode of tube **413** is connected to transformer **415**. Also shown on **Fig.20E** are a relay **419** associated with ion gauge **255**, and focused x-ray tube **263** associated with ionisation head **240**. The upper input to tube **263** is at 45 V to 80 V (peak-to-peak).

Turning to **Fig.20F**, there is shown tubes **265** and **285**. Directed cathode ray tube **265** is a pentode connected like tube **227**. High frequency discharge tube **285** includes a phosphor screen and is connected to a high frequency source. Also shown on **Fig.20F** is a triode **421** with its anode at 30 V, its cathode at ground, and its control grid at -60 V; a pentode **423** with its anode at 135 V to 1000 V peak to peak, its cathode at ground, its control electrode at 143 V, its grids at 20 V; and a transformer **425**. It should be understood that various arrangements of electrical components other than those described above could be designed to perform the same functions.

The operation of the mixer is best understood with reference to **Fig.17A** to **Fig.17D** and is as follows: Before and during operation, the mixer, and particularly chamber **261** is kept hermetically sealed and evacuated. To begin the mixing process, helium is admitted into the mixer via intake port **203**. Then a vacuum is again drawn, by a vacuum pump (not shown) connected to valve **V38**, to flush the chamber. This flushing is repeated several times to completely cleanse the tubing branches of the mixer. The mixer is now ready. The ionisation heads next to mixing chamber **261** are connected to a voltage corresponding to approximately 36% of the calculated total ionising voltage, DC current is allowed to flow through magnetic coils **297** and **299** around chamber **261**, and high frequency current is allowed to pass through the mixing chamber. Helium is then slowly admitted, via port **203**, into the mixer. From port **203**, the helium passes through ionisation head **219** into glass tubing coil **259**. This glass coil, being outside magnetic coils **297** and **299**, is in the diverging portion of a magnetic field. The helium slowly flowing through glass coil **259** is gently excited. From coil **259**, the helium flows through branch **B45** to ionisation head **275** and from there, via branch **B28**, to ionisation head **229** (see **Fig.17B**). From head **229**, the gas flows through non-directed cathode ray tube **227** to high-frequency discharger **225**. The high frequency discharger **225**, with heating element, discharges, separates or completely neutralises the charge of any radioactive and/or cosmic particles that are in the helium atom in addition to the protons, neutrons and electrons.

The gas exits discharger **225** via branch **B26** and passes to high-frequency discharger **285**. The high frequency discharger **285**, without heating element, disturbs the frequency of oscillation which binds the gas atoms together. This prepares the helium atoms so that the electrons can more easily be split from the nucleus during the excitation and ignition process in the engine. Discharger **285** includes a phosphorus screen or deposit (similar to the coating on a cathode ray tube) which makes discharges in the tube visible. From discharger **285**, the helium passes through directed cathode ray tube **265** and focused x-ray tube **263**. Directed cathode ray tube **265** produces cathode rays which oscillate back and forth longitudinally underneath and along the gas carrying tube. After that, the helium passes successively through branch **B21**, ionisation head **221**, branch **B23**, twin parallel magnetic coil **266**, and branch **B25** into mixing chamber **261**. Helium flows slowly into and through apparatus **201**. The helium atoms become ionised as a result of excitation by magnetic force, high frequency vibrations and charge acquired from the ionisation heads. When sufficient helium has entered the apparatus, the ionisation energy (which is approximately 36% of the total) is totally absorbed. A spectroscopic flash of light in the mixing

chamber signals that the precise, proper quantity of helium has been allowed to enter. The entry of helium is then immediately halted by the closing of valve **V3**.

The next step in preparing the fuel is to add neon to the mixture. The potential on the relevant ionisation heads, particularly head **241** (see **Fig.17C**), is raised by the addition of approximately 26% which results in a total of approximately 62% of the total calculated potential and valve **V31** is opened, thereby allowing neon to slowly enter the mixer via port **245**. This gas passes through branch **B36**, ionisation head **241**, and branch **B35** directly into the mixing chamber. Since the previously admitted helium is fully charged, the neon absorbs all of the increased ionisation potential. As soon as the neon acquires the additional charge, a spectroscopic flash of light occurs and the operator closes valve **V31**.

In the same manner, the potential on the ionisation heads is increased by the addition of approximately 17% for a total of approximately 79% of the total calculated potential and then valve **V30** is opened to admit argon into the mixer via port **243**. This gas passes through branch **B34**, ionisation head **239**, and branch **B33** into mixing chamber **261**. Again, when the proper amount of argon has been admitted, it emits a spectroscopic flash of light and the operator closes valve **V30**. Next, the potential on the ionisation heads is increased by the addition of approximately 13% to result in a total of approximately 92% of the total calculated potential and valve **V58** (see **Fig.17D**) is opened to admit krypton into the system. The krypton gas passes through branch **B51**, ionisation head **271** and branch **B48** into chamber **261**. Upon the emission of a spectroscopic flash of light by the gas, the operator closes valve **V58**. Finally, the potential on the ionisation heads is increased by the addition of approximately 8% which brings the ionisation potential to the full 100% of the calculated ionisation voltage and valve **V56** is opened to admit xenon into the mixer via port **279**. This gas passes through branch **B50**, ionisation head **273** and branch **B47** to the mixing chamber. When the proper amount of gas has been admitted, a spectroscopic flash of light occurs signalling the operator to close valve **V56**. Note that there are two filter/absorber units, labelled **253** and **291**. Unit **253** is connected to the neon and argon inlet branches **B33** and **B35** while unit **291** is connected to the krypton and xenon inlet branches **B47** and **B48**. These two units absorb hydrogen residue and immobilise the water vapour created when the pump circulates the gases and generates vacuum states.

After all the gases are admitted in the desired proportions, all the valves are closed. (The mixture in the mixing chamber and in the adjacent tubing is at one atmosphere pressure at this time). Once this is done, the interval valves of the system are all opened (but the inlet and outlet valves remain closed) to allow the mixture to circulate throughout the tubing as follows: branch **B44**, magnetic coils **267** and **269**, ionisation head **240**, branch **B29**, ionisation head **231**, branch **B24**, ionisation head **219**, pump **217**, branches **B15** and **B39A**, ionisation gauge **255**, branches **B38** and **B42**, ionisation head **275**, branch **B28**, ionisation head **229**, non-directed cathode ray tube **227**, quadruple magnetic coil **272**, ionisation head **221**, branch **B23**, twin parallel magnetic coil **266**, branch **B25** and mixing chamber **261**. When this circuit is initially opened, the pressure of the mixture drops 40-50% because some of the tubing had previously been under vacuum. Pump **217** is then started to cause the gases to be slowly and evenly mixed.

Because of dead space in the tubing and the reaction time of the operator, it may occur that the proportions of the gases are not exactly those set forth above. This is remedied during the circulation step. As the gas flows through ionisation gauge **255**, excess gas is removed from the mixture so that the correct proportions are obtained. To do this the grid of gauge **255** is subjected to 100% ionisation energy and is heated to approximately 165 degrees F. This temperature of 165 degrees F is related to xenon's boiling point of -165 degrees F in magnitude but is opposite in sign. Xenon is the heaviest of the five inert gases in the mixture. As the gas mixture flows through ionisation gauge **255**, the gas atoms that are in excess of their prescribed percentages are burned out of the mixture and their charge is acquired by the remaining gas atoms from the grid of the ionisation gauge. Because the gases are under a partial vacuum, the ionisation gauge is able to adjust the gas percentages very precisely. (Note: The steps described in the last two paragraphs are repeated if the finished gases are rejected in the final quality control step described below).

The next step involves purifying the mixture so that only the five inert gases remain, absorbing any free electrons and regulating the electrical charge in the mixture. To do this, the circuit consisting of the following components is opened: Branch **B44**, magnetic coil **267**, magnetic coil **269**, ionisation head **240**, branch **B29**, ionisation head **231**, branch **B24**, ionisation head **219**, pump **217**, branches **B15** and **B39**, magnetic coil **287** (see **Fig.17D**) polariser **289**, branch **B17**, ionising and filtering unit **215**, branches **B16**, **B42**, and **B41**, x-ray tube **263**, branch **B21**, ionisation head **221**, branch **B23**, magnetic coil **266**, branch **B25**, and mixing chamber **261**. The gases should complete this circuit at least three times.

The last step required to prepare the mixture for bottling is polarisation of the argon. The circuit required to do this consists of the following components: mixing chamber **261**, branch **B44**, magnetic coil **267**, magnetic coil **269**, ionisation head **240**, cathode ray tube **265**, branch **B40**, tubing coil **257**, branches **B49** and **B30**, ionisation head **231**, branch **B24**, ionisation head **219**, pump **217**, branches **B15** and **B39**, twin parallel magnetic coil **287** (see

Fig.17D), polariser **289**, branch **B17**, ionising and filtering unit **215**, branches **B16**, **B42** and **B20**, ionisation head **229**, cathode ray tube **227**, magnetic coil **237**, ionisation head **221**, branch **B23** and magnetic coil **266**. This too is repeated at least three times. The key to the polarisation of argon is polariser **289** and twin parallel magnetic coil **287** that encircles it. Polariser **289** is a glass bottle which is filled with finely powdered soft iron which can be easily magnetised. The filled bottle is, in effect, the iron core of the coils. The iron particles align themselves with the magnetic lines of force, which lines radiate from the centre toward the north and south poles. The ionised gas mixture is forced through the magnetised iron powder by means of pump pressure and vacuum, thereby polarising the argon gas. Filters **293** and **295** are disposed as shown in order to filter metallic particles out of the gas.

The mixture is now double-checked by means of spark chamber **251** at atmospheric pressure since the fusion reaction in the engine is started at one atmosphere. Because the gases in mixing apparatus **201** are at a partial vacuum, sufficient gases must be pumped into spark chamber **251** to attain atmospheric pressure. To do this valves **V33**, **V36** and **V40A** are closed and circulating pump **217** pumps the gases in the mixing apparatus via branches **B15** and **B39A**, through check valve **V39A** into spark chamber **251** until the vacuum and pressure gauge **242** indicates that the gases within spark chamber **251** are at atmospheric pressure. Valve **V34** is then closed. The spark chamber is similar to a cloud chamber. Six or more high capacity brass capacitor plates are spaced 1/8" to 1/4" apart in the chamber. A small plastic container holds the thorium 232. One side of the chamber is equipped with a thick glass window through which sparks in the chamber may be observed. A potential is placed on the brass plates in the chamber and the current flowing between the plates is measured. If this current exactly corresponds to the ionisation current, the mixture is acceptable. A difference of greater than 5% is not acceptable. A lesser difference can be corrected by recirculating the gas in the mixer and particularly through ionisation gauge **255** as previously described in the circulation step. A second test is then given the gases that pass the first test. A calculated high frequency current is gradually imposed on the spark chamber capacitor plates. This excitation causes neutrons to be emitted from the thorium 232 which, if the mixture is satisfactory, can be easily seen as a thin thread of light in the chamber. If the mixture is not satisfactory, light discharges cannot be seen and the high frequency circuit will short out and turn off before the desired frequency is reached.

To bottle the mixture, valve **V33** is opened and valves **V36** and **V40** are closed. During bottling polariser **289**, twin parallel magnetic coil **287**, ionisation unit **215** and ion gauge **255** are electrically energised (all electrical circuits are previously de-energised) to improve the stability of the mixture. The prepared gases are withdrawn from the mixing apparatus via branches **B24** and **B16**, ionisation unit **215**, branch **B17**, filters **293** and **295**, polariser **289**, twin parallel magnetic coil **287**, branch **B39**, ion gauge **255**, check valve **V39A**, branch B38 and spark chamber 251. If desired, after bottling the mixer may be exhausted by opening valves **V12, V13, V14, V23, V24, V29, V32, V57** and **V59**. Of course, one can also automate the fuel preparation process to be continuous so that it would never be necessary to exhaust the gas.

In operation of mixing apparatus **201**, certain operational factors must be considered. For one, no electrical devices can be on without the pump being in operation because an electrical device that is on can damage adjacent gas that is not circulating. For another, it should be noted that directed cathode ray tube **265**, non-directed cathode ray tube **227** and focused x-ray tube **263** serve different functions at different points in the mixing process. In one mode, they provide hot cathode radiation, which can occur only in a vacuum. When gases are flowing through these devices, they provide a cold cathode discharge. For example, during argon polarisation and the circulation step, focused x-ray tube **263** is under vacuum and affects the gases flowing through ionisation head **240** by way of hot cathode radiation. During the introduction of the different gases into mixing apparatus **201** and during the recirculation step, the gases are flowing through focused x-ray tube **263**, which affects the gases by way of a cold cathode discharge.

It is preferred that each switchable electrical component in mixing apparatus **201** be wired into a separate circuit despite the fact that one of the poles of each could be commonly wired. In a common ground circuit if one device is turned on, all of the other units may also turn on because the gases in the device are conductive. In addition, if one unit on a common circuit were energised with high frequency current, the others would also be affected. In the same vein, the high frequency current cannot be used when the cathode ray tubes, the x-ray tubes or the dischargers are heated and under vacuum because the heater filaments will burn out.

Finally, the current source, the variable rectifiers and the electrical measuring instruments must be located more than ten feet from mixing apparatus **201** because the high frequency current is harmful to the rectifiers, causing them to burn out or short out.

It is hoped that a brief summary of the concepts used by the inventor in developing the above invention will be helpful to the reader, it being understood that this summary is in no way intended to limit the claims which follow or to affect their validity. The first concept is that of using an inert gas mixture at approximately one atmosphere at TDC (at ignition) as a fuel in a thermonuclear energy production process. The second concept is the layering of

the various inert gases, which layering is designed to confine the input energy in the innermost layers during pre-excitement and ignition, to provide thermal insulation for the container walls during and after ignition, to transmit power resulting from the ignition through the layers in turn to the piston, to absorb the pressure generated during ignition to protect the cylinder walls, and to provide an orderly, predictable positioning of the argon layer during the BDC to TDC portion of the engine cycle. The third concept of this invention involves utilising electric current produced in one cylinder of a pair to perform functions in the other cylinder of that pair. This concept includes the sub-concepts of generating electric current by atomic recombination and of electric generation in place resulting from the rotation of layered inert gases within each cylinder because of the changed polarity of the encircling coils at BDC, from judicious placement of coils which produce magnetic field lines which are cut by a near perfect conductor (polarised argon), and from movement of said near perfect conductor through the magnetic field.

The fourth and fifth concepts of this invention are the transformation of rapid, intense, but short duration thermonuclear reactions into pressure that is transmitted from inert gas to inert gas until it creates linear kinetic energy at the piston, which energy is converted into rotary kinetic energy by a crankshaft, and the use of a shaft-driven generator to provide power to spaced field coils during the BDC to TDC portion of the cycle of each cylinder.

The sixth concept concerns adequate pre-excitement of the inert gas fuel and more particularly involves the sub-concepts of pre-exciting the fuel in the mixing process, of manipulation of the currents in the coils surrounding each cylinder, of discharging the capacitors surrounding each cylinder at predetermined times in the cycles, of causing a stream of electrical particles to flow between electrodes and a conductive discharge point on the piston, of emitting alpha, beta and gamma rays from an anode and a cathode containing low level radioactive material to the piston's discharge point, of accelerating the alpha, beta and gamma rays by the application of a high-voltage field, and of situating capacitor plates 90 degrees from the anode and cathode to slow and reflect neutrons generated during ignition. The seventh concept involves the provision of a minute, pellet-type fission ignition, the heat from which causes a minute fusion as the result of the ignition chamber shape and arrangement, as a result of the collision of the alpha, beta and gamma rays and the electrical particles at a focal point in conjunction with the discharge of the capacitors that surround the cylinder through the electrodes, and as a result of increasing the magnetic field in the direction of the movement of each piston.

Robert Britt's Inert Gas Engine

US Patent 3,977,191 **31st August 1976** **Inventor: Robert G. Britt**

ATOMIC EXPANSION REFLEX OPTICS POWER SOURCE (AEROPS) ENGINE

ABSTRACT

An engine is provided which will greatly reduce atmospheric pollution and noise by providing a sealed system engine power source which has no exhaust nor intake ports. The engine includes a spherical hollow pressure chamber which is provided with a reflecting mirror surface. A noble gas mixture within the chamber is energised by electrodes and work is derived from the expansion of the gas mixture against a piston.

SUMMARY OF THE INVENTION

An atomic expansion reflex optics power source (AEROPS) engine, having a central crankshaft surrounded by a crankcase. The crankcase has a number of cylinders and a number of pistons located within the cylinders. The pistons are connected to the crankshaft by a number of connecting rods. As the crankshaft turns, the pistons move in a reciprocating motion within the cylinders. An assembly consisting of a number of hollow spherical pressure chambers, having a number of electrodes and hollow tubes, with air-cooling fins, is mounted on the top of each cylinder. The necessary gaskets are provided as needed to seal the complete engine assemblies from atmospheric pressure. A means is provided to charge the hollow spherical pressure chamber assembly and the engine crankcase with noble gas mixtures through a series of valves and tubes. A source of medium-voltage pulses is applied to two of the electrodes extending into each of the hollow spherical pressure chambers.

When a source of high-voltage pulses is applied from an electrical rotary distributor switch to other electrodes extending into each of the hollow spherical pressure chambers in a continuous firing order, electrical discharges take place periodically in the various hollow spherical pressure chambers. When the electrical discharges take place, high energy photons are released on many different electromagnetic frequencies. The photons strike the atoms of the various mixed gases, e.g., xenon, krypton, helium and mercury, at different electromagnetic frequencies to which each is selectively sensitive, and the atoms become excited. The first photons emitted are reflected back into the mass of excited atoms by a reflecting mirror surface on the inside wall of any particular hollow spherical pressure chamber, and this triggers more photons to be released by these atoms. They are reflected likewise and strike other atoms into excitation and photon energy release. The electrons orbiting around the protons of each excited atom in any hollow spherical pressure chamber increase in speed and expand outward from centre via centrifugal force causing the atoms to enlarge in size. Consequently, a pressure wave is developed, the gases expand and the pressure of the gas increases.

As the gases expand, the increased pressure is applied to the top of the pistons in the various cylinders fired selectively by the electrical distributor. The force periodically applied to the pistons is transmitted to the connecting rods which turn the crankshaft to produce rotary power. Throttle control valves and connecting tubes form a bypass between opposing hollow spherical pressure chambers of each engine section thereby providing a means of controlling engine speed and power. The means whereby the excited atoms are returned to normal minimum energy ground-state and minimum pressure level, is provided by disrupting the electrical discharge between the medium-voltage electrodes, by cooling the atoms as they pass through a heat transfer assembly, and by the increase in the volume area above the pistons at the bottom of their power stroke. The AEROPS engine as described above provides a sealed unit power source which has no atmospheric air intake nor exhaust emission. The AEROPS engine is therefore pollution free.

BRIEF OBJECTIVE OF THE INVENTION

This invention relates to the development of an atomic expansion reflex optics power source (AEROPS) engine, having the advantages of greater safety, economy and efficiency over those disclosed in the prior art. The principal object of this invention is to provide a new engine power technology which will greatly reduce atmospheric pollution and noise, by providing a sealed system engine power source which has no exhaust nor intake ports.

Engine power is provided by expanding the atoms of various noble gas mixtures. The pressure of the gases increases periodically to drive the pistons and crankshaft in the engine to produce safe rotary power. The objects and other advantages of this invention will become better understood to those skilled in the art when viewed in light of the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION

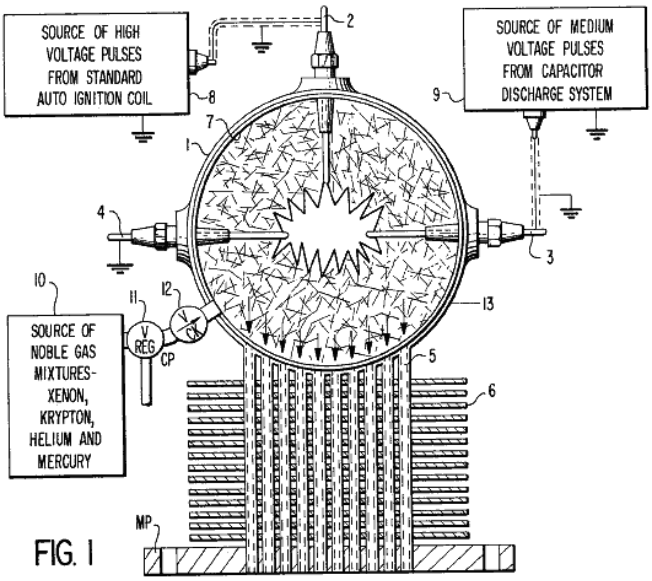

FIG. 1

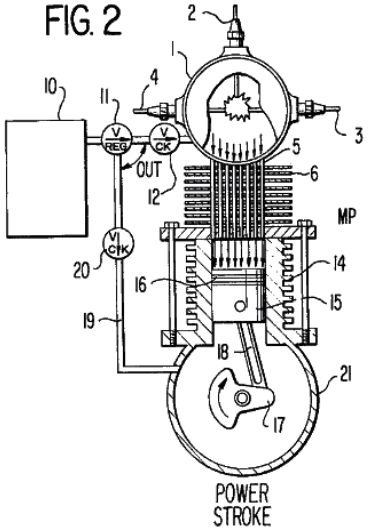
Referring to **Fig.1** of the drawings, the AEROPS engine comprises a hollow spherical pressure chamber **1** having an insulated high-voltage electrode **2** mounted on the top, an insulated medium-voltage electrode **3** mounted on the right, and an insulated common ground electrode **4** mounted on the left, as shown in this particular view. Electrodes **2, 3** and **4** extend through the wall of the hollow spherical pressure chamber **1** and each electrode forms a pressure seal. A plurality of hollow tubes **5** arranged in a cylindrical pattern extend through the wall of the hollow spherical pressure chamber **1**, and each hollow tube is welded to the pressure chamber to form a pressure seal. The opposite ends of hollow tubes **5** extend through the mounting plate **MP** and are welded likewise to form a pressure seal. A plurality of heat transfer fins **6** are welded at intervals along the length of said hollow tubes **5**. A bright reflecting mirror surface **7** is provided on the inner wall of the hollow spherical pressure chamber **1**. A source of high-voltage **8** is periodically connected to the insulated high-voltage electrodes **2** and **4**. A source of medium-voltage **9** from a discharge capacitor is connected to the insulated medium-voltage electrodes **3** and **4**. A source of noble gas mixtures **10**, e.g., xenon, krypton, helium and mercury is applied under pressure into the hollow spherical pressure chamber **1** through pressure regulator valve **11** and check valve **12**.

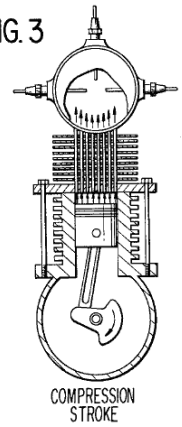
FIG. 2



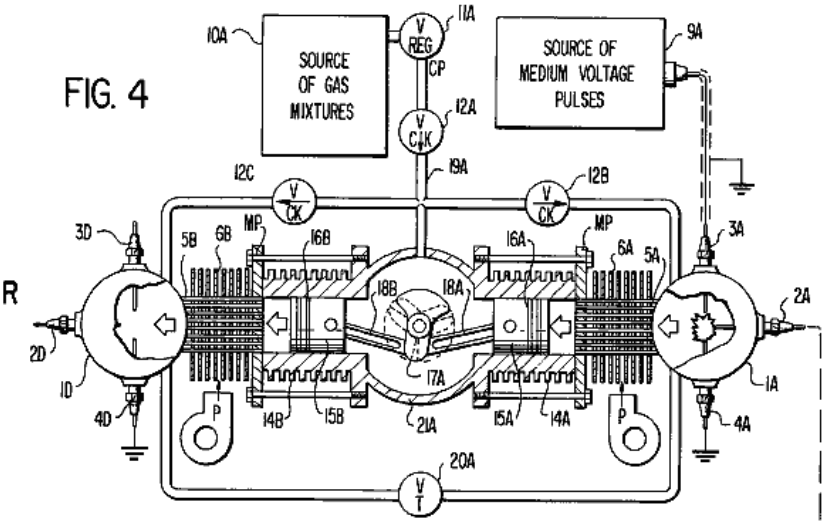
Referring now to **Fig.2** of the drawings, the complete assembly **13** shown in **Fig.1** is mounted on the top of the cylinder **14** via mounting plate **MP**. The necessary gaskets or other means are provided to seal the engine and prevent loss of gases into the atmosphere. The piston **15** located within cylinder **14** has several rings **16** which seal against the inner wall of the cylinder. The piston **15** is connected to the crankshaft **17** by connecting rod **18**. The source of noble gas mixtures **10** is applied under pressure into the crankcase **21** through pressure regulator valve **11**, check valve **12** and capillary tube **19**. The piston **15** is now balanced between equal gas pressures. Assuming that the engine is running and the piston **15** is just passing Top-Dead-Centre (TDC), a source of medium-voltage from a capacitor discharge system **9** (**Fig.6**, a single typical capacitor section) is applied to electrodes **3** and **4**. A source of high-voltage pulses from a standard ignition coil **8** (such as shown in **Fig.7**) is applied to electrodes **2** and **4** and the gases within the hollow spherical pressure chamber **1** are ionised and made electrically conductive. An electrical discharge takes place between electrodes **3** and **4** through the gases in the hollow spherical pressure chamber **1**.

The electrical discharge releases high energy photons on many different electromagnetic frequencies. The photons strike the atoms of the various gases, e.g., xenon, krypton, helium and mercury at different electromagnetic frequencies to which each atom is selectively sensitive and the atoms of each gas become excited. The first photons emitted are reflected back into the mass of excited atoms by the reflecting mirror surface **7**. This triggers more photons to be released by these atoms, and they are reflected likewise from the mirror surface 7 and strike other atoms into excitation and more photons are released as the chain reaction progresses. The electrons orbiting around the protons of each excited atom increase in speed and expand outward in a new orbital pattern due to an increase in centrifugal force. Consequently, a pressure wave is developed in the gases as the atoms expand and the overall pressure of the gases within the hollow spherical pressure chamber **1** increases. As the gases expand they pass through the hollow tubes **5** and apply pressure on the top of piston **15**. The pressure pushes the piston **15** and the force and motion of the piston is transmitted through the connecting rod **18** to the crankshaft **17** rotating it in a clockwise direction. At this point of operation, the power stroke is completed and the capacitor in the medium-voltage capacitor discharge system **9** is discharged. The excited atoms return to normal ground state and the gases return to normal pressure level. The capacitor in the medium-voltage capacitor discharge system **9** is recharged during the time period between (TDC) power strokes.

FIG. 3

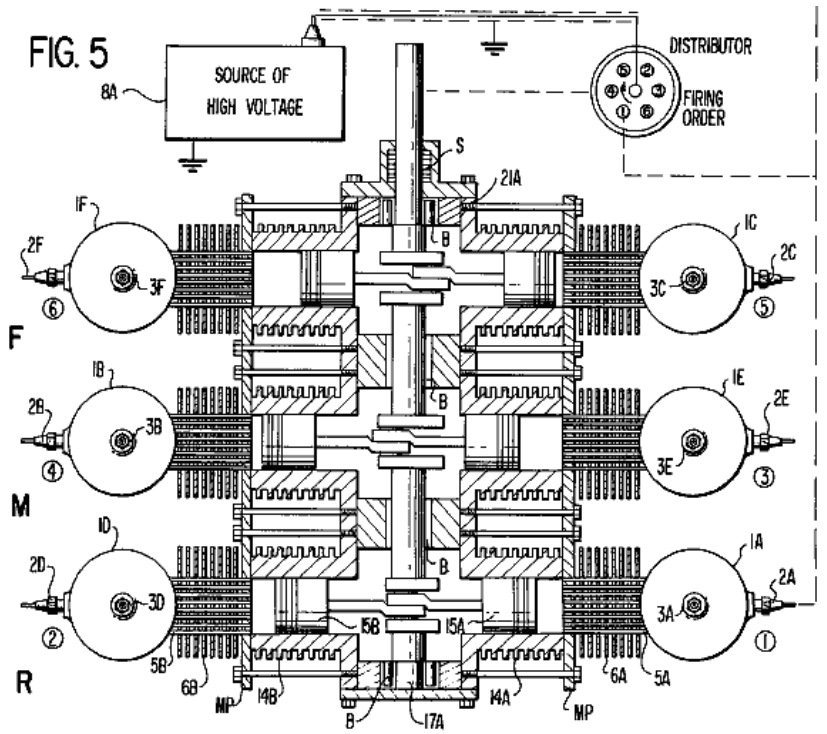


Referring now to **Fig.3** of the drawings, the compression stroke of the engine is shown. In this engine cycle the gases above the piston are forced back into the hollow spherical pressure chamber through the tubes of the heat transfer assembly. The gases are cooled as the heat is conducted into the fins of the heat transfer assembly and carried away by an air blast passing through the fins. An example is shown in **Fig.4**, the centrifugal air pump **P** providing an air blast upon like fins.



Some of the basic elements of the invention as set forth in **Fig.1**, **Fig.2**, and **Fig.3** are now shown in **Fig.4** and **Fig.5** which show complete details of a six-cylinder horizontally-opposed AEROPS engine.

Referring now to **Fig.4** and **Fig.5** of the drawings. **Fig.4** is a view of the rear section of the engine showing the crankshaft, centre axis and two of the horizontally-opposed cylinders. In as much as the rear **R**, middle **M** and front **F** sections of the engine possess identical features, only the rear **R** engine section will be elaborated upon in detail in order to prevent repetition and in the interest of simplification. The crankshaft **17A** consists of three cranks spaced 120 degrees apart in a 360 degree circle as shown. Both connecting rods **18A** and **18B** are connected to the same crank. Their opposite ends connect to pistons **15A** and **15B**, located in cylinders **14A** and **14B** respectively. Each piston has pressure sealing rings **16A** and **16B**. The hollow spherical pressure chamber assemblies consisting of **1A** and **1D** are mounted on cylinders **14A** and **14B** via mounting plates **MP**. The necessary gaskets are provided as needed to seal the complete engine assemblies from atmospheric pressure.



The source of gas mixtures **10A** is applied under pressure to pressure regulator valve **11A** and flows through check valve **12A**, through check valve **12B** to the hollow spherical pressure chamber **1A**, and through check valve

12C to the hollow spherical pressure chamber **1D**. The gas flow network consisting of capillary tubes below point **19A** represents the flow of gases to the rear section **R** of the engine. The middle section **M** and the front section **F** both have gas flow networks identical to that consisting of capillary tubes below point **19A**, while the gas flow network above is common to all engine sections. Throttle valve **20A** and the connecting tubing form a variable bypass between hollow spherical pressure chambers **1A** and **1D** to control engine speed and power. Engine sections **R**, **M** and **F** each have this bypass throttle network. The three throttle valves have their control shafts ganged together. A source of medium-voltage pulses **9A** is connected to medium-voltage electrodes **3A** and **3D**. In one particular embodiment the medium-voltage is 500 volts. A source of high-voltage pulses **8A** is connected to electrode **2A** through the distributor as shown. Electrode **4A** is connected to common ground. Centrifugal air pumps **P** force air through heat transfer fins **6A** and **6B** to cool the gases flowing in the tubes **5A** and **5B**.

Fig.5 is a top view of the AEROPS engine showing the six cylinders and crankshaft arrangement consisting of the rear **R**, middle **M** and front **F** sections. The crankshaft **17A** is mounted on bearings **B**, and a multiple shaft seal **S** is provided as well as the necessary seals at other points to prevent loss of gases into the atmosphere. The hollow spherical pressure chambers **1A, 1B, 1C, 1D, 1E** and **1F** are shown in detail with high-voltage electrodes **2A, 2B, 2C, 2D, 2E, 2F** and medium-voltage electrodes **3A, 3B, 3C, 3E** and **3F**. The common ground electrodes **4A, 4B, 4C, 4D, 4E, 4F** are not shown in **Fig.5** but are typical of the common ground electrodes **4A** and **4D** shown in **Fig.4**. It should be noted that the cranks on crankshaft **17A** are so arranged to provide directly opposing cylinders rather than a conventional staggered cylinder design.

FIG. 6

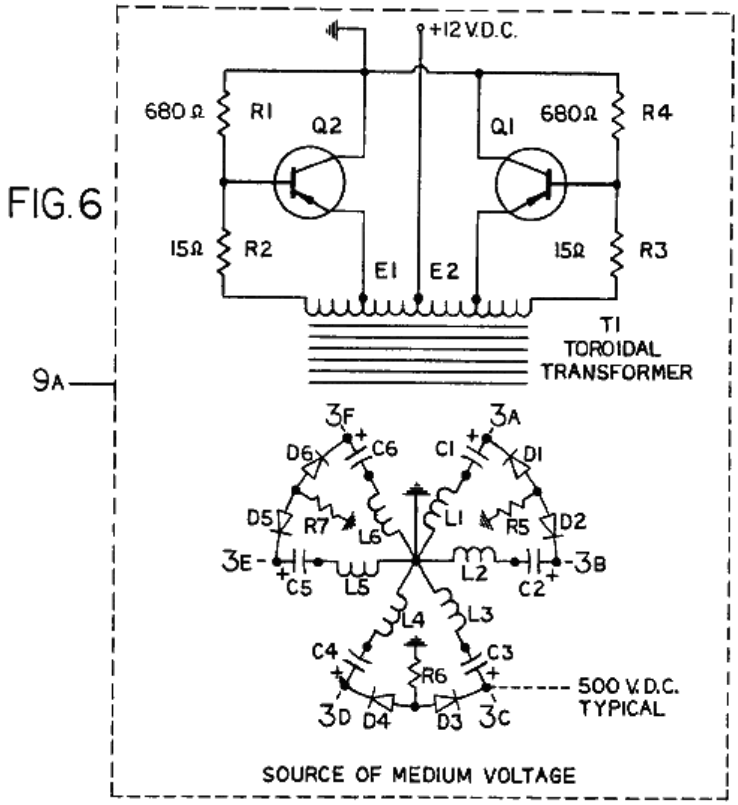


Fig.6 is an electrical schematic of the source of medium-voltage **9A**. The complete operation of the converter is explained as follows: The battery voltage 12 VDC is applied to transformer **T1**, which causes currents to pass through resistors **R1, R2, R3** and **R4**. Since it is not possible for these two paths to be exactly equal in resistance, one-half of the primary winding of **T1** will have a somewhat higher current flow. Assuming that the current through the upper half of the primary winding is slightly higher than the current through the lower half, the voltages developed in the two feedback windings (the ends connected to **R3** and **R2**) tend to turn transistor **Q2** on and transistor **Q1** off. The increased conduction of **Q2** causes additional current to flow through the lower half of the transformer primary winding. The increase in current induces voltages in the feedback windings which further drives **Q2** into conduction and **Q1** into cut-off, simultaneously transferring energy to the secondary of **T1**. When the current through the lower half of the primary winding of **T1** reaches a point where it can no longer increase due to the resistance of the primary circuit and saturation of the transformer core, the signal applied to the transistor from the feedback winding drops to zero, thereby turning **Q2** off. The current in this portion of the primary winding drops immediately, causing a collapse of the field about the windings of **T1**. This collapse in field flux, cutting across all of the windings in the transformer, develops voltages in the transformer windings that are opposite in polarity to the voltages developed by the original field. This new voltage now drives **Q2** into cut-off

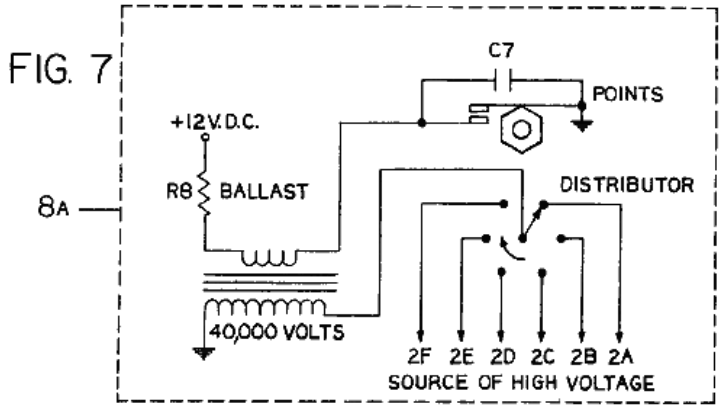
and drives **Q1** into conduction. The collapsing field simultaneously delivers power to the secondary windings **L1, L2, L3, L4, L5** and **L6**. The output voltage of each winding is connected through resistors **R5, R6** and **R7** and diode rectifiers **D1, D2, D3, D4, D5** and **D6**, respectively, whereby capacitors **C1, C2, C3, C4, C5** and **C6** are charged with a medium-voltage potential of the polarity shown. The output voltage is made available at points **3A, 3B, 3C, 3D, 3E** and **3F** which are connected to the respective medium-voltage electrodes on the engine shown in **Fig.4** and **Fig.5**.



Referring now to **Fig.7** of the drawings, a conventional "Kettering" ignition system provides a source of high-voltage pulses **8A** of approximately 40,000 volts to a distributor, which provides selective voltage output at **2A, 2B, 2C, 2D, 2E** and **2F**, which are connected to the respective high-voltage electrodes on the engine shown in **Fig.4** and **Fig.5**. The distributor is driven by the engine crankshaft **17A** (**Fig.5**) at a one to one mechanical gear ratio.

Referring again to **Fig.4** and **Fig.5** of the drawings, the operation of the engine is as follows: Assuming that a source of noble gas mixtures, e.g., xenon, krypton, helium and mercury is applied under pressure to the hollow spherical pressure chambers **1A, 1B, 1C, 1D, 1E** and **1F** and internally to the crankcase **21A** through pressure regulator valve **11A** and check valves **12A**, **12B** and **12C**; and the source of medium-voltage **9A** is applied to electrodes **3A, 3B, 3C, 3D, 3E** and **3F**; and a source of high-voltage pulse **8A** is applied to electrode **2A** through the timing distributor, the gas mixtures in the hollow spherical pressure chamber **1A** is ionised and an electrical discharge occurs immediately between electrodes **3A** and **4A**.

High-energy photons are released on many different electromagnetic frequencies. The photons strike the atoms of the various gases, e.g., xenon, krypton, helium and mercury at different electromagnetic frequencies to which each is particularly sensitive and the atoms of each gas become excited. The first photons emitted are reflected back into the mass of excited atoms by the internal reflecting mirror surface on the inside wall of the hollow spherical pressure chamber **1A**. This triggers more photons to be released by these atoms and they are reflected likewise from the mirror surface and strike other atoms into excitation and more photons are released as the chain reaction progresses. The electrons orbiting around the protons of each excited atom in the hollow spherical pressure chamber **1A** increase in speed and expand outward in a new orbital pattern due to an increase in centrifugal force. Consequently, a pressure wave is developed in the gases as the atoms expand and the overall pressure of the gases within the hollow spherical pressure chamber **1A** increases.

As the gases expand they pass through the hollow tubes **5A** applying pressure on the top of piston **15A**. The pressure applied to piston **15A** is transmitted through connecting rod **18A** to the crankshaft **17A** rotating it in a clockwise direction. As the crankshaft **17A** rotates it pushes piston **15B** via connecting rod **18B** in the direction of a compression stroke, forcing the gases on the top of the piston through hollow tubes **5B** into the hollow spherical pressure chamber **1D**. As the gases pass through the hollow tubes **5A** and **5B** the heat contained in the gases is conducted into the heat transfer fins **6A** and **6B**, where it is dissipated by a blast of air passing through said fins from the centrifugal air pumps **P**. At this point of operation the power stroke of piston **15A** is completed and the capacitor in the medium-voltage capacitor discharge system **9A** is discharged. The excited atoms return to normal ground state and the gases return to normal pressure level. The capacitor in the medium-voltage capacitor discharge system **9A** is recharged during the time period between the power strokes of piston **15A**.

The above power stroke cycle occurs exactly the same in the remaining cylinders as the high-voltage firing order progresses in respect to the position of the distributor switch. In as much as the AEROPS engine delivers six power strokes per single crankshaft revolution, the crankshaft drives the distributor rotor at a one to one shaft ratio. The complete high-voltage firing order is 1, 4, 5, 2, 3, 6, whereas, the high-voltage is applied to electrodes **2A, 2B, 2C, 2D, 2E** and **2F** respectively. A means of controlling engine speed and power is provided by a plurality of throttle control valves and connecting tubes which form a bypass between opposing hollow spherical pressure chambers of each engine section.

The AEROPS engine as described above provides a sealed unit power source which has no atmospheric air intake nor exhaust emission and is therefore pollution free.

Floyd Sweet

Recently, some additional information on Floyd Sweet's device, has been released publicly by an associate of Floyd's who goes just by his first name of "Maurice" and who, having reached the age of seventy has decided that it is time to release this additional information.

Maurice says: After observing the comments made over the past year regarding the Sweet-VTA Energy Device, I decided to "come out of the woodwork" and explain what basically is NOT known regarding Floyd Sweet ("Sparky") and his energy device.

Keep in mind that I am 70 years old, quite computer illiterate, my background Being mainly Political Science (Graduate Degree); consulting with State Legislatures; Mental Health (former Executive Director of five clinics); and, acquiring Venture Capital for High Tech. Equipment (such as medical equipment) and various Projects. My story is very unusual and strange, but, nevertheless TRUE! At my age I have no one to impress with what I am about to tell you. My only interest is to correct error where possible and to make certain information known!

Remember, that I have never had any education in electronics. This was a real advantage for me because I did not have any electrical principles which I had to UN-LEARN in anything that Floyd told us. Unfortunately, one of my brothers who trained for 35 years in electronics was "blown away" when Floyd told him that "he needed to reverse the concepts which he was taught about the action of an electron and treat it like it was positive". Therefore, for Sparky's modelling, electrons were flowing and acting in the opposite direction to what was normally modelled by a trained physicist. See what I mean? The Dean of the School of Science of MIT that verified that Sparky had an MSEE degree and came third in his class of more than two hundred.

Hopefully sincere researchers will be able to obtain some useful information in what I attempt to explain in the future that will help them to duplicate what Floyd had. In this respect, one day after Floyd had repeatedly asked me: "What is this device Maurice?" and I repeatedly gave him the wrong answer, saying that it was an energy device, I finally realised that what was important to him was that he considered the device to be a TIME MACHINE - his emphasis was NOT on the energy. He told me never to forget that the most important thing was that the device was a "Time Machine".

Maurice draws attention to the fact that Floyd Sweet graduated as an M.S.E.E. from the Massachusetts Institute of Technology in 1969 and his thesis "Dynamics of Magnetic Domains" is considered by the M.I.T. scientific community to be unparalleled in magnetic concepts. He received the coveted Dean's Award for his scientific research and his academic level in Electrical Engineering achievement ranks third in the history of the M.I.T. School of Science. He has an extraordinary talent in the area of Engineering Mathematics not to mention his concept of electromagnetic and related electrical phenomena and understanding of abstract intangibles needed to predict the unforeseen.

Maurice says: In about 1988 John, who my two brothers and I were involved with in the High Tech field realised that my brother, who was a Doctor (Doctor brother), was interested in negative energy devices for the treatment of the physical body (similar to Rife/Tesla Frequency Machines). John had formerly been employed at NASA with Floyd Sweet. John lived in California close to Floyd (Sherman Oaks).

My doctor brother and I were introduced to Floyd by John and we waited patiently for the time when we could see the VTA device. We saw it on the table at his house during various visits but it was not operating. Floyd was like many inventors who played games with you. Each time we would drive 13 hours to see him thinking we could see the device operating, but he would have some excuse for not turning it on, or he would just ignore the purpose of our visit.

On one visit, I looked over at Floyd and he was “showing off” his Barium Ferrite bar magnet. The magnet was approximately 1/2” thick, 7” long and 3” wide. He had a small piece of metal that was standing on the top of the magnet at a 45 degree angle. As I recall, he claimed that the 45 degree angle was needed in the treatment of the magnet so that it could capture Scalar waves. The magnets were mainly functioning as a “gate” for the Scalar waves. Additionally, if you placed a piece of thin “flexible” (ribbon type) metal flat on the top of the magnet, the middle of the “ribbon metal” would be “sucked down” flat at the middle of the magnet and both ends of the “ribbon metal” would be bowed-up at each end of the magnet. Also, I came to understand from another inventor that we introduced later on to Floyd that the “figure eight” design (flux flow?) on the top of the magnet played an important part in the functioning of the magnet - I don’t really know about the concept and can’t relay any additional information.

On another visit, Floyd demonstrated the flowing flux of the magnet. He had a TV monitor and he would place the magnet by the screen and you could see all the beautiful colours of the flux as it moved across the monitor screen. My electronics brother told me that Floyd had told him that he had a way of treating the magnet by calibrating the Scalar wave angle coming in using the TV monitor. A side note is that Floyd delighted in telling people, when they asked how he treated his magnets, they should get the magnets real hot first. This apparently "screwed up" the magnetism and he enjoyed doing this for some weird reason!

Finally, after 12 trips across the California Desert, Floyd agreed to show us the Device in operation. In his defence, Floyd did claim that on some earlier planned demonstrations that his magnets had been "pulverized" by artificial earthquakes coming up through Mexico. He designed some type of buffer in the Device that eliminated the problem, but, it was an on-going problem for quite a period of time. This reminds me now that I must digress because I need to tell you about the Government (or who?) involvement with us.

When we first started to visit Floyd, our phones were all "tapped" - I do not know by whom. My electronics brother worked full-time with the Air National Guard and his specialty was electronic Security, Crypto, etc. tied in with SAC bases in our area and the surrounding States. Additionally, he had set-up the "clean room" for the President of the United States when he visited our State. I mention this because even my electronics brother was doubtful in the beginning that we were all being monitored. On one occasion, my doctor brother had his complete prior telephone conversation played back to him when he answered the phone (twenty minutes later) - I think it was probably some type of "screw-up" by whoever was monitoring our phones. My biggest complaint was the consistent early morning 3am call and then a "hang-up" when you answered - for what reason I don't know other than for harassment purposes.

I give you the above information so that you can understand the seriousness of what we were involved with.

Floyd's Energy Device was mainly three things:

(1) It was a healing device - negative electricity - negative time. In theory, you could re-set the template in your DNA with this energy source and therefore cleanse the body of all impurities that your ancestors had acquired over time. Additionally, you could kill current disease (virus/bacteria) in the body by using the right frequencies, and this did not disturb any other body cells. This is why Floyd needed my doctor brother to help him arrive at the proper medical protocol for using his technology. Additionally, if you note in the Payroll Expenses attachment of this e-mail, a one-line item of expenditure is for AIDS-related materials in which Floyd and my doctor brother had a real interest. My doctor brother had an agreement with Floyd to build three medical interferometers which would all have a noble gas plasma inside them. I actually witnessed one of these devices in operation. At the end of the (approximately 20 inch long) tube-like structure you could feel a pulsing being emitted at the end of the tube on to whichever part of the body you wanted treated. My doctor brother had ordered two Interferometers from Floyd which were about 4 feet long.

(2) The VTA energy device is probably the world's worst weapon. Floyd claimed that like Nicola Tesla, you could cause "artificial earthquakes" - besides destroying buildings. As I understood from people in the intelligence world, which we de-briefed after we saw the device operate, three countries have what is called the "Tesla Cannon"; Russia, America and I never found out who the third country was. As mentioned earlier, this energy source is what disabled Floyd's VTA equipment over many months until he got his "buffer" built into his device. Further, this is why the Federal Government had such an interest in what we were doing with Floyd during the time we spent with him.

(3) The device was an Energy source for the home (could change negative energy to positive energy). It was also an energy source for the car and many other purposes. The cost of building one of these energy devices was only about US $200.00 - incredible!

Description of the VTA device:

On the day that we finally got to see the device operating, my doctor brother and I had finally convinced my electronics brother to accompany us to Sherman Oaks, California to see the demonstration. My doctor brother and I had made ALL the preliminary trips to see Floyd minus our electronics brother because he was literally a "doubting Thomas", being heavily involved in the electronics field and full of Maxwell's Theories of electronics, etc. Yes, you could say that he was a traditional electronics person. But, for this reason, we needed my electronics brother to be our DEBUNKER in case the device was not what it was portrayed to be. We had one other witness "Gary", an associate of mine who was to bring in

the venture capital funding if the device proved to be as good as claimed.

The day when we witnessed the VTA device operating is a day which I shall never forget. To actually see a device working, which cost only $200 dollars to make and which could create all the clean energy you would ever need, was "awesome". I know I have been "altered" ever since knowing that such a device existed. Now for a brief description of the Device:

These are not exact measurements but only approximations. The device was on what I believe to be "Plexi glass" (acrylic). Nothing was hidden. You could see everything, top and bottom through the plastic. The Plexi glass structure was approximately 18" square. We were allowed to pick-up the device and carry it around Floyd's living room so you could see that there were no other electrical connections to it.

On top of the Plexi glass case there were three toroidal coils wound with thin windings of varnished copper wire. There were two barium ferrite bar magnets (approx. 7"x 3"x 1/2"). Present was a volt meter which displayed 120v when the device was turned on. Also, there was an ampere meter which measured the electrical currents flowing when Floyd switched different things on-and-off during the demonstration. The items used for load demonstration included the burner part of the stove, a hair dryer, a fan, and five one-hundred watt globe lights. The fascinating thing to me about the light demo was that the lights had a glow like the overhead lights in your kitchen - a very soft, COOL appearance. Not the look of a traditional bright light bulb such as you have in your lamp on a traditional night stand.

I forgot to mention that the device was started by attaching a 9-volt battery which, I understand, started the magnetic flux in motion. Floyd would then connect the "pigtail" on the device and it would become just one circular energy unit.

As Floyd put more load on the device, the ambient temperature around the device (coils) would start to get lower. Additionally, depending on how much load you added, the device would start to lose some of its weight and you then had levitation beginning to take place. I should note at this point that on one meeting with Floyd, his wife Rose, used some expletives when telling how one day, Floyd kept adding more-and-more load to the device and he almost "brought down" the Apartment Complex he lived in at Sherman Oaks. He turned off the equipment, went out on his patio and pretended that it was a California Earthquake! His neighbours never did know what he had in his apartment. In this respect, I never did find out what the big piece of equipment was in his bedroom. It literally stretched from the ceiling to the floor. It was so heavy that the floor was bowed-in and sunken and that "big sucker" had a growling noise when it was on - I never did find out what it was. It was big like some kind of transformer.

The Rest of The Story:

You are probably wondering what the article on Ron Brandt is about. It's a long story, but after I moved Ron and his laboratory all the way from the mouth of Zion's National Park to "someplace" Oregon to hide him out - he was using "Tachyon Beams" with his medical equipment and after only a couple of minutes the "Black Helicopters" would show up - soooo at my doctor brother's request I moved Ron to Oregon. At the time I thought Ron was a "real flake" because when I helped him forward his mail from a small town in Southern Utah, he asked me how to spell the word "electric" so he could put in the full address of "Brandt Electric". Further, Ron said he was only here on this Earth until 2012 - It was now 1987-88 - and then he had to leave to go to another planet! I now wanted to shoot my doctor brother who got me into this whole moving-Ron thing! My doctor brother told me that Ron had to move fast because Ron had told him that an earthquake was coming in the next few days - Right!

Well, guess what happened a few days later? The largest earthquake in many years in that particular location took place and it even wiped out the hot springs at the Resorts along the Virgin River which runs through Zion's National Park and through the small town of Virgin where Ron lived. I since found out that Ron had invented earthquake equipment along with Philo T. Farnsworth's (Inventor of Television) grandson and six months ahead, they had actually predicted the previous great earthquake in California and their prediction was off by only six minutes! The Government is insisting that they want the equipment, so that is one of the reasons for everyone "hiding out".

Now, why am I giving you all this preliminary information regarding Ron Brandt? Well it seems that Ron has a Magnet Motor which weighs only 75 pounds and which can generate power equivalent to that of a 300 horsepower internal combustion engine. Also, the motor can be a retro-fit in any existing car without the need to design a whole new car. This is the connection I will explain later regarding Ron who could not even spell "electric" and Floyd who was placed 3rd in all the inventions to ever come out of MIT - All I can say is "WOW"!

EVENTS SURROUNDING FLOYD'S DEATH:

I will now leave it up to you to decide whether or not Floyd died of natural causes or was "taken out" by some person, group, or some Government.

In the summer of 1994, my doctor brother suddenly "passed out" at one of our Venture Capital meetings and was rushed to the hospital. After an MRI of his head, it was discovered that he had a brain tumour and it was of the worst kind (very fast growing). This seemed impossible as my doctor brother had always monitored his body daily as he did an occasional experiment on himself with certain medicines. By 11th November 1994, my doctor brother had died. He told us prior to death that "they" (whoever "they" were) had succeeded in placing the fastest growing cancer tumour into his brain - How? - I have no idea! I never did find out. What is important to the free-energy field was that my doctor brother was in daily contact with Floyd and his Associates regarding the energy devices. I was not that important and basically only accompanied my doctor brother to meetings and kind of "got lost in the woodwork". Intellectually, I really was not a threat to anyone. I was only there at meetings to help acquire venture capital.

On the very day that my doctor brother died, my electronics brother and I were at the home of John, (Floyd's Associate from NASA) who for some strange reason had followed my brothers and I to our home city where we lived, bought a home and took up residence there. We did not complain as he was our go-between with Floyd. But the move still seemed strange to me. The reason my electronics brother and I were with John is that John had arranged a conference call with Floyd and us, to see if there was a possibility for Floyd to make some type of energy device which could power the magnet motor that Ron Brandt had. My brothers and I had all the contractual rights to Ron's Magnet Motor which could be used in any car. I thought to myself that now I can really find out how "real" Ron (who could not even spell "electric") was when I matched him up with Floyd from MIT. I could not believe what I heard as Floyd and Ron conversed at the highest electronic levels - "who the 'hell' is Ron?" I thought. Floyd agreed that he would have no problem doing the prototype for Ron's Magnet Motor to power the car.

Floyd mainly worked with my electronics brother on this project as Floyd needed old vacuum tubes which my electronics brother had to acquire for the device and my electronics brother was a real "bench" person which Floyd seemed to favour over academic Electrical Engineers.

During the Spring of 1995, while Floyd was working on our energy device for the car, John (from NASA) and Floyd were elated that there was supposed to be an announcement from the White House regarding Floyd's VTA Energy Device. It seems that Floyd was a past friend of Senator John Glen (the former NASA astronaut) and he had given Glen one of the energy devices. Unfortunately, Glen gave the device to the Department of Energy, who, according to Floyd, passed the device on to General Motors. Floyd was furious and as I understood Floyd was then going to sue GM for two hundred million dollars. As far as I know Floyd never got the device back. I will always remember the extreme disappointment on the faces of Floyd and John when they realised that the trip to Washington DC for the announcement, was not going to take place.

In July 1995, Floyd let us know that the Energy Device was finished and we were to take possession of it. Floyd now lived in Desert Palms, California and that is where we would pick it up. After much thought, we decided we better not board a plane with the device as we were not sure of any magnetic effects on the instruments of the plane in having it transported - it was new technology which still had many questions to be answered. Instead, we decided to drive our car to Desert Palms and bring the device back ourselves.

Floyd called us the day before we were to leave and asked us if he could keep the device for a couple of extra days. He said he had "someone" coming (I thought he said China) and wanted to show them the device. We said ok, we would plan to pick it up when he was done.

A day later, at about 7:00 am Pacific time, there was a frantic call from Floyd's wife Violet (Floyd's wife Rose had died and he had re-married) to my electronics brother's house. My electronics brother was not at home and my sister-in-law, his wife, took the call from Violet. Violet was very traumatised when she told my sister-in-law that Floyd was dead. There was a lot of shouting going on in the background. The people who were there claimed they were from the FBI and that Floyd's equipment belonged to them. Rose was extremely confused with the death of Floyd and people she had never seen before taking all the equipment out of her house to waiting vans. She asked my sister-in-law what to do and my sister-in-law had NO idea as she was not aware of what my brothers and I had going on!

Violet also said that about 5:00 pm the previous night, two men whom she had never seen before, showed up to see Floyd. Floyd was with them for a period of time and then they left. At about 8:00 pm, Floyd was having a cup of coffee when he fell out of the chair on to the floor. She called for an ambulance and when they arrived they would not let her ride with them. Violet was 75 years old and didn't drive. About twenty minutes later the ambulance called back to Violet and told her they didn't think Floyd was going to "make it"!! As I understand it, Floyd's body was cremated. How soon afterwards, I don't know. The end result for my brothers and I is that ALL of our energy equipment that Floyd made for us was taken - By Whom??

Who were the two men who met with Floyd a few hours before his death? Was anything put in Floyd's coffee by these men? Violet said she had never seen them before and they seemed strange!
Why could Violet not go with her husband in the ambulance? I have seen it happen many times when family is allowed, especially where age is concerned!

How did the FBI (if that is who they were) know that Floyd was dead and show up in the very early morning (about 6:00 am) just hours after he died late at night?

YOU BE THE JUDGE - ALL I KNOW IS THAT ALL OF OUR ENERGY DEVICES (MEDICAL AND CAR-MAGNET MOTOR) ARE GONE!!! WHERE ARE THEY AND WHO ARE THE ONES RESPONSIBLE FOR TAKING THEM ??

Here are some of the known facts about Floyd's energy device:

The invention is a unified-field device and so combines both electromagnetic and gravitational effects in the same unit. For a tiny power input of just 0.31 milliwatt, the unit produces over 500 watts of output power, which is an energy gain of more than 1,500,000. The prototype, has no moving parts, is about 6" x 6" x 4" in size and taps an inexhaustible source of energy. To date, up to one kilowatt of power has been produced in actual tests which required only tiny input power to make the device operate.

Our normal day-to-day energy is "positive energy". The energy produced by Floyd's device is "negative energy" but in spite of this, it powers ordinary equipment, producing light and heat as normal. A device like this has to have a major impact on the world as we know it, because:

1. **It can be easily built. The components are quite ordinary and the cost of the materials in the demonstration prototype was only a few hundred US dollars and it was constructed in just a few hours, using simple tools and equipment.**

2. **The test results are so impressive that there can be no question of errors of measurement when the energy gain is of the order of 1,500,000 times.**

3. **It demonstrates with laboratory precision that the 'law' of Conservation of Energy does not appear to apply during the operation of this device, which is something which most scientists have difficulty in accepting.**

The device has very high performance. When a 1-milliwatt 60Hz sine wave is fed into it, the out put powers 500 watts of standard mains-voltage light bulbs, producing both heat and light. The device has a positive-feedback loop so it's gain is depends directly on the output load and the input power remains unchanged. So to increase the output power, all that is necessary is to connect extra light bulbs or equipment across the output.

When a motor was connected in addition to the light bulbs, the motor ran perfectly well under load and the light bulbs remained as bright as ever. Because it is a "cold electricity" device, the wires feeding the load can be very much smaller in diameter than would be normal for the load and these wires run cold at all times. When the power hits the resistance of the filaments of the light bulbs, it converts into conventional "hot electricity" and the filaments perform in exactly the same way as they do when powered by "hot electricity".

In 1988, Floyd produced a paper which he considered to be very important. The following text is an attempt to reproduce the content his highly mathematical style of presentation. If you are not into complicated mathematical presentations, then just move on past and don't worry about the following technical material, or alternatively, take a quick skim through it and don't bother with the maths. Floyd says:

What is thought of as "empty space" actually contains almost everything in the universe. It is home to all kinds of invisible energy fields and is seething with all kinds of very real forces.

Every kind of matter produces an energy field and these energy fields interact with each other in many complicated ways, producing all sorts of additional effects. These energy fields are the "stuff" of space, or as it is sometimes described, "the virtual vacuum". Space is packed full of all sorts of things but because it does not contain air, we tend to think that there is nothing at all in it. Most people think that "vacuum" means "without air" but when scientists speak of space as "the vacuum" they do not mean that at all, and they use the word "vacuum" to describe to describe (loosely speaking) the place which is between the stars and planets of the universe, and Floyd refers to that vast place as "the vacuum", so please don't think that it has anything to do with air, as it definitely doesn't.

Floyd says: We all think that we know what light is, but the reality is that a particle of light is nothing more than a large interference in the electromagnetic field. Unless it interacts with matter or with another field, any electromagnetic field with not be changed in any way by the vacuum. Electromagnetic fields are a fundamental part of the structure of the vacuum itself. The whole universe is permeated by a constant magnetic field. That field is made up of countless numbers of North and South pole magnets in a completely random scatter.

Einstein has pointed out that $E = mC^2$ which is one way of saying that energy and matter are interchangeable (or are two different faces of the same thing). The energy everywhere in the universe is so great that new particles of matter pop into existence and drop back into their energy form many trillions of times per second. Actually, they exist for such a very short time that calling them "particles" is not really appropriate, so perhaps "virtual particles" might be a better description.

However, if we generate a moving magnetic field, it alters the random nature of this energy in the tiny part of the vacuum where we happen to be, and the vacuum energy becomes much less random and allows a very large amount of vacuum energy to be drawn into our equipment and do what we think of as "useful work" - producing heat and light, powering motors and vehicles, etc. This was proved in laboratory experiments during the week of 19th June 1988 and it is the underlying operating principle of my "Phase-Conjugated Vacuum Triode" device.

The energy produced by this device is "negative energy" which is the reverse of the energy with which we are familiar. The spark caused by a short-circuit in a negative energy system is excessively bright and cold and it produces a barely audible hiss with no explosive force. Melting of wires does not occur and this type of negative current passes through the human body with only the feeling of a chill.

Wires which carry a lot of negative energy remain cool at all times and so tiny wires can feed equipment with hundreds of watts of power. This has been demonstrated in the laboratory and the source of energy is unlimited as it is the virtual vacuum of space itself.

The Nature of Space:

Space itself is the ability to accommodate energy. Consider for a moment, the following illustration:

> **A signal (energy) is transmitted from point "A" to point "B" which are separated by a finite distance. Consider three periods of time:**
>
> **1. The signal is launched from point A.**
> **2. The signal resides in the space between point A and point B.**
> **3. The signal arrives at point B.**
>
> **If 3. occurs simultaneously with 1. we say that the signal has travelled at infinite velocity. If that were the case, then the signal never resided in the intervening space and therefore there must be no space between point A and point B and so both points A and B must be at the same location. For real space to exist between the two points, it is necessary that a signal moving between them has to get "lost" to both points, that is, out of touch with both points for a finite period of time.**

Now, we know that for real space to exist between two points, a signal passing between them has to move at a finite speed between them and if it can't do that, then there can't be any space between them. If space can't accommodate a signal passing between two points, then it has no function and no reality. We are left then with the only real space, the home of the real and virtual vacuum - space which supports a finite, non-zero signal velocity.

A similar argument applies to the impedance of space. A medium can only accommodate positive energy if the medium resists it to a reasonable degree. Neither an infinitely strong spring nor an infinitely weak spring can absorb energy by being compressed. Neither an infinitely large mass nor an infinitely small mass can absorb or accommodate energy imparted by a collision and the same holds true for space.

Energy cannot enter a space of zero impedance any more than a force can bear on a mass of zero magnitude. Similarly, energy could not enter space which has an infinite impedance. It follows therefore, that real space must have:

1. Finite propagation velocity and
2. Finite impedance.

Another way of looking at this is instead of considering the actual speed of propagation of a signal through space, to consider the length of time "t" which it takes the signal to pass through that part of space. We can think of a section of space as being, say, 1 nanosecond wide if it takes a signal 1 nanosecond to traverse it. That is, the energy or signal entering that part of space, leaves it again 1 nanosecond later. Signal propagation speed in the space in which we live is at the speed of light.

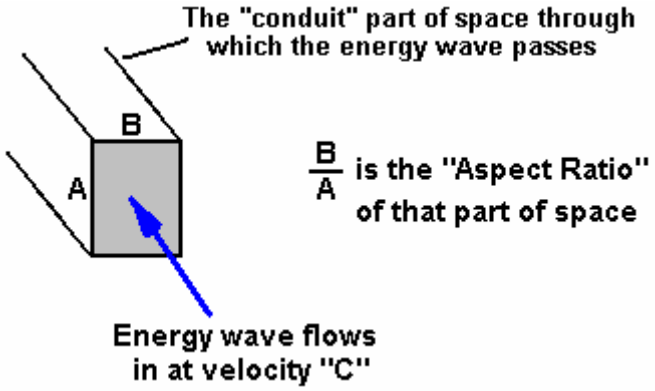
General Description of Energy Transfer:
Consider energy flowing straight and level down a transmission line. The energy does not "know" the width of the channel through which it is passing. If the energy flow reaches a point where the conductivity of the channel lowers but the size and shape of the channel remain the same, then not as much energy can flow and some gets reflected back along the channel. The energy current will not "know" if (a) the conductivity has changed or (b) the geometry has changed. The energy current can change direction very easily and so as far as it is concerned, the change caused by (a) is equivalent to the change caused by (b).

The channel through which the energy flows has width and height and the width divided by the height is called the "aspect ratio" of the channel. Energy current has an aspect ratio and if that aspect ratio is forced to change, then some of the flowing energy will reflect so as to keep the *overall* aspect ratio unchanged.

The aspect ratio of energy current is much like the aspect ratio of space itself. While the aspect ratio of space itself can change, it's fundamental velocity of "C" the speed of light in space can't really change. That speed is just our way of visualising time delay when energy resides in a region of space. Uniform space has only two parameters:

(1) Aspect ratio and
(2) Time delay

Aspect ratio defines the shape (but not the magnitude) of any energy flow which enters a given region of space. Velocity or length define the time during which that energy can be accommodated in a region of space.



Does an energy flow travel unimpeded through an interface, or does a large part of it get reflected? Space has quiet zones through which energy glides virtually unreflected. It also has noisy zones where the energy current becomes incoherent, bounces around and splits apart. These noisy zones in space either have either rapidly changing geometry or rapidly changing impedance.

Electromagnetic Energy:

The rate of flow of energy through a surface can be calculated using "E" the Electric field, and "H" the Magnetic field intensity. The energy flow through space is E x H per unit area (of it's "conduit's" cross-sectional area) and the energy density is E x H / C where C is the speed of light in space.

If there happen to be two signals of exactly the same strength, passing through each other in opposite directions in such a way that their "H" fields cancel out, then if each has a strength of E/2 and H/2, the

energy density will be E x H / 2C and it will have the appearance of a steady E-field. In the same way, if the E fields cancel out, the result will appear to be a steady "H" field.

Modern physics is based on the faulty assumption that electromagnetics contains two kinds of energy: electric and magnetic. This leads to the Baroque view of physical reality. Under that view, energy seems to be associated with the square of the field intensity, rather than a more reasonable view that it is directly to the field intensity. It is worth remembering that neither Einstein nor most modern physicists were, or are, familiar with the concept of "energy current" described here. However, their work still survives by ignoring the energy current concept, scalar electromagnetics, the works of Tom Bearden, kaluza-Klein and others who dispute Heaviside's interpretations of Maxwell's equations.

The Fallacy of Displacement Current:

Conventional electromagnetic theory proposes that when an electric current flows down a wire into a capacitor, it spreads out across the plate, producing an electric charge on the plate which in turn, leads to an electric field between the plates of the capacitor. The valuable concept of continuity is then retained by postulating a displacement current "after Maxwell". This current is a manipulation of the electric field "E" between the plates of the capacitor, the field having the characteristics of electric current, thus completing the flow of electricity in the circuit. This approach allows Kirchoff's laws and other valuable concepts to be retained even though superficially, it appears that at the capacitor there is a break in the continuous flow of electric current.

The flaw in this model appears when we notice that we notice that the current entered the capacitor at only one point on the capacitor plate. We are then left with the major difficulty of explaining how the electric charge flowing down the wire suddenly distributes itself uniformly across the entire capacitor plate at a velocity in excess of the speed of light. This paradoxical situation is created by a flaw in the basic model. Work in high-speed logic carried out by Ivor Catt has shown that the model of lumped capacitance is faulty and displacement current is an artefact of the faulty model. Since any capacitor behaves in a similar way to a transmission line, it is no more necessary to postulate a displacement current for the capacitor than it is necessary to do so for a transmission line. The removal of "displacement current" from electromagnetic theory has been based on arguments which are independent of the classic dispute over whether the electric current causes the electromagnetic field or vice versa.

The Motional E-Field:

Of all of the known fields; electric, magnetic, gravitational and motional E-field, the only ones incapable of being shielded against are the induced motional E-field and the gravitational field. The nature of the motionally-induced electric field is quite unique. In order to understand it more fully, we must start by discarding a few misleading ideas. When magnetic flux is moved perpendicularly across a conductor, an electromotive force ("e.m.f.") is electromagnetically induced "within" the conductor. "Within" is a phrase which comes from the common idea of comparing the flow of electric current within a wire to the flow of water in a pipe. This is a most misleading comparison. The true phenomenon taking place has little been thought of as involving the production of a spatially- distributed electric field. We can see that the model's origins are likely to have arising from the operation called "flux cutting" which is a most misleading term. A better term "time-varying flux modulation" does not imply any separation of lines of flux. Truly, lines of flux always form closed loops and are expressed mathematically as line integrals.

It is a fallacy to use the term "cutting" which implies time-varying separation which does not in fact ever occur. A motionally-induced E-field is actually created within the space occupied by the moving magnetic flux described above. The field is there whether or not a conductor is present in the space. In terms of a definition, we can say that when magnetic flux of vector intensity B-bar is moved across a region of space with vector velocity V-bar, an electromagnetically induced electric field vector B x V appears in the space at right angles to both B-bar and V-bar. Therefore:

$$E = \text{B-bar} \times \text{V-bar} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

It is this field which is related to gravity and which is virtually unshieldable. This field may be called the Motional E-field. According to Tom Bearden, "It seems that the charged particles in the atom act like tiny magnets and their motion in the space surrounding the atom would create this motional E-field". The fields created by both the positive and negative charges would cancel to some degree, but due to the high orbital velocity of the negative electron relative to that of the positive proton, the induced field of the electron would dominate the resulting field. The field produced as a result of these charges would vary in proportion to the inverse square of the distance as gravity does. The field produced by the translational motion of the charges would vary inversely as the cube of distance. This concept totally unites the

electromagnetic and gravitational field theories and accounts for the strong and weak force within the atom.

Field Super-Position and the Vacuum Triode:

Electromagnetic induction with no measurable magnetic field is not new. It is well known that in the space surrounding a properly wound toroidal coil, there is no magnetic field. This is due to the superposition of the fields. However, when alternating current is surging through a transformer, an electric field surrounds it. When we apply the principle of super-position to the vacuum triode, it becomes more obvious how the device is operating.

The principle of super-position states that "in order to calculate the resultant intensity of superimposed fields, each field must be dealt with individually as though the others were not present" The resultant is produced by the vector addition of each of the fields considered on its own. Consider for a moment, the construction of the triode which includes two bi-filar coils located within the fields of two conditioned magnets. When the current in one half of the conductors in the coils (that is, just one strand of the twin windings in each coil) is increasing, both the current and the magnetic field follow the right-hand rule. The resulting motional E-field would be vertical to both and directed inwards. At the same time, the current in the other strand of each winding is decreasing and both the current and the magnetic field also follow the right-hand rule. The resulting motional E-field is again vertical to both, and directed inwards. So, the resultant combined field intensity is double the intensity produced by either one of the conductors considered on its own. Expressed mathematically, this is:

$$E = (B \times V) + (-B \times -V) \text{ or}$$

$$E = 2\,(B \times V) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (2)$$

Where: E is the electric field intensity
B is the magnetic field intensity and
V is the electron drift velocity

(B x V), the first term in the equation, represents the flow of the magnetic field when the electrons are moving in one direction, while (-B x -V), the second term in the equation, defines the flow of the magnetic field when the electrons are moving in the other direction. This indicates that field intensity is directly proportional to the square of the current required by the load placed on the device. This is due to it's proportional relationship with the virtual value of the magnetic field which theory states is proportional to the current. Electrometer readings were always close to parabolic, indicating that the source was of infinite capacity. It was further determined through experiment, that the magnetic field does not change with temperature. Also, there is no reason yet identified, which would lead one to believe that electron drift velocity changes. It has been found remarkable that the vacuum triode runs approximately $20^{O}F$ below ambient.

Induced Electromotive Force - Positive Energy:

When an e.m.f. ("electromotive force") is applied to a closed metallic circuit, current flows. The e.m.f. along a closed path "C" in space is defined as the work per unit charge (that is, W / Q) done by the electromagnetic fields on a small test charge moved along path C. Since work is the line integral of Force ("F"), the work per unit charge is the line integral of force per unit charge (in Newtons per Coulomb) we have:

$$\text{e.m.f.} = \int_C F / Q \times \text{dtdl volts} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (3)$$

The scalar product "(F/Q) x dtdl" is the product of (F/Q) x Cosθ x dl where θ denotes the angle between the vectors F/Q and dl.

The electric force per unit charge is the electric field intensity ("E") in volts per metre. The magnetic force per unit charge is V x B where "V" denotes the velocity of the test charge in metres per second and "B" denotes the magnetic flux density in webers per metre squared. In terms of the smaller angle θ between V and B, the cross product of V and B is a vector having the magnitude VBSinθ. The direction of vector V x B is at right angles to the plane which contains vectors V and B in accordance with the right-hand rule (that is, V x B is in the direction of the thumb while the fingers curl through the angle θ from V towards B). Since the total force per unit charge is E + VB, the total e.m.f. in terms of the fields is:

$$\text{e.m.f.} = \int_C (E + V \times B)\, dt dl \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

It appears from equation (4) that the e.m.f. depends on the forward velocity with which the test charge moves along the path C. This, however, is not the case. If V and dl in equation (4) have the same direction, then their associated scalar product is zero. So, only the component of V which is not aligned with dl (that is, with $\theta = 0$), can contribute to the e.m.f. This component has value only if the differential path length dl has a sideways motion. So, V in equation (4), represents the sideways motion of dl, if there is any. The fields E and B in equation (4) could well be represented as functions of time as well as functions of the space co-ordinates. In addition, the velocity V of each differential path length dl, may vary with time. However, equation (4) correctly expresses the e.m.f. or voltage drop along path C as a function of time. That component of the e.m.f. consisting of the line integral V x B is the motional E-field since it has value only when path C is ,moving through a magnetic field, traversing lines of magnetic flux. For stationary paths, there is no motional E-field and the voltage drop is simply the integral of the electric field "E". Devices which separate charges, generate e.m.f.s and a familiar example of this is a battery which utilises chemical forces to separate charge. Other examples include the heating of a thermocouple, exposure of a photovoltaic cell to incident light or the rubbing together of different material to produce electrostatic charge separation. Electric fields are also produced by time-varying magnetic fields. This principle is already exploited extensively in the production of electrical power by the utility companies.

The line integral of electric field intensity "E" around any closed path "C" equals $-d\varphi/dt$ where φ represents the magnetic flux over any surface "S" having the closed path "C" as it's contour. The positive side of the surface S and the direction of the line integral around contour C, are related by the right-hand rule (the curled fingers are oriented so as to point around the loop in the direction of integration and the extended thumb points out the positive side of the surface S). The magnetic flux φ is the surface integral of magnetic flux density "B" as shown here:

$$\varphi = \iint_S B \times ds \quad \text{webers} \ldots\ldots\ldots\ldots\ldots (5)$$

In Equation (5), the vector differential surface "ds" has an area of ds and in direction, it is perpendicular to the plane of ds, projecting out of the positive side of that surface. The partial time derivative of φ is defined as:

$$\frac{\partial \varphi}{\partial t} = \iint_S \frac{\partial b}{\partial t} \times ds \quad \text{volts} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

This is referred to as the magnetic current through surface S. For a moving surface S, the limits of the surface integral in equation (6) are functions of time, but the equation still applies. It is important to clarify at this point, that when we evaluate the value of $d\varphi/dt$ over a surface which is moving in proximity to magnetic field activity, we treat the surface as though it were stationary for the instant under consideration. The partial time derivative of φ, is the time rate of change of flux through surface S, due only to the changing magnetic field density B. Any increase of φ due to the motion of the surface in the B-field, is not included in that calculation.

Continuing this discussion leads us to note that an electric field must be present in any region containing a time-varying magnetic field. This is shown by the following equation:

$$\oint_C E \times dl = \frac{-\partial \varphi}{\partial t} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

In this equation, φ is the magnetic flux in webers out of the positive side of any surface having path C as its contour. Combining equations (7) and (4), we are able to calculate the e.m.f. about a closed path C as shown here:

$$\text{e.m.f.} = \oint_C E \times dl + (V \times B)\, dl \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

or in another form:

$$\text{e.m.f.} = \frac{-\partial \varphi}{\partial t} + \oint_C (V \times B)\, dl \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

So, the e.m.f. around a closed path consists in general of two components. The component dφ/dt is the variational e.m.f. and the second component is the motional E-field. In equation (9), (V x B)dl can, by means of a vector identity, be replaced with B x (V x dl)A. V is the sideways velocity of d: the vector V x dl has magnitude Vdl and a direction normal to the surface ds swept out by the moving length dl in time dt. Letting Bn denote the component of B normal to this area, we can see that the quantity -B x (V x dl) becomes -BnVdl and equation 9 can be re-written as:

$$\text{e.m.f.} = \frac{-\partial \varphi}{\partial t} + \oint_C Bn\ V\ dl \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Clearly, the integral of BnV around the closed contour C with sideways velocity of magnitude V for each length dl traversed, is simply the time rate of change of the magnetic flux through the surface bounded by C. This change is directly due to the passage of path C through lines of magnetic flux. Hence, the complete expression for e.m.f. in equation (10) is the time rate of change of the magnetic flux over any surface S, bounded by the closed path C, due to the changing magnetic field and the movement of the path through the magnetic field. Equation (10) may be written:

$$\text{e.m.f.} = -d\varphi / dt \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Note: The distinction between equations (7) and (11) is that equation (7) contains only the variational e.m.f. while equation (11) is the sum of the variational and motional e.m.f. values. In equation (7), the partial time derivative of magnetic flux φ is the rate of flux change due only to the time-varying magnetic field, while equation (11) includes the total time derivative of the rate of flux change due to the time-varying magnetic field and path C's passage through the magnetic field. If the closed path C is not passing through lines of magnetic flux, then equation (7) and equation (11) are equivalent.

It is also important to point out that dφ/dt in equation (11) does not necessarily mean the total time rate of change of the flux φ over the surface S. For example, the flux over surface S is bounded by the closed contour C of the left portion of the electric circuit shown in Fig.1.

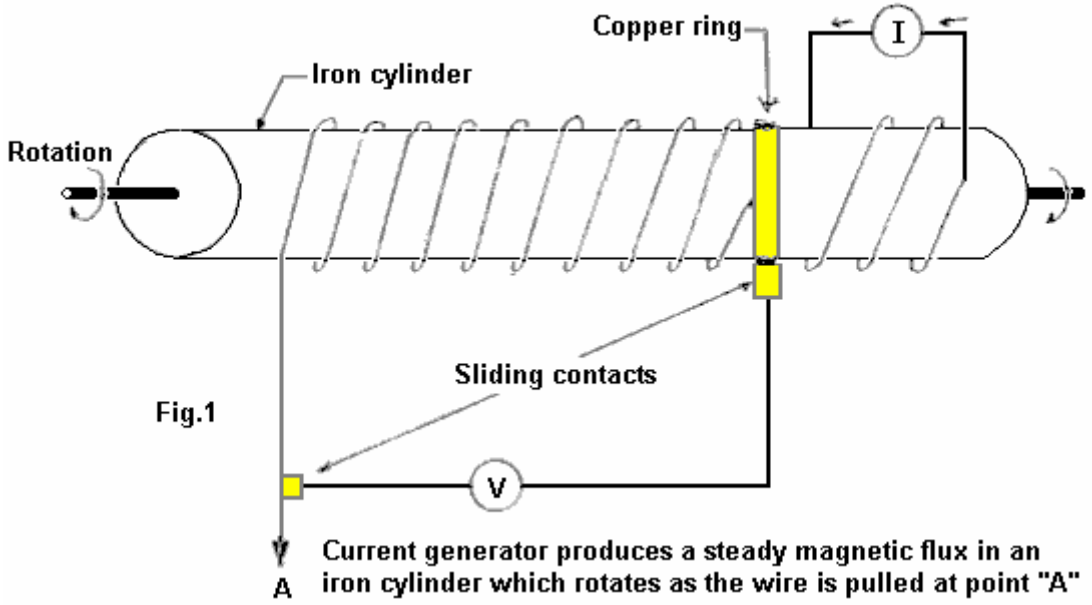


Fig.1

The flux is changing as the coil is unwound by the rotation of the cylinder, as illustrated. However, since B is static, there is no variational e.m.f. and since the conductors are not modulating lines of flux, there is

no motional e.m.f. Thus, dφ/dt in equation (11) is zero, even though the flux is changing with time. Note that dφ/dt was defined as representing the right hand part of the expression in equation (10) and dφ/dt must not be interpreted more broadly than that.

In the application of the present equations, it is required that all flux densities and movements are referred to a single, specified co-ordinate system. In particular, the velocities will all be with respect to this system alone and not interpreted as relative velocities between conductors or moving lines of flux. The co-ordinate system is selected arbitrarily and the magnitudes of variational and motional fields depend upon the selection.

Example 1:

A fundamental electric generator is shown in Figure 2:

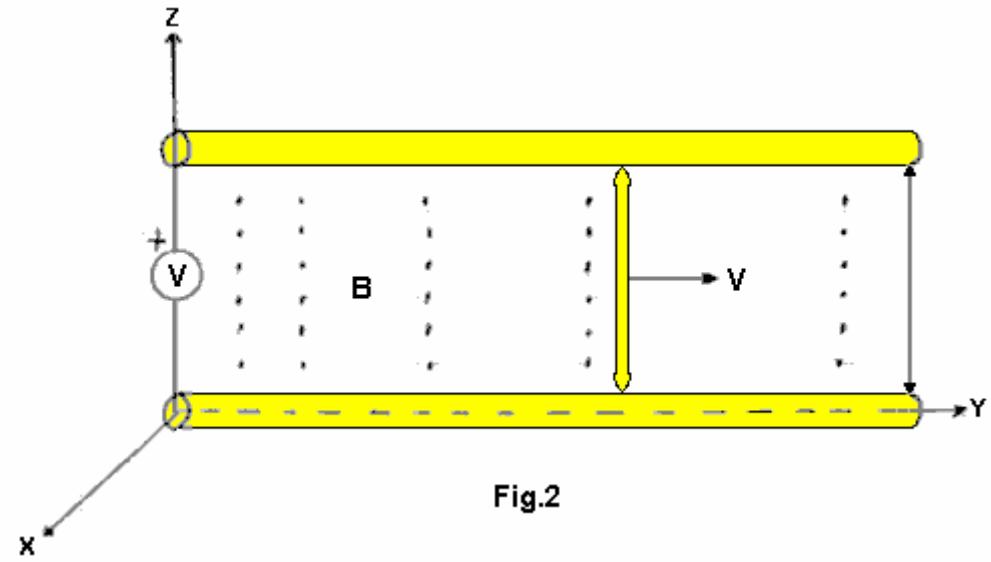

Fig.2

The parallel, stationary conductors, separated by distance "l", have a stationary voltmeter connected across them. The circuit is completed by a moving conductor connected to the parallel conductors by means of two sliding contacts. This conductor is connected at y = 0 at time t = 0, and it moves to the right at a constant velocity V = Vay. The applied flux B is represented by dots on Fig.2 and has a magnitude of $B = B_O$ CosBy Coswt ax. The unit vectors in the direction of the co-ordinate axes are ax, ay and az respectively.

Solution: Let S denote the plane rectangular surface bounded by the closed electric circuit, with a positive side selected as the side facing you. The counter-clockwise e.m.f. around the circuit is dφ/dt with φ signifying the magnetic flux out of the positive side of S (As ds = 1 dy ax). The scalar product B x ds is B_O l CosBy, Coswt dy; integrating from y = 0 to y = y gives:

$$\varphi = B_0 l \sin By_1 \cos wt \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

With y_1 denoting the instantaneous y position of the moving wire. The counter-clockwise e.m.f. is found by replacing y with vt and evaluating dφ/dt. The result is:

$$\text{e.m.f.} = wB_0 l / B\sin Bvt \sin wt - B_0 l v \cos Bvt \cos wt \quad \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

The variational (transformer) component is determined with the aid of equation (12) and is $wB_Ol/B\sin By$ sinwt where y = vt. This is the first component on the right hand side of equation (13).
Note: y_1 was treated as a constant when evaluating the partial time derivative of φ.

The motional E-field is the line integral of V x B along the path of the moving conductor. As V x B is $-B_O$ $vcosBy_1$ coswt ax and As dl is dz ax, evaluation of the integral $-B_O$ $vcosBy_1$ coswt dz from Z = 0 to Z = 1 results in a motional E-field of $-B_O$ $lvcosBv_1$ coswt. This component results from modulation of the lines of flux by the moving conductor. If the voltmeter draws no current, there can be no electromagnetic force on the free electrons of the wire. Therefore, the e.m.f. along the path of the metal conductors including the moving conductor, is zero.

Example 2:

Suppose the conductor with the sliding taps is stationary (V = 0) and it is located at $y = y_1$. Also, suppose that the magnetic field B is produced by a system of moving conductors which are not shown in Fig.2 and those conductors are travelling with a constant velocity V = Vay. At time t = 0, the magnetic field B is B_O sinBy ax. Determine the voltage across the voltmeter.

Solution: There is no motional E-field because the conductors in Fig.2 are at rest (stationary) with respect to our selected co-ordinate system. However, the magnetic field at points fixed with respect to the co-ordinate system is changing with time and as a result, there is a variational e.m.f. Since the B-field at time t = 0 is B_O sinBy ax and has a velocity of V = Vay, it can be calculated that the B-field as a function of time is BOsin[B(y-vt)] ax. This is verified by noting that an observer located at time t = 0 who is travelling at the constant velocity (V = Vay) of the moving current, would have a y co-ordinate of y = y + Vt and an accordingly different expression for B. He would observe a constant field where the magnetic current density is:

$$\frac{\partial B}{\partial t} = -BvB_o \cos B(y - Vt)\, ax$$

The counter-clockwise e.m.f. can be arrived at by taking the negative of an integral of the above expression for the rectangular surface bounded by the electric circuit with the positive side facing you, with the limits of zero and y. The resulting e.m.f. equals:

$$B_o lv[\sin B(y_1 - vt) + \sin Bvt]$$

which is the voltage across the meter.

Induced Motional Field - Negative Energy:

Conventional theory says that electric fields and magnetic fields are different things. Consider for a moment, a charge with an electric field around it. If the charge is moved, then a magnetic field develops and the moving charge constitutes a current. If an observer were to move along with the charge, then he would see no relative motion, no current and no magnetic field. A stationary observer would see motion, current and a magnetic field. It would appear that a magnetic field is an electric field observed from a motional reference frame. Similarly, if we take a mass with a gravity field around it, and we move the mass and create a mass current, a new field is also created. It is a different kind of gravity field with no source and no sink. It is called the "Protational field" and is also known as the "Lense-Thirring Effect". This field and it's governing principles will form the basis for future anti-gravitational devices (see figures 1 to 4).

Fig.3

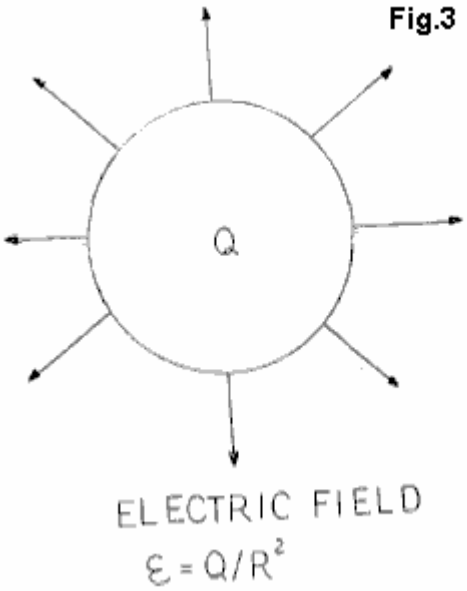

Fig.4

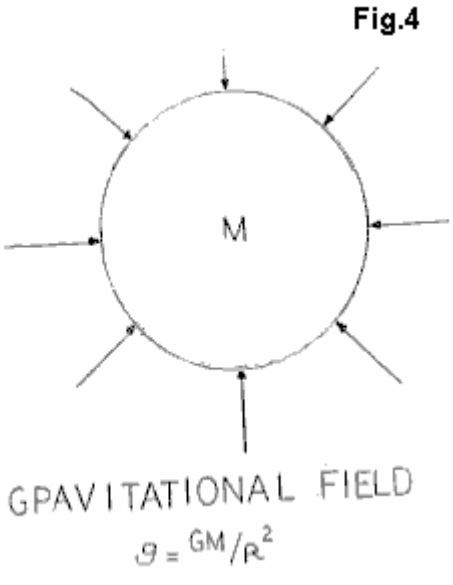

Within the confined are of the Vacuum Triode box, the space-time continuum is reversed by the fields which are produced in the presence of excited coherent space flux quanta. These quanta have been attracted form, and ultimately extracted from the virtual vacuum, the infinitely non-exhaustible Diac Sea. For a more detailed mathematical format see Tom Bearden's paper "The Phase Conjugate Vacuum Triode" (23rd April 1987). Much of the theory which likely applies to the vacuum triode has been developed in the field of phase-conjugate optics.

With regards to over-unity phenomena, it is important to note that so long as positive energy is present in a positively-flowing time regime, then unity and over-unity power gains are not possible. The summation of the losses due to resistance, impedance, friction, magnetic hysteresis, eddy currents and windage losses of rotating machinery will always reduce overall efficiency below unity for a closed system. The laws of conservation of energy always apply to all systems. However, the induced motional E-field changes the system upon which those laws need to be applied. Since the vacuum triode operates in more than four dimensions and provides a link between the multi-dimensional reality of the quantum state and the Dirac Sea, we are now dealing with an open-ended system and not the "closed system" within which all conservation and thermodynamic laws were developed.

To achieve unity, the summation of all magnetic and ohmic losses must equal zero. To achieve this state, negative energy and negative time need to be created. When this is achieved, all ohmic resistance becomes zero and all energy then flows along the outside of conductors in the form of a special space field. Negative energy is fully capable of lighting incandescent lights, running motors and performing all of the functions of positive energy tested to date. When run in parallel with positive energy however, cancellation (annihilation) of opposing power types occurs. This has been fully tested in the laboratory.

Once unity has been achieved and the gate to the Dirac sea opened, over-unity is affected by loading the open gate more and more, which opens it further to the point where direct communication / interaction with the nucleus of the atom itself is achieved. Output of the vacuum triode is not proportional to the excitation input as the output produced by the device is directly proportional to the load which is placed on it. That load is the only dependent variable for device output. The triode's output voltage and frequency always remains constant due to the conditioning of the motional E-field in the permanent magnets and the small regulated excitation signal which is provided through a small oscillator. Regulation remains constant and the triode output looks into an in-phase condition ($\cos\theta$=1 Kvar=1) under all load characteristics.

the vacuum triode is a solid-state device consisting of conditioned permanent magnets capable of producing a motional field. This field opens the gate to the Dirac Sea from where negative energy flows into the triode's receiving coils. The coils are wound with very small-diameter wire but in spite of that, they are capable of producing more than 5 kilowatts of useful power. This in itself, is a clear indicator that the type of electrical energy collected by the device is not conventional electrical energy. The wire sizes used in the construction of the device would not be capable of carrying such large currents without excessive heat gain, however, the triode's coils actually run cooler when loaded at 5 kilowatts.

The fundamental magnets have been broken free of the binding forces which constrained them to be steady-state single-pole uniform magnetic flux devices. They are now able to simply support mass, as demonstrated with the transformer steel illustration. They can now easily be made to adopt a dynamic motional field by applying a tiny amount of excitation. Specifically, 1 milliamp at 10 volts (10 milliwatts) of excitation at 60 Hz enables the coils of the triode to receive from the Dirac Sea, more than 5,000 watts of usable negative energy. It has not yet been determined how much more energy can be safely removed.

Meguer Kalfaian's Energy Generator

There is a patent application which has some very interesting ideas and claims. It has been around for a long time but it has not been noticed until recently. Personally, I get the impression that it is more a concept rather than a solidly based prototype-proven device, but that is only my impression and you need to make up your own mind on the matter.

Patent Application GB 2130431A **31st May 1984** **Inventor: Meguer Kalfaian**

Method and means for producing perpetual motion with high power

ABSTRACT

The perpetual static energies, as provided by the electron (self spin) and the permanent magnet (push and pull) are combined to form a dynamic function. Electrons emitted from a heated coil **F** are trapped permanently within the central magnetic field of a cylindrical magnet **M5**. A second magnet **M6**, in opposite polarity to the poles of the electrons causes polar tilt, and precession. This precession radiates a powerful electromagnetic field to a coil **L** placed between the cylindrical magnet and a vacuum chamber **C** - wound in a direction perpendicular to the polar axes of the electrons. Alternatively, the electromagnetic radiation is emitted as coherent light. The original source of electrons is shut off after entrapment.

SPECIFICATION

Method and means for producing perpetual motion with high power. This invention relates to methods and means for producing perpetual motion. An object of the invention is, therefore, to produce useful perpetual motion for utility purposes.

BRIEF EMBODIMENT OF THE INVENTION

The electron has acquired self spin from the very beginning of its birth during the time of creation of matter, and represents a perpetual energy. But self spin alone, without polar motion is not functional, and therefore, useful energy cannot be derived from it. Similarly, the permanent magnet represents a source of perpetual energy, but since its poles are stationary, useful energy cannot be derived from it.

However, the characteristics of these two types of static energies differ one from the other, and therefore the two types of energies can be combined in such a manner that, the combined output can be converted into perpetual polar motion.

In one exemplary mode, a cylindrical vacuum chamber having a filament and a cathode inside, is enclosed within the central magnetic field of a cylindrical permanent magnet, the magnetisation of which can be in a direction either along the longitudinal axis, or from the centre to the circumferential outer surface of the cylinder. When current is passed through the filament, the electrons emitted from the cathode are compressed into a beam at the centre of the cylindrical chamber by the magnetic field of the cylindrical magnet. Thus, when the current through the filament is shut off, the electrons in the beam remain permanently trapped inside the magnetic field.

In such an arrangement, the poles of the electrons are aligned uniformly. When a second permanent magnet is held against the beam in repelling polarity, the poles of the electrons are pushed and tilted from their normal longitudinal polar axes. In such tilted orientations, the electrons now start wobbling (precessing) in gyroscopic motions, just like a spinning top when it is tilted to one side. The frequency of this wobbling (precessional resonance) depends upon the field strengths of the two magnets, similar to the resonance of the violin string relative to its tensional stretch. The polar movements of the electrons radiate an electromagnetic field, which can be collected by a coil and then converted into any desired type of energy. Because of the uniformly aligned electrons, the output field is coherent, and the output power is high.

Observed examples upon which the invention is based:

The apparatus can best be described by examples of a spinning top in wobbling motion. Thus, referring to the illustration of **Fig.1**, assume that the spinning top **T** is made of magnetic material, as indicated by their pole signs (**S** and **N**). Even though the top is magnetic, the spin motion does not radiate any type of field, which can be received and converted into a useful type of energy. This is due to the known fact that, radiation is created only when the poles of the magnet are in motion, and in this case, the poles are stationary.

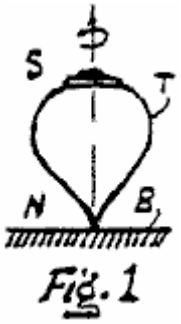

Fig. 1

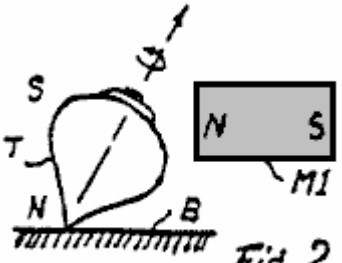

Fig. 2

When a magnet **M1** is held from a direction perpendicular to the longitudinal polar axis of the top, as shown in **Fig.2**, the polar axis of the top will be tilted as shown, and keep on spinning in that tilted direction. When the magnet **M1** is removed, however, the top will try to regain its original vertical posture, but in doing so, it will wobble in gyroscopic motion, such as shown in **Fig.3**. The faster the top spins, then the faster the wobbling motion will be.

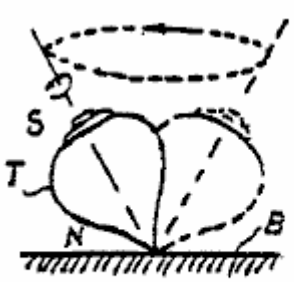

Fig. 3

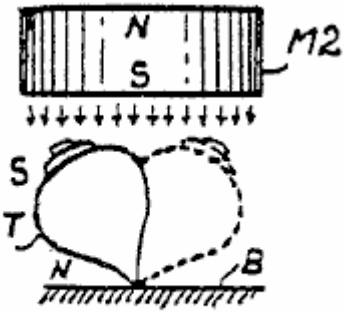

Fig. 4

The reason that the top tilts angularly, but does not wobble when the magnet **M1** is held from horizontal direction, is that, the one-sided pull prevents the top from moving away from the magnetic field for free circular wobble. Instead of holding the magnet **M1** from the side of the top, we may also hold the magnet from a direction above the top, as shown in **Fig.4**. In this case, however, the polar signs between the magnet and the top are oriented in like signs, so that instead of pulling action, there is pushing action between the magnet and the top - causing angular tilt of the top, such as shown in **Fig.4**. The pushing action of the magnetic field from above the top is now equalised within a circular area, so that the top finds freedom to wobble in gyroscopic rotation.

The important point in the above given explanation is that, the top tries to gain its original vertical position, but it is prevented from doing so by the steady downward push from the static magnetic field of magnet **M2**. So, as long as the top is spinning, it will wobble in a steady state. Since there is now, polar motion in the wobbling motion of the top, this wobbling motion can easily be converted into useful energy. To make this conversion into perpetual energy, however, the top must be spinning perpetually. Nature has already provided a perpetually spinning magnetic top, which is called, "the electron" - guaranteed to spin forever, at a rate of 1.5×10^{23} (one hundred fifty thousand billion billion revolutions per second).

BRIEF DESCRIPTION OF THE DRAWINGS

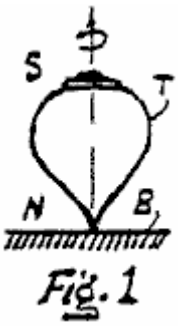

Fig. 1

Fig.1 illustrates a magnetic spinning top, used to describe the basic principles of the invention.

BEST MODE OF CARRYING OUT THE INVENTION

Referring to the exemplary illustration of **Fig.4**, the spinning top **T** is pivoted to the base B by gravity.

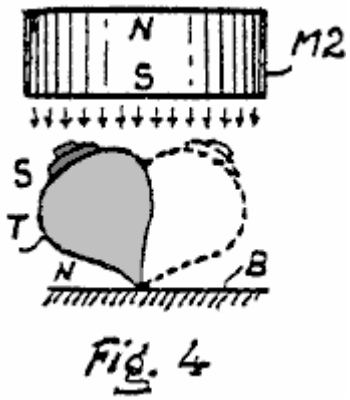

Fig. 4

In the case of the electron, however, it must be held tightly between some magnetic forces. So, referring to the illustration of **Fig.5**, assume that an electron **e** is placed in the centre of a cylindrical magnet **M4**. The direction of

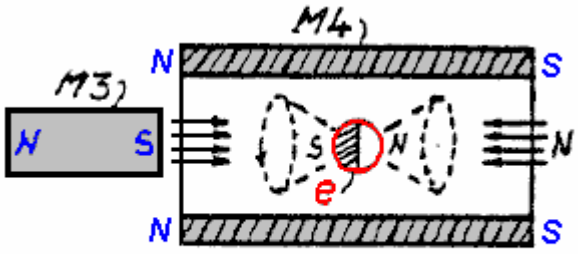

Fig. 5

magnetisation of the magnet **M4**, and the polar orientation of the electron **e** are marked in the drawing. In this case, when a permanent magnet **M3** is placed at the open end of the cylindrical magnet **M4**, the electron **e** will precess, in a manner, as described by way of the spinning top. The difficulty in this arrangement is that, electrons cannot be separated in open air, and a vacuum chamber is required, as in the following:

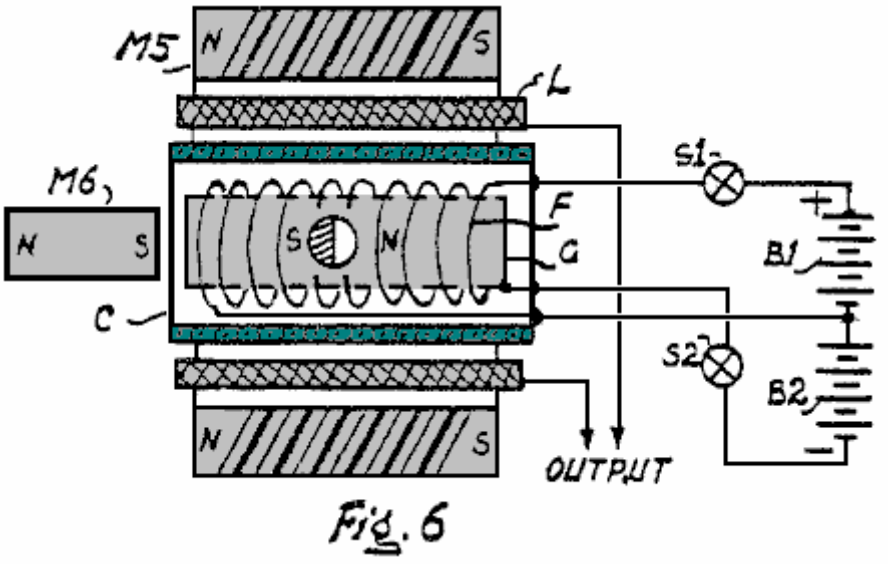

Fig. 6

Fig.6 shows a vacuum chamber **C**, which contains a cylindrically wound filament **F**, connected to the battery **B1** by way of the switch **S1**. Thus, when the switch **S1** is turned ON, the filament **F** is lighted, and it releases electrons. External to the vacuum chamber **C** is mounted a cylindrical permanent magnet **M5**, which compresses the emitted electrons into a beam at the centre of the chamber.

When the beam is formed, the switch is turned OFF, so that the beam of electrons is permanently trapped at the centre of the chamber.

The permanent trapping of the electrons in the chamber **C** represents a permanent storage of static energy. Thus, when a permanent magnet **M6** is placed to tilt the polar orientations of the uniformly poled electrons in the beam, they start precessing perpetually at a resonant frequency, as determined by the field strengths of the magnets **M5** and **M6**.

The precessing electrons in the beam will radiate quadrature phased electromagnetic field in a direction perpendicular to the polar axes of the electrons.

Thus, a coil **L** may be placed between the magnet **M5** and the vacuum chamber **C**, to receive the radiated field from the beam. The output may then be utilised in different modes for practical purposes, for example, rectified for DC power use.

The electron beam-forming cylindrical magnet **M5**, which may also be called a focusing magnet, is shown to be bipolar along the longitudinal axis. The direction of magnetisation, however, may be from the central opening to

the outer periphery of the magnet, as shown by the magnet **M7**, in **Fig.8** but the precessing magnet **M6** will be needed in either case.

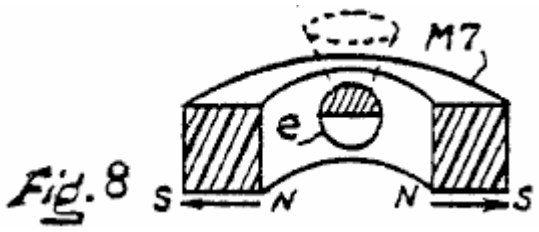

Fig. 8

In the arrangement of **Fig.6**, I have included a current control grid **G**. While it is not essential for operation of the arrangement shown, it may be connected to a high negative potential **B2** by the switch **S2** just before switching the **S1** in OFF position, so that during the cooling period of the filament, there will occur no escape of any electrons from the beam to the cathode. Also, the grid **G** may be switched ON during the heating period of the cathode, so that electrons are not forcibly released from the cathode during the heating period, and thereby causing no damage to the cathode, or filament.

Biological precessional resonance

Electron precessional resonance occurs in living tissue matter, as observed in laboratory tests. This is called ESR (Electron Spin Resonance) or PMR (Paramagnetic Resonance). In tissue matter, however, the precessing electron is entrapped between two electrons, as shown in **Fig.7**, and the polar orientations are indicated by the polar signs and shadings, for clarity of drawing.

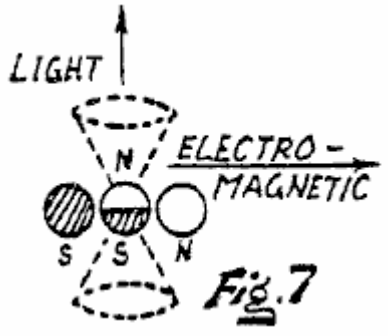

Fig. 7

Simulation

The arrangement of **Fig.7** may be simulated artificially in a manner as shown in **Fig.9**, wherein, the electron trapping magnet is a pair of parallel spaced magnets **M8**. In actual practice, however, the structure of this pair of magnets **M8** can be modified. For example, a second pair of magnets **M8** may be disposed between the two pairs, so that the directions of the transverse fields between the two pairs cross mutually perpendicular at the central longitudinal axis of the vacuum chamber. The inner field radiating surfaces of these two pairs of magnets may be shaped circular, and the two pairs may be assembled, either by physical contact to each other, or separated from each other.

Modifications

Referring to the arrangements of **Fig.6**, **Fig.9** and **Fig.10**, when the electron is in precessional gyroscopic motion, the radiated field in a direction parallel to the polar axis of the electron, is a single phased corkscrew waveform, which when precessed at light frequency, the radiation produces the effect of light.

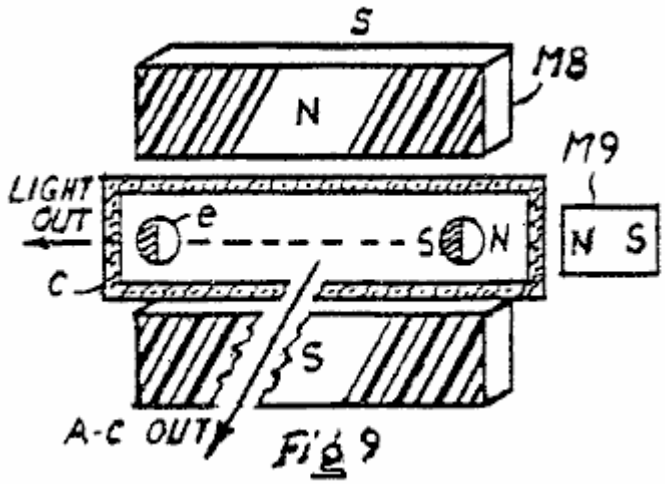

Fig 9

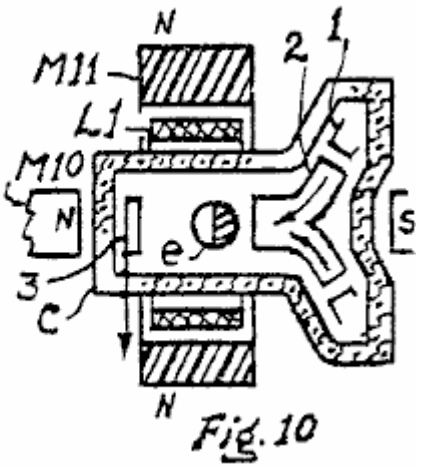

Fig. 10

Whereas, the field in a direction perpendicular to the axis of the electron produces a quadrature phased electromagnetic radiation. Thus, instead of utilising the output of electron precession for energy purposes, it may be utilised for field radiation of either light or electromagnetic waves, such as indicated by the arrows in **Fig.9**. In this case, the output will be coherent field radiation.

In reference to the arrangement of **Fig.6**, the electron emission is shown to occur within the central magnetic field of the focusing magnet **M5**. It may be practically desired, however, that these electrons are injected into the central field of the cylindrical magnet from a gun assembly, as shown in an exemplary arrangement of **Fig.10**. In this case, the vacuum chamber **C** is flanged at the right hand side, for mounting an electron emitting cathode **1** (the filament not being shown), and a curved electron-accelerating gun **2**. The central part of this flange is recessed for convenience of mounting an electron-tilting magnet (as shown), as close as possible to the electron beam. In operation, when current is passed through the filament, and a positive voltage is applied (not shown) to the gun **2**, the emitted electrons from the cathode are accelerated and injected into the central field of the magnet **11**. Assuming that the open end of the gun **2** overlaps slightly the open end of the cylindrical central field of the magnet **M1**, and the positive accelerating voltage applied to the gun **2** is very low, the accelerated electrons will enter the central field of the magnet **M1**, and travel to the other end of the field. Due to the low speed acceleration of the electrons, however, they cannot spill out of the field, and become permanently entrapped therein.

In regard to the direction in which the coil **L1** is positioned, its winding should be in a direction perpendicular to the longitudinal axis of the beam to which the polar axes of the electrons are aligned uniformly in parallel. In one practical mode, the coil **L1** may be wound in the shape of a surface winding around a tubular form fitted over the cylindrical vacuum chamber.

In regard to the operability of the apparatus as disclosed herein, the illustration in **Fig.7** shows that the field output in a direction parallel to the polar axis of the electron is singular phased, and it produces the effect of light when the precessional frequency is at a light frequency. Whereas, the output in a direction perpendicular to the polar axis of the electron is quadrature phased, which is manifested in practiced electromagnetic field transmission.

In regard to experimental references, an article entitled "Magnetic Resonance at high Pressure" in the "Scientific American" by George B. Benedek, page 105 illustrates a precessing nucleus, and indicates the direction of the electromagnetic field radiation by the precessing nucleus. The same technique is also used in the medical apparatus "Nuclear magnetic resonance" now used in numerous hospitals for imaging ailing tissues (see "High Technology" Nov. Dec. 1982. Refer also to the technique of detecting Electron Spin Resonance, in which electrons (called "free radicals") are precessed by the application of external magnetic field to the tissue matter. In all of these practices, the electromagnetic field detecting coils are directed perpendicular to the polar axes of the precessing electrons or the nuclei.

In regard to the production of light by a precessing electron, in a direction parallel to the polar axis of the precessing electron, see an experimental reference entitled "Free electrons make powerful new laser" published in "high Technology" February 1983 page 69.

In regard to the aspect of producing and storing the electrons in a vacuum chamber, it is a known fact by practice that the electrons are entrapped within the central field of a cylindrical permanent magnet, and they will remain entrapped as long as the magnet remains in position.

With regard to the performance of obtaining precessional resonance of the electron, the simple example of a

wobbling top is sufficient, as proof of operability.

Having described the preferred embodiments of the invention, and in view of the suggestions of numerous possibilities of modifications, adaptations, adjustments and substitutions of parts, it should be obvious to the skilled in related arts that other possibilities are within the spirit and scope of the present invention.

CLAIMS

1. The method of effecting perpetual retaining and precession of electrons, for obtaining perpetual field radiation from the polar motions of said precessing electrons, comprising the steps of:

producing electrons;
compressing said produced electrons into a perpetually retainable state; and
precessing said compressed electrons for effecting perpetual field radiation by the polar motions of said precessing electrons.

2. The method of producing perpetual field radiation for conversion into perpetual energy, the method comprising the steps of:

producing electrons;
imposing a first perpetually occurring electron controlling force from a first direction upon said produced electrons into a perpetually retainable state; and
imposing a second perpetually occurring electron controlling force from a second direction upon said retained electrons, for inducing precessional motions to the electrons, and thereby obtaining said perpetual field radiation for conversion into perpetual energy.

3. The method of generating perpetual simultaneous single phased and quadrature phased coherent field radiations, comprising the steps of:

producing electrons;
imposing a first perpetually occurring electron controlling force from a first direction upon said produced electrons into a uniformly polarised perpetually retainable compressed state; and
imposing a second perpetually occurring electron controlling force from a second direction upon said compressed electrons, for effecting precessional motions of the electrons, thereby causing a quadrature phased coherent field radiation in a direction perpendicular to the uniformly polarised polar axes of said electrons, and a simultaneous single phased coherent field in a direction parallel to the polar axes of said electrons.

4. The method of producing perpetual dynamic motions for conversion into energy, comprising the steps of:

trapping and compressing a concentrated quantity of electrons within a first electron controlling field in a vacuum space, whereby forming a tightly confined permanent concentration of statistically spinning electrons, both of their polar axes and polar orientations being uniformly aligned; and
tilting the polar axes of said trapped electrons by a second permanent electron controlling field, for inducing precessional gyrations to the electrons in the form of perpetual dynamic motions, which are adaptively convertible into energy.

5. Apparatus for producing perpetual dynamic motions, which comprises:

a vacuum chamber having an electron-emitting means; an auxiliary means for causing emission of electrons from said electron-emitting means;
a first permanent magnet disposed externally of said chamber for trapping and compressing a quantity of said emitted electrons within its magnetic field, with uniform alignments of the polar axes and polar orientations of said electrons;
means for stopping said auxiliary means from further causing emission of electrons from said electron emitting means, whereby forming a tightly confined concentration of statistically spinning electrons permanently entrapped within said first permanent magnet; and
a second permanent magnet, the field projection of which is oriented to tilt the polar a axes of said trapped electrons, for causing precessional gyrations of the electrons, as representation of said dynamic motions.

6. Apparatus comprising:
a vacuum chamber having an electron emitting means;

an auxiliary means for causing emission of electrons from said electron emitting means;
a first permanent magnet disposed externally of said chamber for permanently trapping and compressing a quantity of said emitted electrons within its magnetic field, with uniform alignments of the polar axes and polar orientations of said electrons; and
a second permanent magnet so oriented with respect to said entrapped electrons that, the field projection from the second magnet causes precessional gyrations of the uniformly aligned entrapped electrons.

7. The apparatus as set forth in claim 6, wherein said first permanent magnet is cylindrical magnet surrounding said chamber, and the magnetisation of said first magnet is in a direction along the longitudinal axis of the cylinder.

8. The apparatus as set forth in claim 6, wherein said first permanent magnet is cylindrical magnet surrounding said chamber, and the magnetisation of said first magnet is in a direction from the central hollow space to the outer surface of said cylinder.

9. The apparatus as set forth in claim 6, wherein the polar sign of field projection from said second magnet to said entrapped electrons is in repelling polar sign.

10. The apparatus as set forth in claim 6, wherein is included a field responsive coil mounted between said first magnet and said vacuum chamber, for receiving the field radiation that is effected by the motions of said gyrating electrons.

11. The apparatus as set forth in claim 6, wherein is included a field responsive coil mounted between said first magnet and said vacuum chamber, the turns of winding of said coil being in a direction perpendicular to the polar axes of said compressed electrons.

12. Apparatus for producing perpetual motion, the apparatus being substantially as hereinbefore described with reference to, and as illustrated by, the accompanying drawings.

US Patent App. 20090096219 16th April 2009 Inventors: Theodore Annis & Patrick Eberly

ENERGY GENERATION APPARATUS AND METHODS BASED UPON MAGNETIC FLUX SWITCHING

ABSTRACT

Methods and apparatus generate electricity through the operation of a circuit based on a single magnetic flux path. A magnetisable member provides the flux path. One or more electrically conductive coils are wound around the member, and a reluctance or flux-switching apparatus is used to control the flux. When operated, the switching apparatus causes a reversal of the polarity (direction) of the magnetic flux of the permanent magnet through the member, thereby inducing alternating electrical current in each coil. The flux-switching apparatus may be motionless or rotational. In the motionless embodiments, two or four reluctance switches are operated so that the magnetic flux from one or more stationary permanent magnet(s) is reversed through the magnetisable member. In alternative embodiments, the flux-switching apparatus comprises a body composed of high-permeability and low-permeability materials, such that when the body is rotated, the flux from the magnet is sequentially reversed through the magnetisable member.

FIELD OF THE INVENTION

The present invention relates to methods and apparatus wherein the magnetic flux from one or more permanent magnets is reversed repeatedly in polarity (direction) through a single flux path around which there is wound a conducting coil or coils for the purpose of inducing electricity in the coils.

BACKGROUND OF THE INVENTION

The electromechanical and electromagnetic methods involved in motional electric generators and alternators are well known. Alternators and generators often employ permanent magnets and usually have a rotor and a stator and a coil or coils in which an EMF (electromotive force) is induced. The physics involved for producing electricity is described by the generator equation $V = \int(vxB).dl$.

Permanent magnets made of materials that have a high coercively, a high magnetic flux density a high magnetic motive force (mmf), and no significant deterioration of magnetic strength over time are now common. Examples include ceramic ferrite magnets (Fe2O3); samarium cobalt (SmCO5); combinations of iron, neodymium, and boron; and others.

Magnetic paths for transformers are often constructed of laminated ferrous materials; inductors often employ ferrite materials, which are used for higher frequency operation for both devices. High performance magnetic materials for use as the magnetic paths within a magnetic circuit are now available and are well suited for the (rapid) switching of magnetic flux with a minimum of eddy currents. An example is the FINEMET® nanocrystalline core material made by Hitachi of Japan.

According to Moskowitz, "Permanent Magnet Design and Application Handbook" 1995, page 52, magnetic flux may be thought of as flux lines which always leave and enter the surfaces of ferromagnetic materials at right angles, which never can make true right-angle turns, which travel only in straight or curved paths, which follow the shortest distance, and which follow the path of lowest reluctance.

A "reluctance switch" is a device that can significantly increase or decrease (typically increase) the reluctance (resistance to magnetic motive force) of a magnetic path in a direct and rapid manner and subsequently restore it to its original (typically lower) value in a direct and rapid manner. A reluctance switch typically has analog characteristics. By way of contrast, an off/on electric switch typically has a digital characteristic, as there is no electricity "bleed-through." With the current state of the art, reluctance switches have magnetic flux bleed-through. Reluctance switches may be implemented mechanically, such as to cause keeper movement to create an air gap, or electrically by several means, or by other means. One electrical means is that of using control coils wound around the flux paths.

Another electrical means is the placement within the flux path of certain classes of materials that change (typically increase) their reluctance upon the application of electricity. Another electrical means is to saturate a region of the switch material so that the reluctance increases to that of air by inserting conducting electrical wires into the material as described by Konrad and Brudny in "An Improved Method for Virtual Air Gap Length Computation," in IEEE Transactions on Magnetics, Vol. 41, No. 10, October 2005.

The patent literature describes a number of constructs that have been devised to vary the amounts of magnetic flux in alternate flux paths by disproportionately dividing the flux from a stationary permanent magnet or magnets between or among alternate flux paths repeatedly for the purpose of generating electricity. The increase of flux in one magnetic path and the corresponding decrease in the other path(s) provide the basis for inducing electricity when coils are wound around the paths. The physics involved for producing electricity by these constructs is described by the transformer equation $V = -\int dB/dt.ds$. A variety of reluctance switching means have been employed to cause the flux to be increased/decreased through a particular alternate path with a corresponding decrease/increase in the other path and to do so repeatedly.

A means of switching flux along alternate paths between the opposite poles of a permanent magnet have included the flux transfer principle described by R. J. Radus, Engineers' Digest, July, 1963.

A result of providing alternate flux paths of generally similar geometry and permeability is that, under particular conditions, the alternate path first selected or the path selected for the majority of the flux will remain a "preferred path" in that it will retain more flux and the other path, despite the paths having equal reluctance. (There is not an automatic equalization of the flux among similar paths.)

Moskowitz, "Permanent Magnet Design and Application Handbook" 1995, page 87 discusses this effect with regard to the industrial use of permanent magnets to lift and release iron and steel by turning the permanent magnet on and (almost) off via reluctance switching that consists of the electric pulsing of coils wound around the magnetic flux paths (the reluctance switches).

Experimental results with four iron rectangular bars (relative permeability=1000) placed together in a square with a bar permanent magnet (flux density measured at one pole=5000 Gauss) between two of the opposing bars roughly in a centre position showed that removal and replacement of the one of the end bars that is parallel to the bar magnet will result in about 80% of the flux remaining in the bar that remained in contact. The results further showed that the preferred path must experience an increase of reluctance about IOx of that of the available alternate path before its disproportionate flux condition will yield and transfer to the alternate path.

Flynn U.S. Pat. No. 6,246,561; Patrick, et al. U.S. Pat. No. 6,362,718; and Pedersen U.S. Pat. No. 6,946,938 all disclose a method and apparatus for switching (dividing) the quantity of magnetic flux from a stationary permanent magnet or magnets between and among alternate paths for the purpose of generating electricity (and/or motive force). They provide for the increase of magnetic flux in one path with a corresponding decrease in the other path(s). There are always at least two paths.

SUMMARY OF THE INVENTION

The present invention relates to methods and apparatus for the production of electricity through the operation of a circuit based upon a single magnetic flux path. A magnetisable member provides the flux path. One or more electrically conductive coils are wound around the member, and a reluctance or flux switching apparatus is used to control the flux. When operated, the switching apparatus causes a reversal of the polarity (direction) of the magnetic flux of the permanent magnet through the member, thereby inducing alternating electrical current in each coil.

According to the invention, the flux switching apparatus may be motionless or rotational. In the motionless embodiments, four reluctance switches are operated by a control unit that causes a first pair of switches to open (increasing reluctance), while another pair of switches close (decreasing reluctance). The initial pair is then closed as the other pair is opened, and so on. This 2x2 opening and closing cycle repeats and, as it does, the magnetic flux from the stationary permanent magnet(s) is reversed in polarity through the magnetisable member, causing electricity to be generated in the conducting coils. An alternative motionless embodiment uses two reluctance switches and two gaps of air or other materials.

In alternative embodiments, the flux switching apparatus comprises a body composed of high-permeability and low-permeability materials, such that when the body is rotated, the flux from the magnet is sequentially reversed through the magnetisable member. In the preferred embodiment the body is cylindrical having a central axis, and the body rotates about the axis. The cylinder is composed of a high-permeability material except for section of low-permeability material that divided the cylinder into two half cylinders. At least one electrically conductive coil is wound around the magnetisable member, such that when the body rotates an electrical current is induced in the coil. The body may be rotated by mechanical, electromechanical or other forces.

A method of generating electrical current, comprises the steps of providing a magnetisable member with an electrically conductive coil wound therearound, and sequentially reversing the flux from a permanent magnet through the member, thereby inducing electrical current in the coil.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

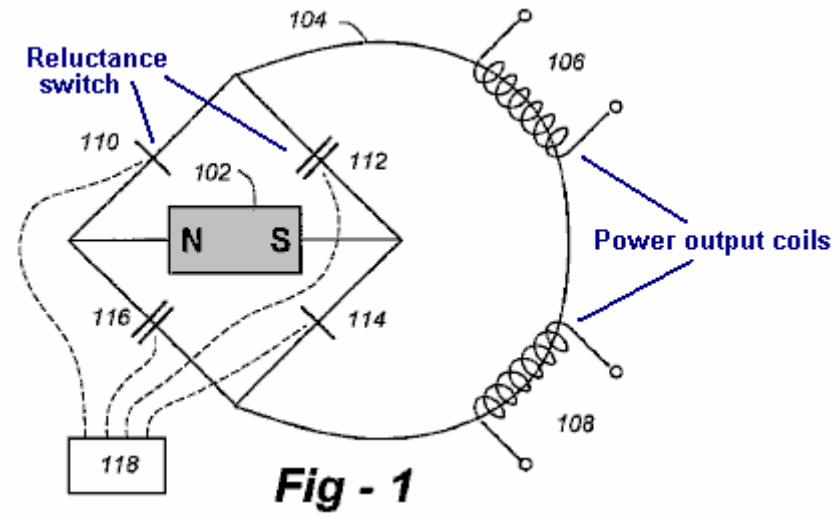

Fig - 1

Fig.1 is a schematic diagram of a magnetic circuit according to the invention utilizing a motionless flux switch. The circuit includes the following components: a permanent magnet 102, single flux path 104, conducting coils 106, 108, and four reluctance switches 110, 112, 114, 116. Under the control of unit 118, reluctance switches 110, 114 open (increasing reluctance), while switches 112, 116 close (decreasing reluctance). Reluctance switches 110, 114 then close, while switches 112, 116 open, and so on. This 2x2 opening and closing cycle repeats and, as it does, the magnetic flux from stationary permanent magnet 102 is reversed in polarity through single flux path 104, causing electricity to be generated in conducting coils 106, 108.

An efficient shape of permanent magnet 102 is a "C" in which the poles are in close proximity to one another and engage with the flux switch. The single flux is carried by a magnetisable member 100, also in a "C" shape with ends that are in close proximity to one another and also engage with the flux switch. In this, and in other embodiments, the 2x2 switching cycle is carried out simultaneously. As such, control circuit 118 is preferably implemented with a crystal-controlled clock feeding digital counters, flip-flops, gate packages, or the like, to adjust rise time, fall time, ringing and other parasitic effects. The output stage of the control circuit may use FET (Field-Effect Transistor switches) to route analog or digital waveforms to the reluctance switches as required.

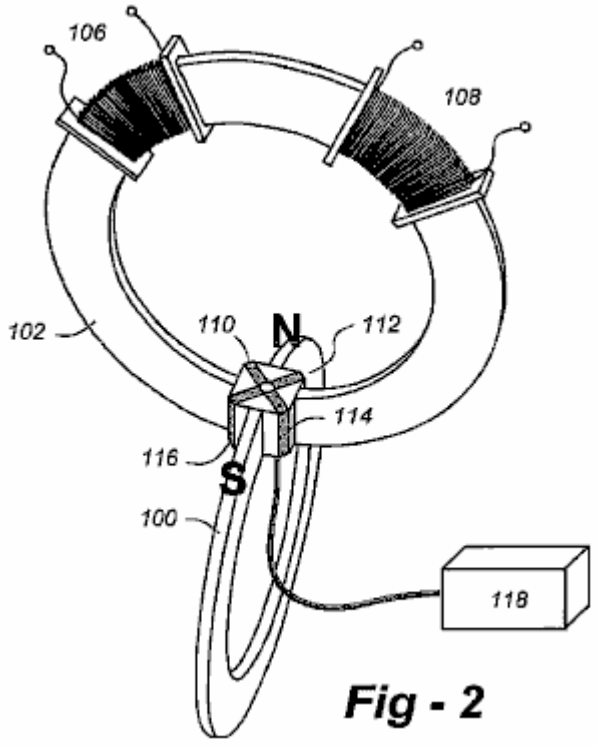

Fig - 2

Fig.2 is a perspective of one possible physical embodiment of the apparatus using the components of Fig.1, showing their relative positions to one another. Reluctance switches 110, 112, 114, 116 may be implemented differently, as described below, but will usually occupy the same relative position within the apparatus.

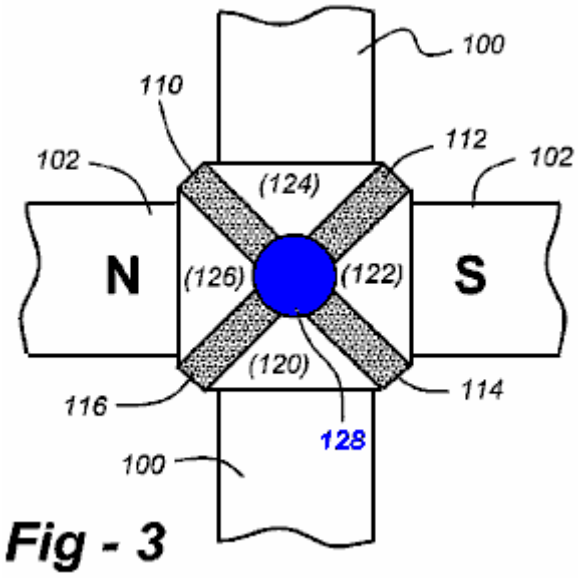

Fig - 3

Fig.3 is a detail drawing of the motionless flux switch. Connecting segments 120, 122, 124, 126 must be made of a high-permeability ferromagnetic material. The central volume 128 may be a through-hole, providing an air gap, or it may be filled with glass, ceramic or other low-permeability material. A super-conductor or other structure exhibiting the Meissner effect may alternatively be used.

In the embodiment depicted in Fig.2 and Fig.3, reluctance switches 110, 112, 114, 116 are implemented with a solid-state structure facilitating motionless operation. The currently preferred motionless reluctance switch is described by Toshiyuki Ueno & Toshiro Higuchi, in the paper "Investigation on Dynamic Properties of Magnetic Flux Control Device composed of Lamination of Magnetostrictive Material Piezoelectric Material," The University of Tokyo 2004, the entirety of which is incorporated herein by reference. As shown in Fig.4, this switch is made of a laminate of a GMM (Giant Magnetostrictive Material 42), a TbDyFe alloy, bonded on both sides by a PZT (Piezoelectric) material 44, 46 to which electricity is applied. The application of electricity to the PZT creates strain on the GMM, which causes its reluctance to increase.

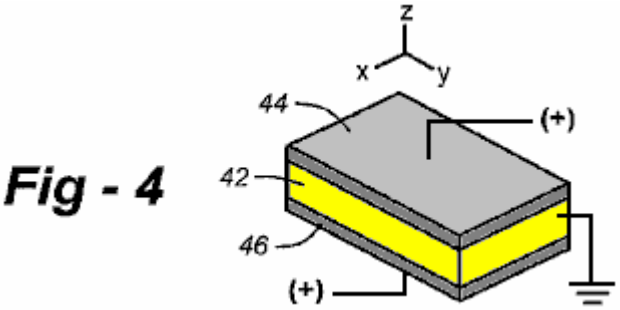

Fig - 4

Other arrangements are applicable, including those disclosed in pending U.S. Patent Application Serial no. 2006/0012453, the entire content of which is incorporated herein by reference. These switches disclosed in this reference are based upon the magnetoelectric (ME) effects of liquid crystal materials in the form of magnetorestrictive and piezoelectric effects. The properties of ME materials are described, for example, in Ryu et al, "Magnetoelectric Effect in Composites of Magnetorestrictive and Piezoelectric Materials," Journal of Electroceramics, Vol. 8, 107-119

Filipov et al, "Magnetoelectric Effects at Piezoresonance in Ferromagnetic-Ferroelectric Layered Composites," Abstract, American Physical Society Meeting (March 2003) and Chang et al., "Magneto-band of Stacked Nanographite Ribbons," Abstract, American Physical Society Meeting (March 2003). The entire content of each of these papers are also incorporated herein.

Further alternatives include materials that may sequentially heated and allowed to cool (or cooled and allowed to warm up or actively heated and cooled) above and below the Currie temperature, thereby modulating reluctance. Gadolinium is a candidate since its Currie point is near room temperature. High-temperature superconductors are other candidates, with the material being cooled in an insulated chamber at a temperature substantially at or near the Currie point. Microwave or other energy sources may be used in conjunction with the control unit to effectuate this switching. Depending upon how rigidly the switches are contained, further expansion-limiting `yokes' may or may not be necessary around the block best seen in Fig.4.

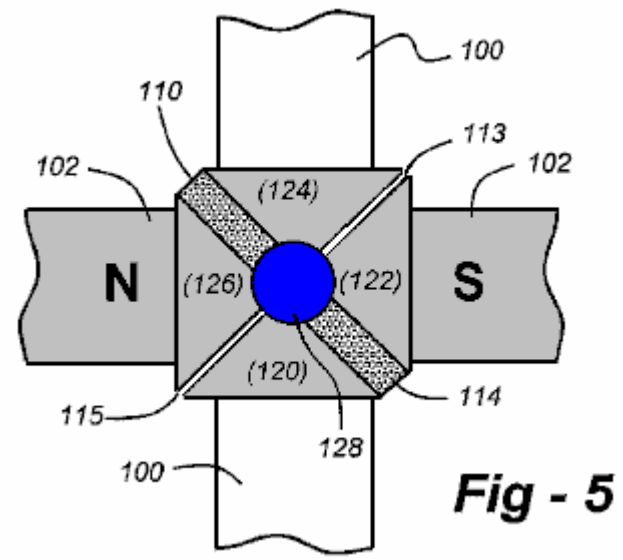

Fig - 5

Fig.5 is a detail drawing of an alternative motionless flux switch according to the invention which utilizes gaps of air or other materials. This embodiment uses two electrically operated reluctance switches 110, 114, and two gaps 113, 115, such that when the switches are activated in a prescribed manner, the flux from the magnet 102 is blocked along the switch segments containing the switches and forced through the gap-containing segments, thereby reversing the flux through the magnetisable member 100. Upon activation of the two reluctance switches 110, 114, the flux, seeking a path of significantly lower reluctance, flips back to the original path containing the (non deactivated) reluctance switches, thereby reversing the flux through the member 100. Note that the flux switches may also be electromagnetic to saturate local regions of the switch such that reluctance increases to that of air (or gap material), creating a virtual gap as described by Konrad and Brudny in the Background of the Invention.

More particularly, flux switching apparatus according to this embodiment uses a permanent magnet having a north pole `N' and a south pole `S' in opposing relation across a gap defining a volume. A magnetisable member with ends `A' and 'B' is supported in opposing relation across a gap sharing the volume, and a flux switch comprises a stationary block in the volume having four sides, 1-4, with two opposing sides interfaced to N and S, respectively and with the other two opposing sides being interfaced to A and B, respectively. The block is composed of a magnetisable material segmented by two electrically operated magnetic flux switches and two gaps filled with air or other material(s). A control unit in electrical communication with the flux switches is operative to:

a) passively allow a default flux path through sides 1-2 and 3-4, then
b) actively establish a flux path through sides 2-3 and 1-4, and
c) repeat a) and b) on a sequential basis.

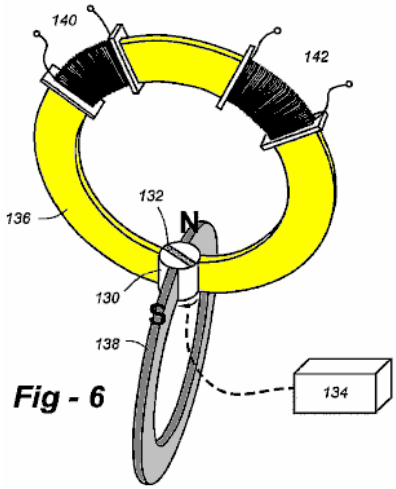

Fig - 6

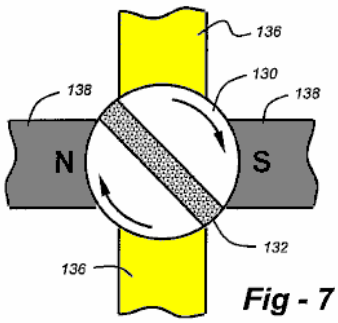

Fig - 7

As an alternative to a motionless flux switch, a rotary flux switch may be used to implement the 2x2 alternating sequence. Referring to Fig.6 and Fig.7, cylinder 130 with flux gap 132 is rotated by a motive means 134. This causes the halves of cylinder 130 to provide two concurrent and separate magnetic flux bridges (i.e., a "closed" reluctance switch condition), in which a given end of magnetisable member 136 is paired up with one of the poles

of stationary permanent magnet 138. Simultaneously, the other end of single flux path carrier 136 is paired up with the opposite pole of stationary permanent magnet 138.

Fig.7 is a detail view of the cylinder. Each 90° rotation of the cylinder causes the first flux bridges to be broken (an "open" reluctance switches condition) and a second set of flux bridges to be created in which the given end of member 136 is then bridged with the opposite pole of stationary permanent magnet 138. A full rotation of cylinder 130 causes four such reversals. Each flux reversal within single flux path 2 causes an electric current to be induced in conducting coil(s) 140, 142. In this embodiment, it is important to keep a precise, consistent spacing between each of the "halves" of (rotating) cylinder 130 in relation to the poles of permanent magnet 138 and the ends of flux path carrier 136 as the magnetic flux bridges are provided by the cylinder 130 as it rotates.

Rotating cylinder 130 is made of high magnetic permeability material which is divided completely by the flux gap 132. A preferred material is a nanocrystalline material such as FINEMET® made by Hitachi. The flux gap 132 may be air, glass, ceramic, or any material exhibiting low magnetic permeability. A superconductor or other structure exhibiting the Meissner effect may alternatively be used.

An efficient shape of magnetisable member 136 is a "C" in which its opposing ends are curved with a same radius as cylinder 130 and are in the closest possible proximity with rotating cylinder 130. Permanent magnet 138 is also preferably C-shaped in which the opposing poles are curved with a same radius as cylinder 130 and are in the closest possible proximity with rotating cylinder 130. Manufacturing and assembly considerations may dictate other shapes.

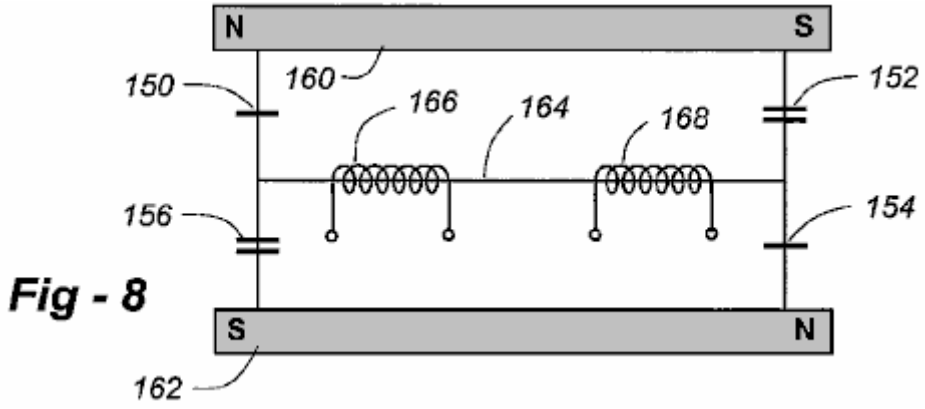

Fig - 8

While the embodiments described thus far utilize a single permanent magnet, other embodiments are possible according to the invention utilizing a plurality of permanent magnets while nonetheless generating a single flux path. Fig.8 depicts a circuit utilizing two permanent magnets and a single flux path. Fig.9 shows one possible physical embodiment of the apparatus based upon the components of Fig.8, including a reluctance switch control unit 158.

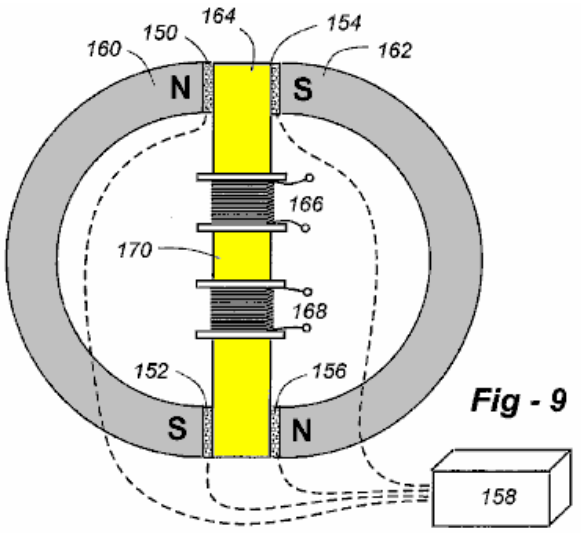

Fig - 9

Under the control of unit 158, reluctance switches 150, 152 open (increasing reluctance), while switches 154, 156 close (decreasing reluctance). Reluctance switches 150, 152 then close, while switches 154, 156 open, and so on. This 2x2 opening and closing cycle repeats and, as it does, the magnetic flux from stationary permanent magnets 160, 162 is reversed in polarity through the magnetisable member, causing electricity to be generated in conducting coils 166, 168.

In the preferred implementation of this embodiment, the magnets are arranged with their N and S poles reversed. The magnetisable member is disposed between the two magnets, and there are four flux switches, SW1-SW4, two between each end of the member and the poles of each magnet. The reluctance switches are implemented with the structures described above with reference to Figs. 1 to 3.

For added particularity, assume the first magnet has north and south poles, N1 and S1, the second magnet has north and south poles, N2 and S2 and the member has two ends A and B. Assuming SW1 is situated between N1 and A, SW2 is between A and S2, SW3 is between N2 and B, and SW4 is between B and S1, the control circuitry operative to activate SW1 and SW4, then activate SW2 and SW3, and repeat this process on a sequential basis. As with the other embodiments described herein, for reasons of efficiency, the switching is carried out simultaneously.

In all of the embodiments described herein the material used for the permanent magnet(s) may be either a magnetic assembly or a single magnetized unit. Preferred materials are ceramic ferrite magnets (Fe_20_3), samarium cobalt ($SmCO_5$), or combinations of iron, neodymium, and boron. The single flux path is carried by a material having a high magnetic permeability and constructed to minimize eddy currents. Such material may be a laminated iron or steel assembly or ferrite core such as used in transformers. A preferred material is a nanocrystalline material such as FINEMET®. The conducting coil or coils are wound around the material carrying the single flux path as many turns as required to meet the voltage, current or power objectives. Ordinary, standard, insulated, copper magnet wire (motor wire) is sufficient and acceptable. Superconducting materials may also be used. At least some of the electricity induced in the conducting coils may be fed back into the switch control unit. In this mode of operation, starting pulses of electricity may be provided from a chemical or solar battery, as required.

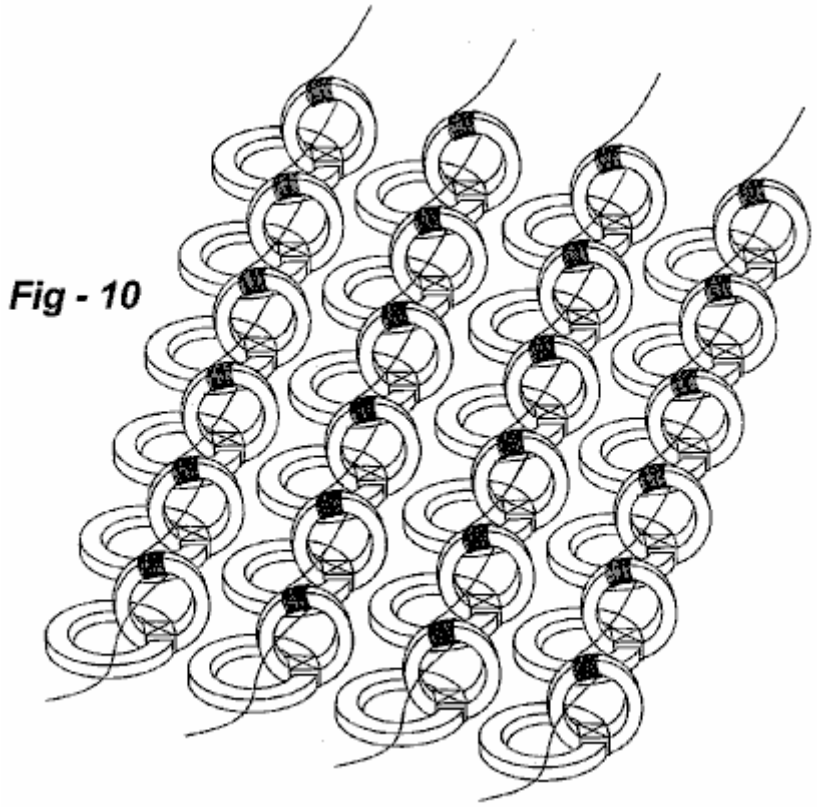

Fig - 10

Although in the embodiments of Fig.2 and Fig.6 the magnet and flux-carrying materials are flat elements lying in orthogonal planes with flux-carrying material lying outside the volume described by the magnet, the flux path may be disposed `within' the magnet volume or configured at an angle. The physical scale of the elements may also be varied to take advantage of manufacturing techniques or other advantages. Fig.10, for example, shows an array of magnetic circuits, each having one or more coils that may be in series, parallel, or series-parallel combinations, depending upon voltage or current requirements. In each case the magnets may be placed or fabricated using techniques common to the microelectronics industry. If mechanical flux switches are used they may be fabricated using MEMs-type techniques. If motionless switches are used, the materials may be placed and/or deposited. The paths are preferably wound in advance then picked and placed into position as shown. The embodiment shown in Fig.9 is also amenable to miniaturization and replication.

CLAIMS

1. An energy generator, comprising: at least one permanent magnet generating flux; a magnetisable member; an electrical conductor wound around the member; and a plurality of magnetic flux switches operative to sequentially reverse the flux from the magnet through the member, thereby inducing electricity in the electrical conductor.

2. The energy generator of claim 1, comprising: first and second loops of magnetisable material; the first loop having four segments in order A, 1, B, 2; the second loop having four segments in order C, 3, D, 4; the magnetisable member coupling segments 2 and 4; the permanent magnet coupling segments 1 and 3, such that the flux from the magnet flows through segments A, B, C, D and the magnetisable member; four magnetic flux switches, each controlling the flux through a respective one of the segments A, B, C, D; and a controller operative to activate switches A-D and B-C in an alternating sequence, thereby reversing the flux through the segment and inducing electricity in the electrical conductor.

3. The energy generator of claim 2, wherein the loops and magnetisable member are composed of a nanocrystalline material exhibiting a substantially square BH intrinsic curve.

4. The energy generator of claim 2, wherein each magnetic flux switch is operative to add flux to the segment it controls, thereby magnetically saturating that segment when activated.

5. The energy generator of claim 2, wherein: each segment has an aperture formed therethrough; and each magnetic flux switch is implemented as a coil of wire wound through one of the apertures.

6. The energy generator of claim 2, wherein the controller is at least initially operative to activate the switches with electrical current spikes.

7. The energy generator of claim 2, wherein the first and second loops are toroids.

8. The energy generator of claim 2, wherein the first and second loops are spaced apart from one another, with A opposing C, 1 opposing 3, B opposing D and 2 opposing 4.

9. The energy generator of claim 2, wherein the first and second loops intersect to form the magnetisable member.

10. The energy generator of claim 2, wherein the flux flowing through each segment A, B, C, D is substantially half of that flowing through the magnetisable member prior to switch activation.

The Energy Conversion Device of William McDavid junior

US Patent 6,800,955 5th Oct. 2004 Inventor: William McDavid jnr.

Fluid-powered energy conversion device

Note: The wording of this patent has been altered to make it easier to understand. An unaltered copy can be downloaded from www.freepatentsonline.com. In this patent, William relates sections of his design according to the direction of flow through the housing and so he calls the first section the "downstream" chamber and the following chamber as the "upstream" chamber. Although water could be used, this patent essentially describes a high-efficiency wind-powered generator. For dimensions: one inch = 25.4 mm.

Abstract:

A fluid-powered energy conversion device which converts energy in a moving fluid into mechanical energy. A rigid cylindrical frame of toroidal baffles forms an "upstream" annular or ring-shaped chamber and a "downstream" annular chamber, each of the chambers having open sides to allow the entry of the fluid. The toroidal baffles create an upstream **drive** vortex in an upstream central vortex chamber, and a downstream **extraction** vortex rotating in the opposite direction in a downstream central vortex chamber. A set of hinged louvers surround the vortex chambers and these allow the fluid to enter each chamber only in the direction of vortex rotation, and prevent the fluid from exiting through the sides of the device. The driving vortex passes through, and rotates, a turbine positioned in a central aperture between the two chambers. The turbine blades are rotated by the rotational momentum of the driving fluid vortex, plus the lift generated by each turbine blade, plus the additional momentum imparted by the vortex reversal.

Description:

BACKGROUND OF THE INVENTION

1. Technical Field of the Invention

The present invention relates generally to electrical generation and energy conversion devices, and more particularly to a fluid-powered energy conversion device which converts the energy of wind or flowing water into mechanical or electrical energy.

2. Description of Related Art

The use of wind or flowing water to provide power for various uses dates back many centuries. In modern times, wind and water have been used to generate electricity. Hydroelectric generating plants have been used to generate large quantities of electrical energy for widespread distribution. However, this requires major permanent environmental changes to the areas where dams are built and reservoirs rise. Wind-powered devices, in general, have been used to perform mechanical work, or to generate electricity, only on a limited scale. With the ever increasing demand for additional, or alternative energy sources, all possible sources are being given more scrutiny. This is particularly true for sources which are non-polluting and inexhaustible. Free-flowing hydro-electric and wind-powered systems provide such sources, and the capturing of increased energy from wind and water has received much consideration.

However, commercial hydro-electric and wind-powered electrical generation devices which are currently in use have several disadvantages. Wind-powered devices, in particular, are expensive, inefficient, dangerous, noisy, and unpleasant to be around. To capture a large volume of wind, existing wind-powered devices are very large. As a result, they cannot be distributed throughout population centres, but must be installed some distance away. Then, like dams with hydro-electric generators, the electrical energy they generate must be transmitted, at considerable cost and with considerable energy loss, to the population centres where the energy is needed.

It would be desirable to distribute smaller water-powered and wind-powered units throughout the population centres. For example, it would be desirable to have a wind-powered unit for each building structure, thus distributing the generating capacity over the entire area, and making the energy supply less vulnerable to local

events such as storms or earthquakes. Such distributed generation would also solve the most common and valid objection to wind power, namely, that the wind does not blow all the time. In a large geographical area, however, wind is almost always blowing somewhere. Therefore, with wind-powered generators which are distributed throughout the area, power could be generated in the areas where the wind is blowing, and then transmitted to the rest of the power grid. However, with existing technology, smaller units suitable for distributing throughout a population area are not efficient enough to provide a sufficient amount of energy to power a structure such as a house or office building. In addition, such units are visually obtrusive and noisy, making them unsuitable for use in residential or other highly populated settings.

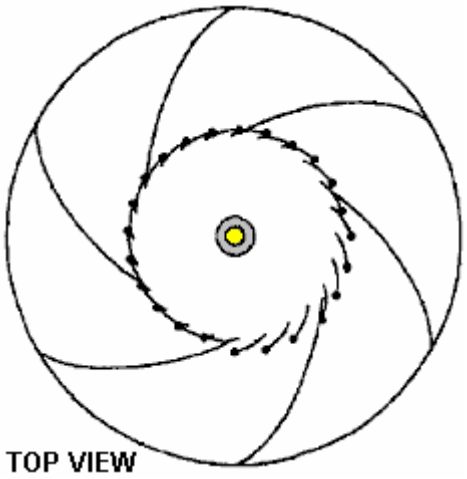
Existing wind-powered electrical generation devices commonly utilise a propeller mounted on the horizontal shaft of a generator which, in turn, is mounted at the top of a tower. This is an inefficient design because energy is extracted from the wind by reducing the wind velocity as it passes through the propeller. This creates a pocket of slow-moving air cantered behind the propeller, which the ambient wind blows around. Therefore, only the outer portion of the propeller blades use the wind efficiently.

To counter this effect, modern windmill designs utilise extremely long propeller blades. The use of such massive blades, however, has its own disadvantages. Firstly, the propellers are known to kill or injure thousands of large birds each year. Secondly, the massive blades can be dangerous if the device fails structurally and the propeller breaks loose. In this case, the propeller can fly a considerable distance and cause serious damage or injury to anything or anyone in its path. Thirdly, the propeller design contains an inherent gravitational imbalance. The rising blades on one side of the propeller's hub are opposing gravity, while the descending blades on the other side of the hub are falling with gravity. This imbalance creates a great deal of vibration and stress on the device. Consequently, the device must be structurally enhanced, at great expense, to withstand the vibration and stress, and thus avoid frequent maintenance and/or replacement.

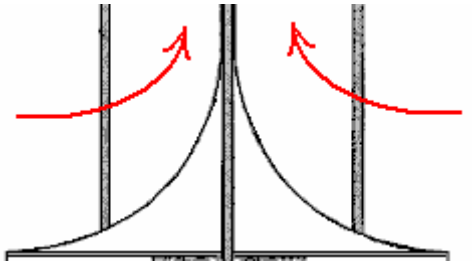
It would therefore be advantageous to have a fluid-powered energy conversion device which overcomes the shortcomings of existing devices. Such a device could utilise wind energy or the energy of flowing water to provide mechanical energy or electrical energy. The present invention provides such a device.

SUMMARY OF THE INVENTION

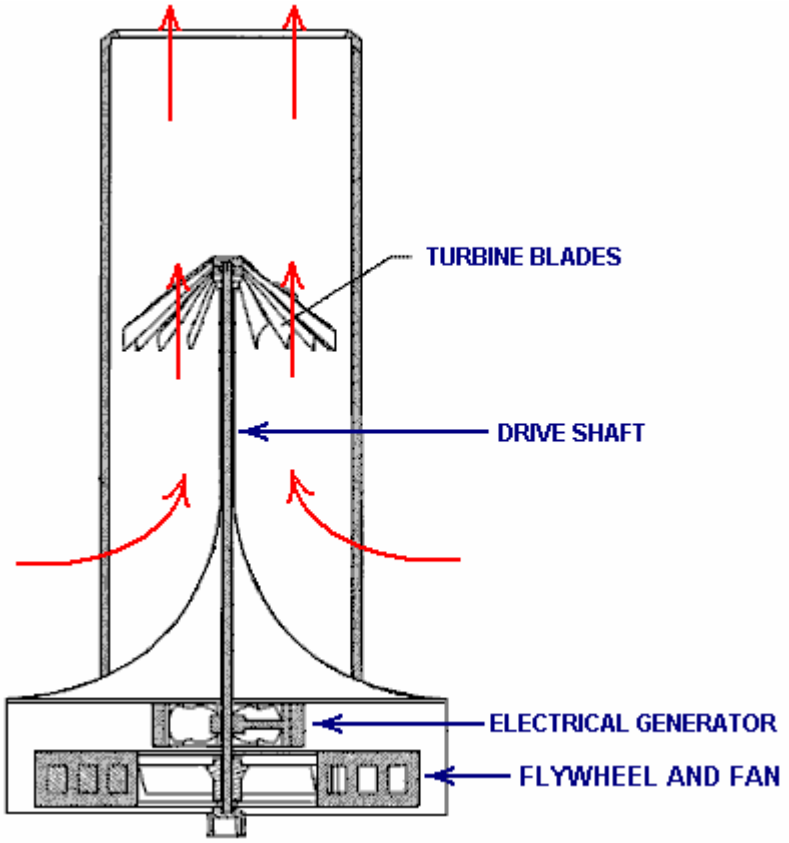
One aspect, the present invention is a fluid-powered energy-conversion device for converting energy in a moving fluid into mechanical energy. The device includes a rigid cylindrical frame which has an “upstream” annular (ring-shaped) chamber and a “downstream” annular chamber. Each of the chambers has sides which are open to allow entry of the moving fluid. A first set of baffles are mounted longitudinally in the upstream chamber, and these create a driving vortex which rotates in a first direction when the moving fluid enters the upstream chamber through the upstream chamber's open sides. A set of hinged louvers are positioned in the openings between these baffles, creating a central vortex chamber centered on the longitudinal axis of the device.



This first set of louvers permits entry of the moving fluid into the upstream central vortex chamber only when the fluid is rotating in the first direction. They also prevent the fluid from exiting from the upstream central vortex chamber through the sides of the device. The device also includes a floor of the upstream annular chamber which slopes upwards towards the downstream chamber as the floor approaches the central longitudinal axis of the device.



This sloping floor causes the drive vortex to flow “downstream” (upwards for air) through the upstream central vortex chamber and pass through a central aperture located between the upstream annular chamber and the downstream annular chamber. A longitudinal drive shaft is mounted centrally in the central aperture, and a turbine is mounted on the drive shaft in the central aperture. The turbine is rotated by the drive vortex as the drive vortex passes through the central aperture.



The device may also include a second set of baffles longitudinally mounted in the “downstream” (upper for air) chamber which operate to create an extraction vortex which rotates in the opposite direction when the moving fluid enters the downstream chamber through the downstream chamber's open sides. Additionally, a second set of hinged louvers may be positioned in the openings between the second set of baffles, encircling a downstream central vortex chamber. The second set of louvers permit entry of the moving fluid into the downstream central vortex chamber only when the fluid is rotating in the direction opposite to the direction of flow in the “upstream” camber. These louvers also prevent the fluid from exiting the downstream central vortex chamber through the sides of the device. In this manner, the turbine is rotated by the drive vortex as the drive vortex passes through the turbine and reverses direction to match the direction of the extraction vortex.

For high-wind conditions or when powered by water flow, the driving vortex and extraction vortex may rotate in the same direction. The first set of hinged louvers form the upstream central vortex chamber, and the second set of hinged louvers form the downstream central vortex chamber. The first set of louvers permit entry of the wind or water into the upstream central vortex chamber only when the fluid is rotating in the first direction.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will be better understood and its numerous objects and advantages will become more apparent to those skilled in the art by reference to the following drawings, in conjunction with the accompanying specification, in which:

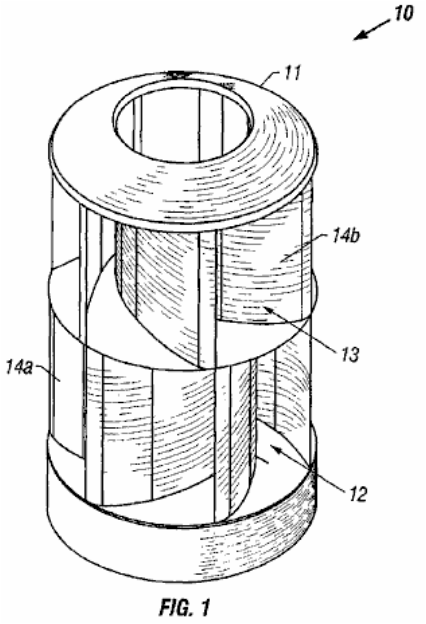


FIG. 1

FIG.1 is a perspective view of a first embodiment of the present invention that converts wind energy to mechanical or electrical energy;

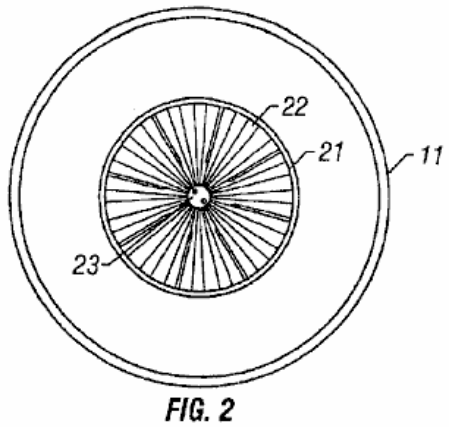

FIG. 2

FIG.2 is a top plan view of the embodiment of Fig.1

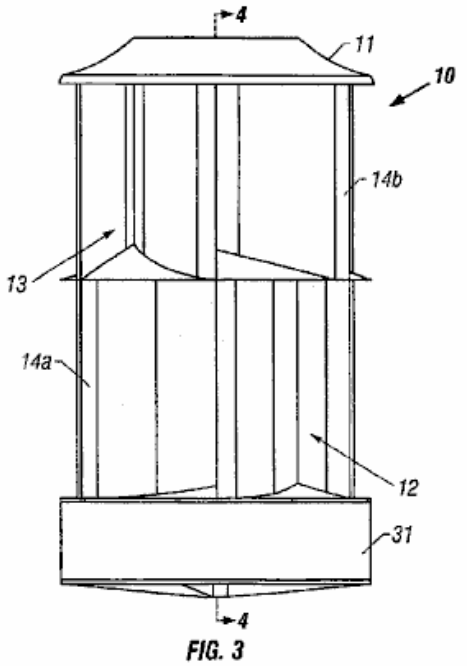

FIG. 3

FIG.3 is a side elevational view of the embodiment of Fig.1

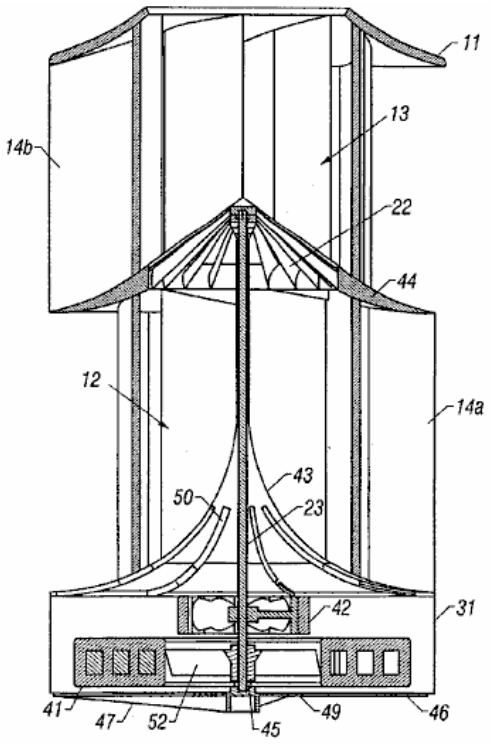

FIG. 4

FIG.4 is a cross-sectional view of the embodiment of Fig.1 taken along line **4** — **4** of Fig.3 with an electrical generator installed to produce electrical energy;

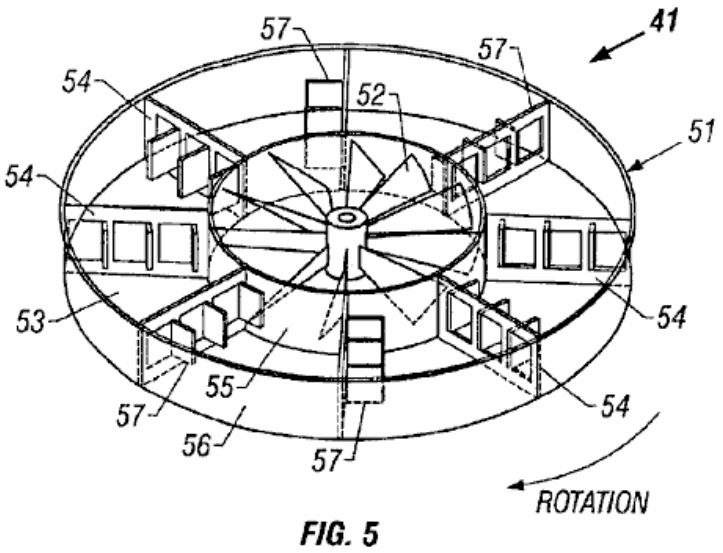

FIG. 5

FIG.5 is a perspective view of a fluid-filled flywheel suitable for use with the present invention;

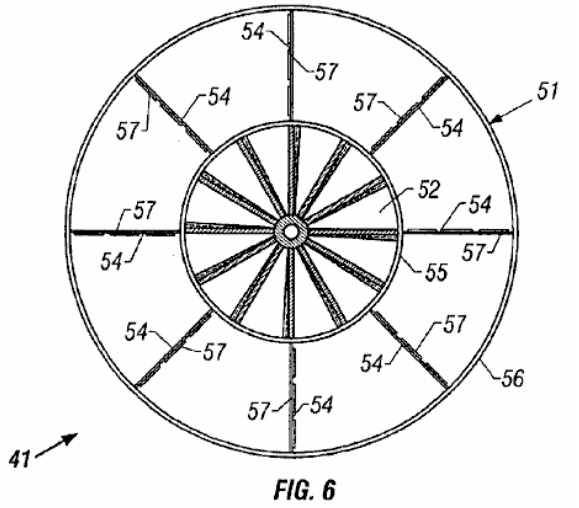

FIG. 6

FIG.6 is a top plan view of the fluid-filled flywheel of Fig.5

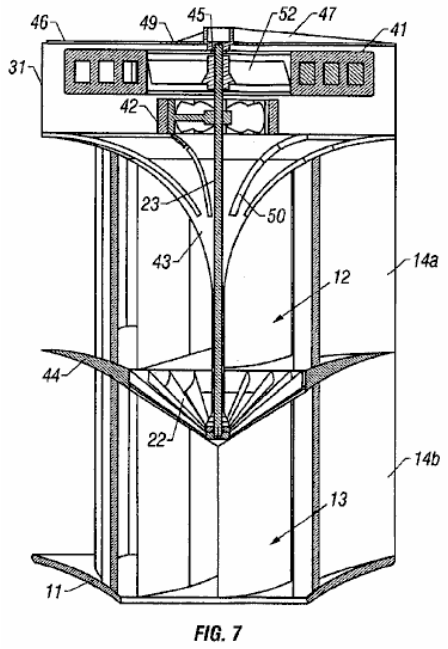

FIG. 7

FIG.7 is a cross-sectional view of an embodiment of the present invention that converts the energy of flowing **water** to electrical energy;

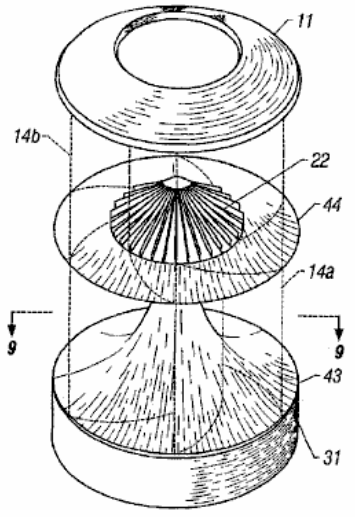

FIG. 8

FIG.8 is a perspective view of the embodiment of Fig.1 with the longitudinal baffles drawn in phantom so that the annular central divider (mid-deck) and turbine can be seen

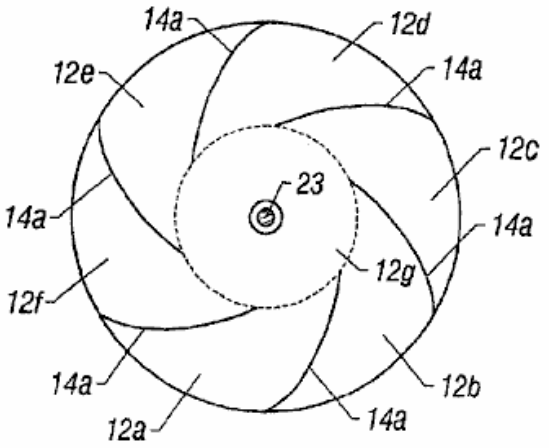

FIG. 9

FIG.9 is a horizontal cross-sectional view of the embodiment of Fig.1 taken along line **9** — **9** of Fig.8

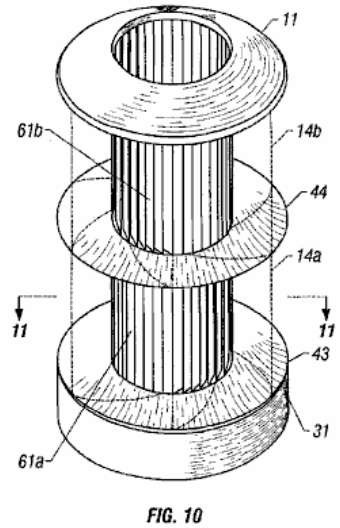

FIG. 10

FIG.10 is a perspective view of a second embodiment of the present invention that converts wind energy to mechanical or electrical energy, with the longitudinal baffles drawn in phantom so that a set of hinged longitudinal louvers can be seen; and

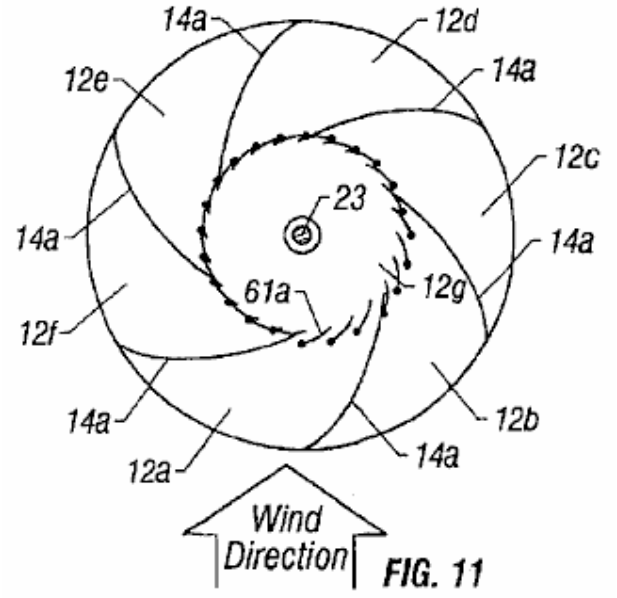

FIG. 11

FIG.11 is a horizontal cross-sectional view of the embodiment of Fig.10 taken along line **11** — **11** .

In the drawings, like or similar elements are designated with identical reference numerals throughout the various views, and the various elements shown are not necessarily drawn to scale.

DETAILED DESCRIPTION OF EMBODIMENTS

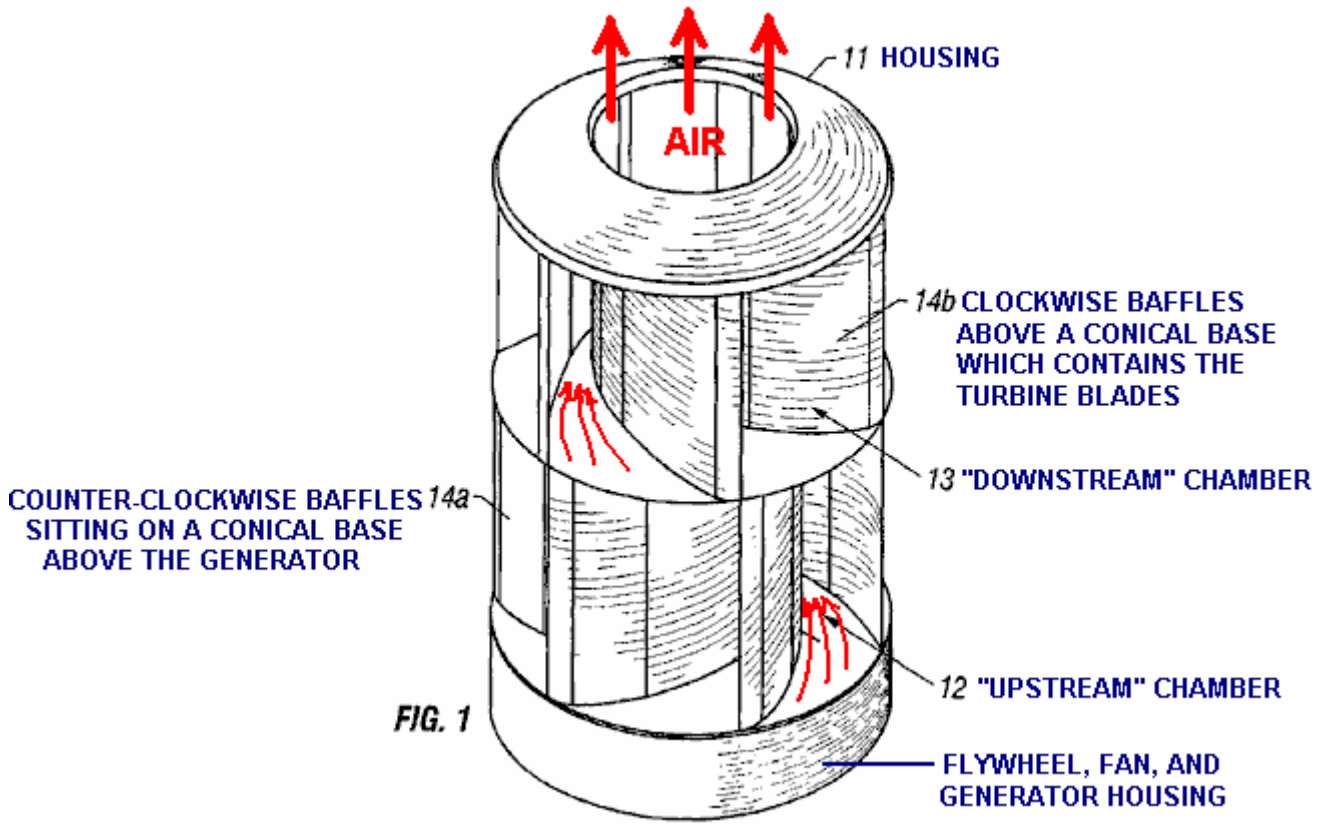

FIG. 1

Fig.1 is a perspective view of an embodiment of the present invention which converts wind energy to mechanical or electrical energy. The energy conversion device **10** includes a stationary cowling **11** surrounding an upstream (lower) ring-shaped or doughnut-shaped chamber **12** and a downstream (upper) ring-shaped chamber **13**. The cowling may be constructed of any suitable rigid material such as wood, plastic, metal, or similar. The cowling may be constructed from a transparent material, making the device visually unobtrusive. In the preferred embodiment of the present invention, the cowling is cylindrical and is constructed of a high-grade, ultraviolet-protected plastic.

The cowling **11** includes a set of longitudinal baffles which are curved and arranged in a toroidal pattern. Upstream baffles **14a** are mounted in the upstream annular chamber **12**, and downstream baffles **14b** are mounted in the downstream annular chamber **13**. In the preferred embodiment of the present invention, approximately six toroidal longitudinal baffles are mounted in each chamber. The baffles function to guide the wind into each chamber. The narrowing cross-sectional area between the baffles causes the air to accelerate as it moves toward the centre of the device, creating two high-velocity vortices (an upstream drive vortex and a downstream extraction vortex). Although the invention is described here primarily as a vertically-oriented cylinder, it should be understood that the device may be installed in other positions, such as a horizontal orientation, which results in the device having an upstream annular chamber and a downstream annular chamber which are at the same height. Alternatively, as noted below in connection with **Fig.7**, the device may be inverted when used in water since water vortices move more readily downwards rather than upwards.

In the embodiment illustrated in **Fig.1**, in which low-speed wind is the input energy source, the upstream baffles **14a** and the downstream baffles **14b** are curved in opposite directions. The baffles therefore create two high-velocity vortices which rotate in opposite directions. As described below in connection with **Fig.4** , the direction of the vortex flow is reversed in a turbine located between the upstream annular chamber **12** and the downstream annular chamber **13**, thereby adding additional rotational power to the turbine. In the hydro-electrical embodiment in which flowing water is the input energy source, and in high-speed wind conditions such as when the device is mounted on a vehicle, the upstream baffles and the downstream baffles may be curved in the same direction. In those particular embodiments, therefore, the baffles create two high-velocity vortices which rotate in the same direction. The device may be converted from a low-wind device to a high-wind device by removing the counter-

rotational downstream annular chamber **13** and replacing it with a downstream annular chamber which creates a vortex rotating in the same direction as the drive vortex.

In the preferred embodiment of the present invention, plastic mesh (not shown) may surround the entry and exit openings of the cowling **11** to prevent birds, animals, or debris from entering the device **10**. In addition, should the device fail structurally, any broken parts are contained by the mesh instead of flying out into the vicinity and causing damage or injury.

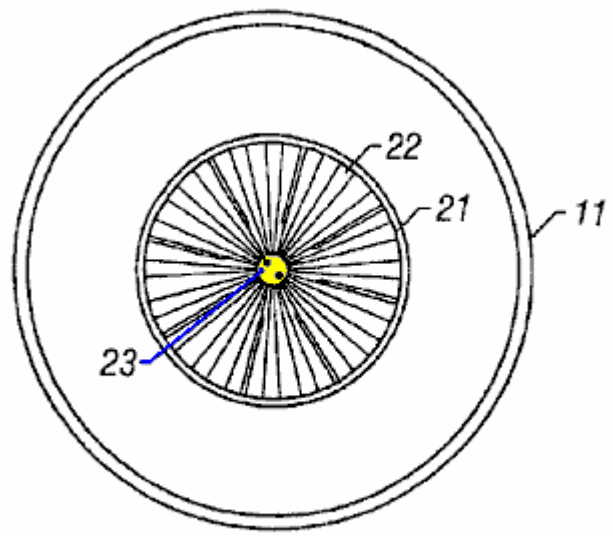

FIG. 2

Fig.2 is a top plan view of the embodiment of **Fig.1**. The top of the cowling **11** includes a central aperture **21** through which the air in the extraction vortex exits the device. In the preferred embodiment, the extraction vortex exits the device rotating in a counter-cyclonic direction (clockwise in the Northern Hemisphere) so that it dissipates rather than creating potentially damaging whirlwinds. The turbine **22** is visible through the aperture. The turbine rotates around a central drive shaft **23** .

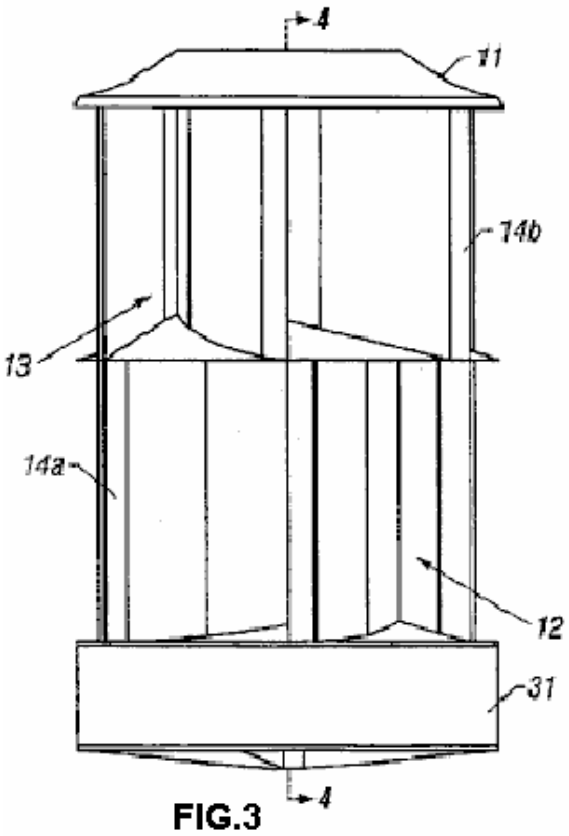

FIG.3

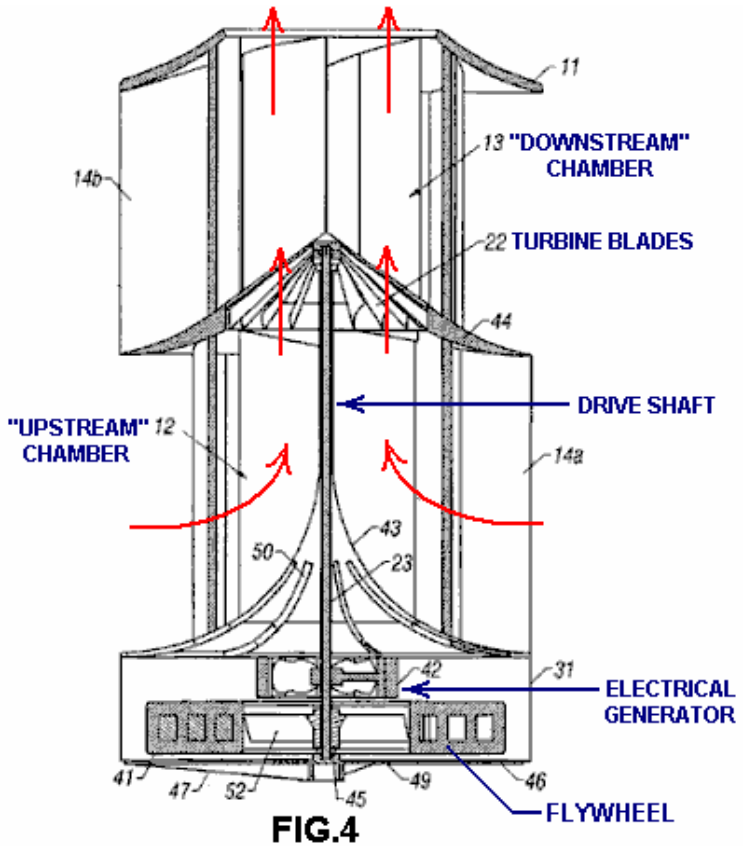

FIG.4

Fig.3 is a side-elevational view of the embodiment of **Fig.1** illustrating the profile of the cowling **11**, the upstream annular chamber **12**, the downstream annular chamber **13**, and the baffles **14a** and **14b**. The cowling may be

mounted on a base **31** and the base **31** may also be used to enclose additional mechanical assemblies such as a flywheel and/or an electrical generator.

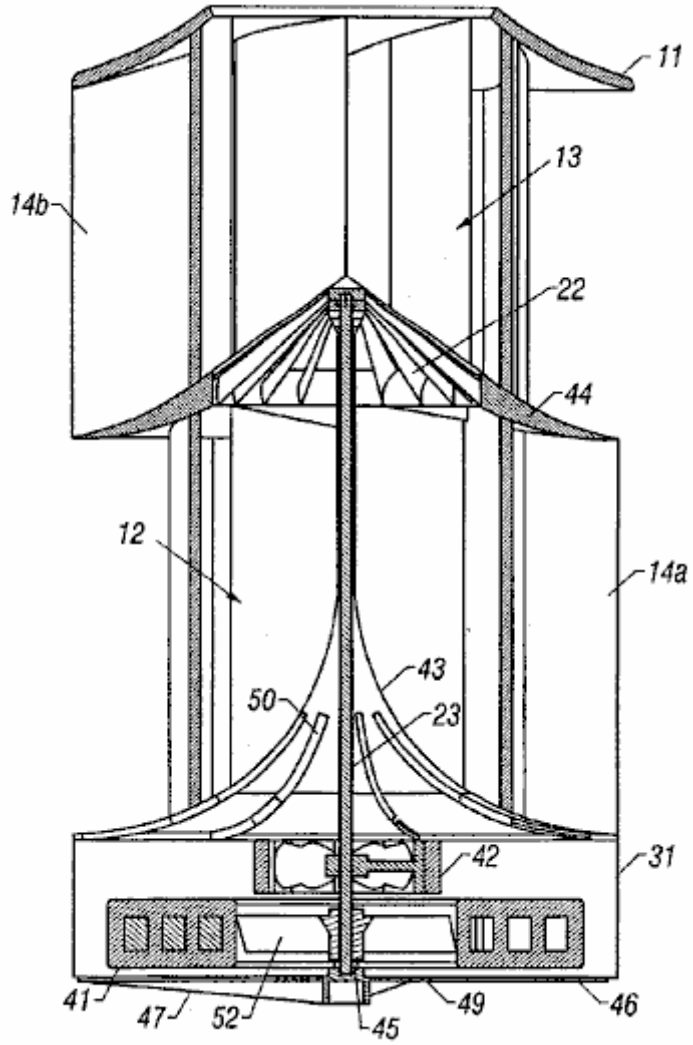

FIG. 4

Fig.4 is a cross-sectional view of the embodiment of **Fig.1** taken along line **4** — **4** of **Fig.3** with a flywheel **41** installed in the base **31** along with an electrical generator **42** to produce electricity. Ambient wind flows simultaneously into the upstream annular chamber **12** through upstream baffles **14a**, and into the downstream annular chamber **13** through the downstream baffles **14b** through the sides of the cowling **11**. The baffles guide the ambient wind towards the centre of the device **10**. A sloping parabolic floor (deck) **43** of the upstream annular chamber **12** causes the wind to flow downstream into the centrally mounted turbine **22** that rotates on the central drive shaft **23**. The device **10** produces power by guiding ambient wind flows into two high-velocity vortices arranged upstream and downstream of the turbine which converts the wind flows to mechanical energy by turning the drive shaft **23**. High-RPM and high-torque are produced by the turbine due to three primary factors:

(1) each blade of the turbine is shaped like a scoop which captures the rotational momentum of the drive vortex;

(2) each blade of the turbine has a cross-sectional shape of an airfoil that generates lift in the direction of rotation of the turbine; and

(3) in low wind conditions, the reversal of the direction of the vortex rotation adds additional force to the turbine in the direction of rotation.

The large flywheel **41** may be attached to the rotating turbine drive shaft **23**. In one embodiment, the flywheel may be a permanent magnet, surrounded by copper windings. The flywheel may serve both as an internal energy storage device due to its angular momentum, and as a dynamo for the generator **42** mounted under the deck **43** of the upstream annular chamber **12**. A solid-state electronic regulator (not shown) may be utilised to control the electrical current load. The regulator maintains a zero load until a preset rotational velocity (RPM) is reached. The load is then increased in order to generate electricity while maintaining the RPM of the turbine at a preselected level.

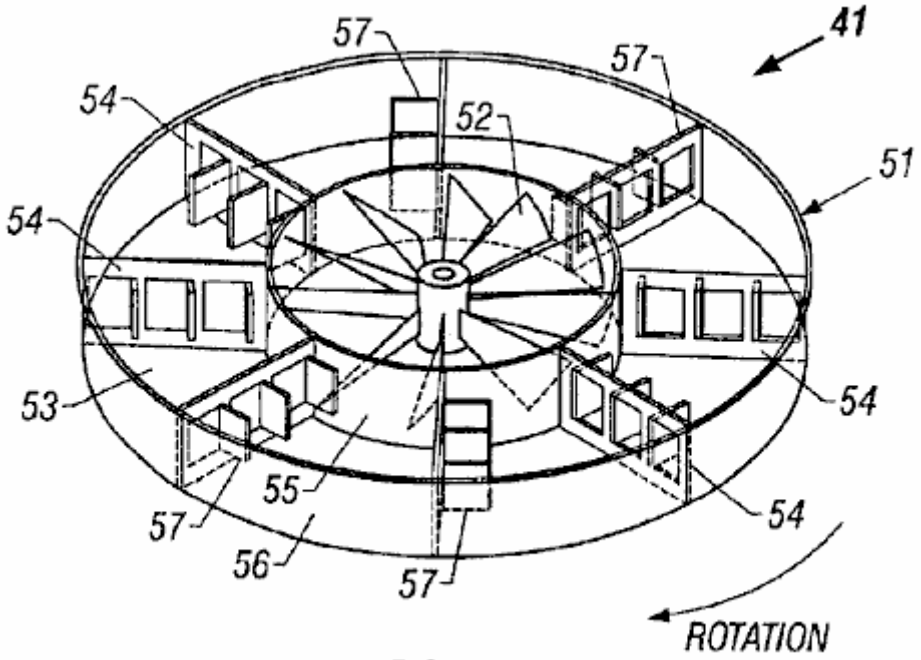

FIG. 5

In **Fig.5** is shown a perspective view of another embodiment of the flywheel **41**. In this embodiment, the flywheel (shown in phantom) includes a hollow disk-shaped shell **51** which is filled with a fluid such as water. The design shown also includes a cooling fan **52** in the hub of the flywheel which rotates with the drive shaft **23** and the flywheel to produce a flow of cooling air that is used to cool the adjacent generator **42** (**Fig.4** and **Fig.7**). The placement of the fan in the hub of the flywheel creates an annular chamber **53** whicht holds the fluid. Within the chamber, there is a set of radial bulkheads **54** extending from the interior wall **55** to the exterior wall **56** of the chamber. Each of the radial bulkheads includes hinged gates or hatches **57**. In the example version shown here, each radial bulkhead has three hinged gates.

During acceleration of the flywheel **41** , these gates **57** open in the opposite direction of rotation. This allows the fluid to flow through the radial bulkheads **54**, reducing start-up inertia. The fluid then slowly comes up to speed due to friction with the interior and exterior walls **55** and **56** of the annular chamber, and due to the motion of the radial bulkheads through the fluid. During deceleration of the flywheel, the gates close because of the forward momentum of the fluid. This creates solid radial bulkheads and causes the flywheel to perform as a solid flywheel. The angular momentum of the flywheel then helps to maintain the angular velocity of the drive shaft **23** when the input power of the wind drops off.

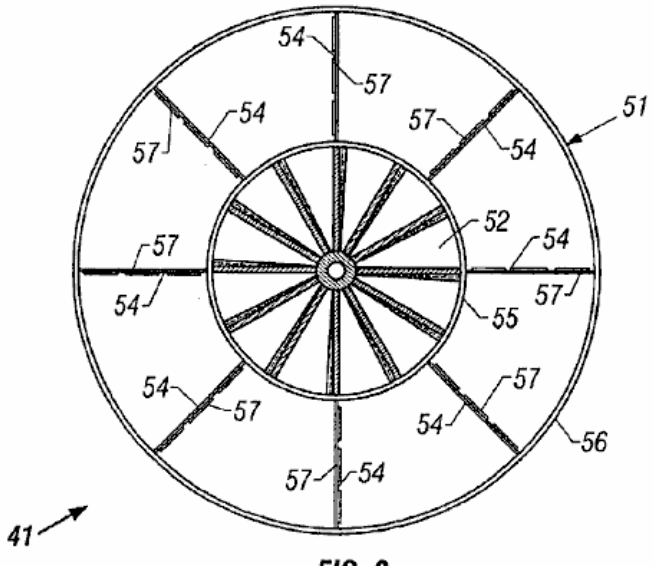

FIG. 6

Fig.6 is a top plan view of the fluid-filled flywheel **41** of **Fig.5** , showing the blades of the cooling fan **52** in the hub of the flywheel, the annular chamber **53**, the radial bulkheads **54**, and the gates **57** in the closed (decelerating) position.

Thus, the fluid-filled flywheel **41** is particularly well suited for use with this energy conversion device **10** of the present invention. The fluid-filled flywheel allows rapid spin-up of the drive shaft **23** by reducing the start-up inertia, but resists deceleration like a solid flywheel. These features can significantly boost the efficiency of a wind-powered or water-powered device that operates with varying input power levels. By simply inverting the flywheel, the fluid-filled flywheel can be used with systems that spin either clockwise or counter-clockwise. As an additional feature, shipping weight is greatly reduced because the fluid can be added at the point of use.

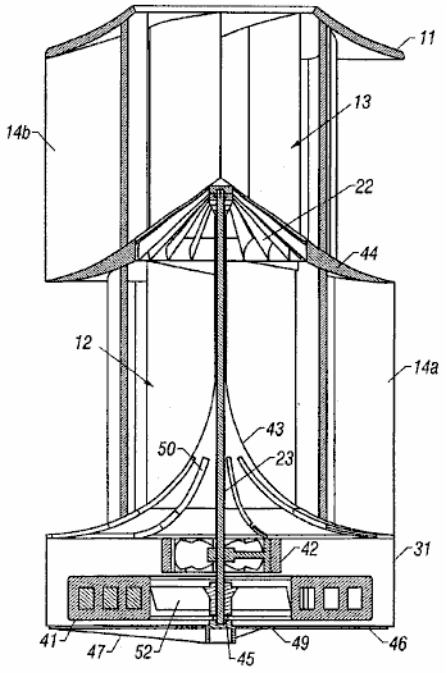

FIG. 4

Referring again to **Fig.4** , an annular central divider (mid-deck) **44** divides the upstream annular chamber **12** from the downstream annular chamber **13**. The top of the mid-deck slopes away from the turbine, causing the ambient wind entering the downstream annular chamber to flow away from the turbine. This creates an area of reduced air pressure on the downstream side of the turbine **22** that increases the flow of air from the upstream annular chamber **12** through the turbine. Each blade of the turbine **22** is a curved airfoil which receives rotational impetus from the rotation of the drive vortex, the reversal of the vortex direction, and aerodynamic lift that is generated by the airfoil in the direction of rotation of the turbine.

In the preferred embodiment of the present invention, the turbine **22** and flywheel **41** may be made of metal. Further, all metal parts may be coated with, for example, plastic, chrome, or paint to prevent corrosion. As discussed above, the flywheel may be a permanent magnet or may be a fluid-filled flywheel. All bearings such as bearing **45** may be magnetic-repulsion-levitation bearings so that there is no physical contact between the moving and stationary elements of the device. The base **31** may be mounted on a support plate **46** and/or a support brace **47**, depending on the structure on which the device is mounted and the orientation of the device.

The central drive shaft **23** may also drive the cooling fan **52** that draws cooling air through vents **49** in the support plate and directs the air through the generator **42**. The heated air may exit through louvers **50** in the parabolic deck **43** of the upstream annular chamber **12** where it then mixes with the driving airflow in the upstream annular chamber to defrost the interior of the device and the turbine **22**.

The device **10** may vary in its dimensions, depending upon the specific application for which it is utilised. For example, the dimensions of a wind-powered device that is mounted on the roof of a house may be between 40 inches and 48 inches in diameter, and between 60 inches and 78 inches in height. In this configuration, the turbine **22** has a diameter approximately one-half the diameter of the exterior of the cowling **11** (i.e. approximately 20 to 24 inches in diameter). Larger versions may be utilised for larger buildings such as factories or office buildings with increased economies of scale. For example, an office building may use a device that is 20 feet in diameter and 20 feet tall with a turbine that is 10 feet in diameter. A vehicle-mounted device (for example, for a passenger car), designed for high-wind conditions, may be about 24 inches in diameter and 6 inches in height. The generator and flywheel, if any, may be mounted inside the contour of the vehicle, or on a luggage rack. A

small hydro-electric version of the device that is placed in a running stream or river may have similar dimensions to the vehicle-mounted device. In addition, since the outflow of the hydro-electric version is directed downward, a deflector may be utilised in shallow bodies of water to prevent erosion of the stream bed.

It should be noted that when the present invention is oriented vertically, the turbine **22**, the generator **42**, and the flywheel **41** rotate around a vertical axis. Therefore, the supporting structures are not subject to the vibration and stress produced by gravity effects in prior art devices in which propellers rotate around a horizontal axis. Moreover, exceptional wind-conversion efficiency is realized from the present invention as it diverts and accelerates the ambient wind flow into vortices that have several times the velocity of the ambient wind flow when they reach the turbine. Additionally, the acceleration of the air flow into the upstream and downstream annular chambers creates a low pressure area that pulls air into the device from an effective cross-sectional area that is greater than the physical cross-sectional area of the device. As a result, the present invention provides a new and improved wind-power conversion device which is quieter, safer, more efficient, and more cost effective than existing devices.

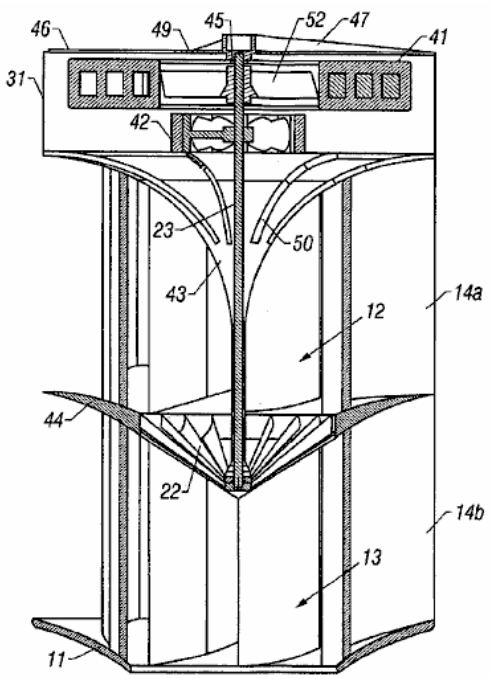

FIG. 7

Referring now to **Fig.7**, there is shown a cross-sectional view of a version of the present invention which converts the energy of flowing water to electrical energy (i.e. a hydro-electrical device). There are three key differences between the hydro-electrical embodiment from the low-wind-powered embodiment of **Figs. 1 to 4**. Firstly, the upstream baffles **14a** and the downstream baffles **14b** curve in the same direction. The baffles therefore create two high-velocity vortices which rotate in the same direction. This is a more efficient design when the fluid flowing through the device is an incompressible fluid such as water. Secondly, the device operates more efficiently when it is inverted and mounted vertically since water vortices move downward due to the force of gravity. The third difference is the ratio of the height of the device to the diameter of the device. As noted above, the hydro-electric embodiment of the device may have a height that is shorter when compared to its diameter, and may have a height that is equal to or less than its diameter.

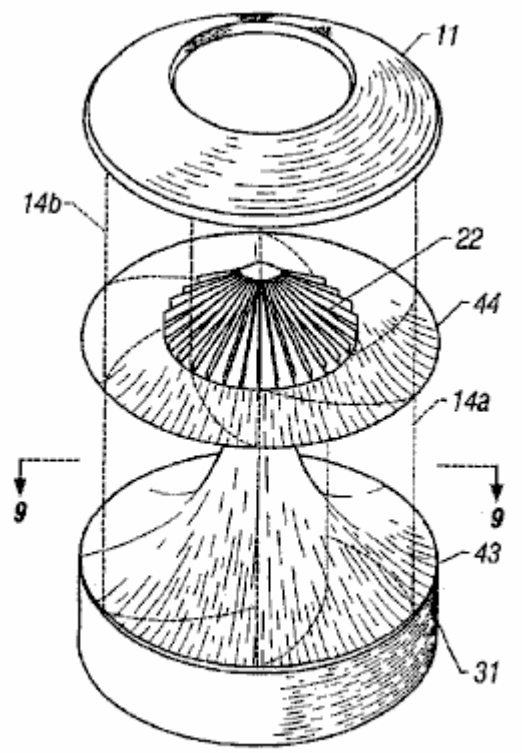

FIG. 8

Fig.8 is a perspective view of the embodiment of **Fig.1** with the toroidal longitudinal baffles **14a** and **14b** drawn in phantom so that the annular central divider (mid-deck) **44** and turbine **22** can be seen.

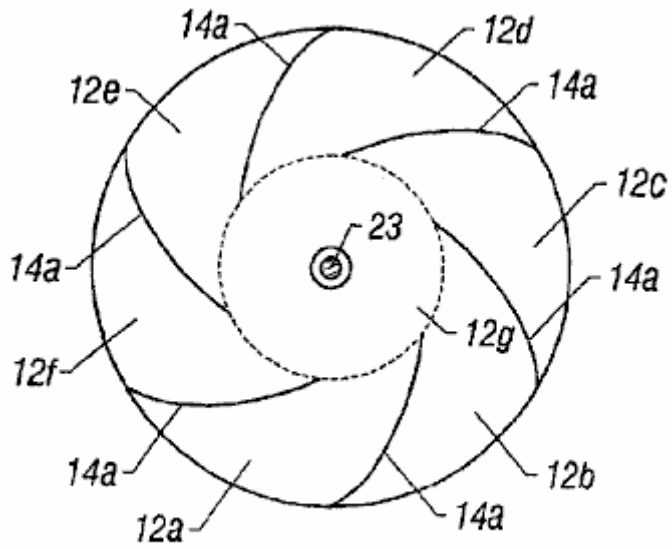

FIG. 9

Fig.9 is a horizontal cross-sectional view of the embodiment of **Fig.1** taken along line **9** — **9** of **Fig.8**. In this view, it can be seen that the upstream annular chamber **12** is divided into a set of smaller chambers **12a** through **12f** by the toroidal longitudinal baffles **14a**. The interior ends of the longitudinal baffles define a central vortex chamber **12g** (illustrated by a dashed circle) in which the upstream vortex is formed, and from which the upstream vortex enters the turbine **22**. The central vortex chamber **12g** has a diameter approximately equal to the diameter of the turbine.

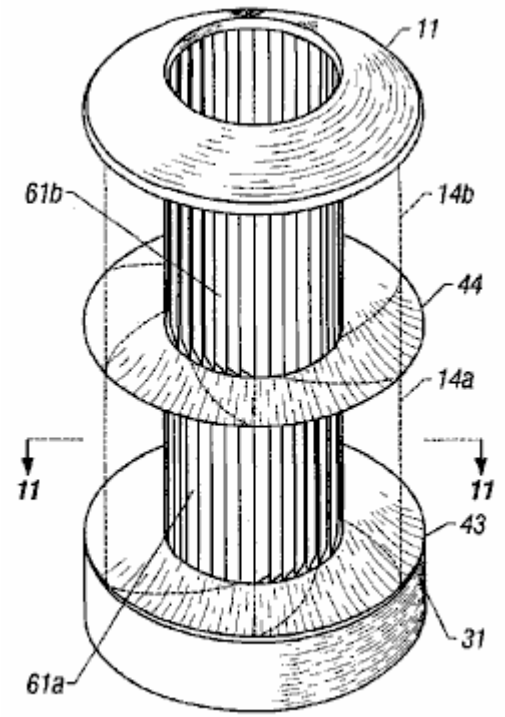

FIG. 10

Fig.10 is a perspective view of a second embodiment of the present invention that converts wind energy to mechanical or electrical energy, with the longitudinal baffles **14a** and **14b** drawn in phantom so that a set of hinged longitudinal louvers **61a** and **61b** can be seen. The hinged louvers are mounted in the openings between the longitudinal baffles. The louvers may be mounted in a circular configuration anywhere from the outside edge of the longitudinal baffles to the inside edge of the baffles. In the version shown, the louvers are longitudinally mounted at the inside edge of the baffles, around the perimeter of the central vortex chamber **12g**. Each of the louvers is hinged on one side (i.e., the windward side as wind enters through the baffles) so that the louver may be opened toward the central vortex chamber by the force of the incoming wind. The width of each louver is slightly greater than the distance between louvers so that each louver slightly overlaps the hinged edge of the next louver. This prevents the louvers from opening outward.

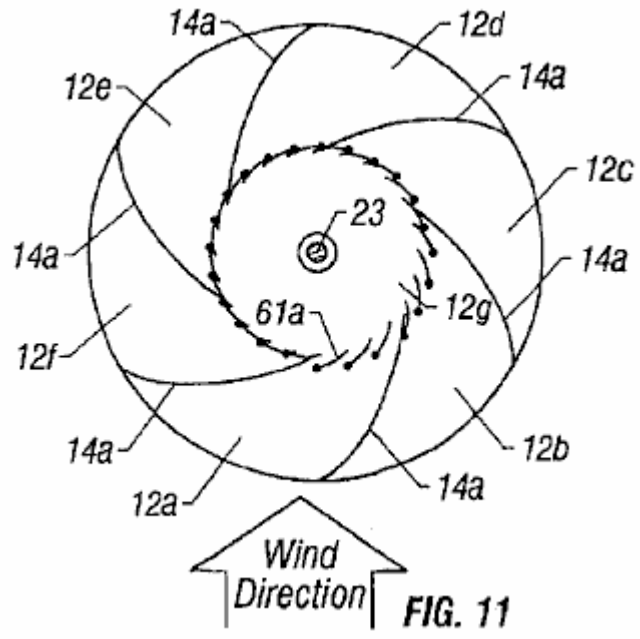

FIG. 11

In **Fig.11** there is shown a horizontal cross-sectional view of the embodiment of **Fig.10** taken along line **11** — **11**. During operation, wind blowing in the direction shown from the outside of the energy conversion device is funnelled by the toroidal longitudinal baffles **14a** into upstream chambers **12a** and **12b**. The baffles block the wind from entering the other chambers **12c** through **12f**. The wind flows through chambers **12a** and **12b**, and enters

the central vortex chamber **12g** by opening the hinged longitudinal louvers **61a** which are mounted between the baffles in the openings defining chambers **12a** and **12b**. The remaining louvers remain closed, preventing the wind from exiting through the sides of the device. Thus, the wind-activated louvers are, in effect, one-way valves allowing the wind to flow into the central vortex chamber through the sides of the device, but only allowing the wind to exit through the top of the chamber, and through the turbine **22**.

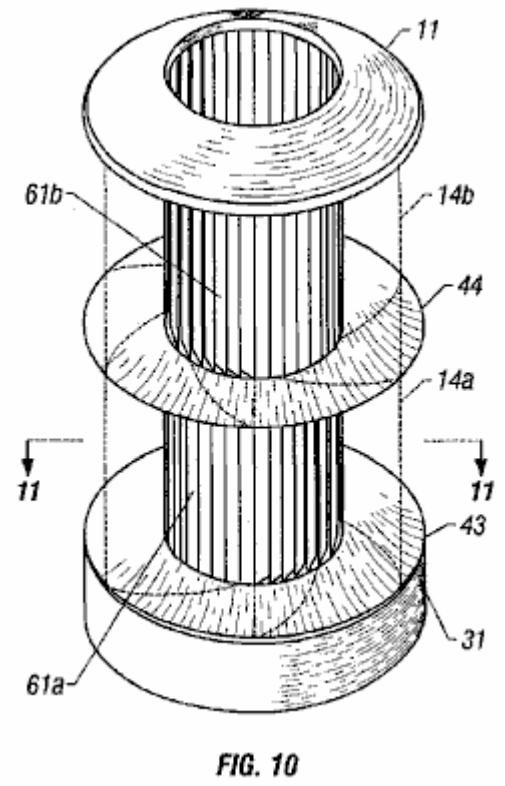

FIG. 10

Referring again to **Fig.10**, it can be seen that the longitudinal louvers **61a** mounted in the upstream chamber **12** are hinged on the opposite side from the louvers **61b** mounted in the downstream chamber **13**. This is because the vortex in the downstream chamber rotates in the opposite direction from the vortex in the upstream chamber, and the downstream toroidal baffles **14b** funnel the wind into the louvers **61b** in the opposite direction. Like the louvers **61a** in the upstream chamber **12**, the louvers **61b** in the downstream chamber **13** act as one-way valves allowing the wind to flow into the central vortex chamber through the sides of the device, but only allowing the wind to exit through the top of the chamber, and out of the device. This configuration helps to maintain the strength of both the upstream and the downstream vortices during operation of the device.

It should be recognized that some degree of improved energy-conversion performance may be obtained in a configuration in which there are toroidal baffles **14a** and hinged louvers **61a** only in the upstream annular chamber **12** because this ensures that all of the wind or other fluid entering the sides of the upstream chamber flows through the turbine. The addition of toroidal baffles **14b** in the downstream annular chamber **13** provides additional improved performance, particularly when the direction of rotation of the downstream vortex is opposite the direction of the upstream vortex. Optimum energy-conversion performance is provided by a device having oppositely configured toroidal baffles **14a** and **14b**, and oppositely hinged louvers **61a** and **61b**, for both the upstream annular chamber **12** and the downstream annular chamber **13**.

It is to be understood that even though numerous characteristics and advantages of the present invention have been set forth in the foregoing description, the disclosure is illustrative only, and changes may be made in detail, especially in matters of size, shape, and arrangement of parts within the principles of the invention to the full extent indicated by the broad general meaning of the terms in which the appended claims are expressed.

Claims:

What is claimed is:

1. A fluid-powered energy conversion device for converting energy in a moving fluid into mechanical energy, said device comprising: a rigid cylindrical frame having an upstream annular chamber and a downstream annular chamber, each of said chambers having sides that are open to allow entry of the moving fluid; a first set of baffles

longitudinally mounted in the upstream chamber that operate to create in the upstream chamber, an upstream drive vortex rotating in a first direction when the moving fluid enters the upstream chamber through the upstream chamber's open sides and through openings between the baffles; a first set of hinged louvers positioned in the openings between the first set of baffles and encircling an upstream central vortex chamber cantered around a central longitudinal axis of the device, said first set of louvers being operable to permit entry of the moving fluid into the upstream central vortex chamber only when the fluid is rotating in the first direction, and to prevent the fluid from exiting the upstream central vortex chamber through the sides of the device; a floor of the upstream annular chamber that slopes toward the downstream chamber as the floor approaches the central longitudinal axis of the device, said floor causing the drive vortex to flow downstream through the upstream central vortex chamber and pass through a central aperture located between the upstream annular chamber and the downstream annular chamber; a longitudinal drive shaft centrally mounted in the central aperture; and a turbine mounted on the drive shaft in the central aperture, said turbine being rotated by the drive vortex as the drive vortex passes through the central aperture.

2. The fluid-powered energy conversion device of claim 1 further comprising a second set of baffles longitudinally mounted in the downstream chamber that operate to create in the downstream chamber, a downstream extraction vortex rotating in a direction opposite to the first direction when the moving fluid enters the downstream chamber through the downstream chamber's open sides and through openings between the baffles, whereby the turbine is rotated by the drive vortex as the drive vortex passes through the turbine and reverses direction to match the direction of the extraction vortex.

3. The fluid-powered energy conversion device of claim 2 further comprising an annular central divider between the upstream chamber and the downstream chamber, said divider having a downstream surface that slopes downstream as it approaches the central longitudinal axis of the device, said downstream surface causing the extraction vortex to flow downstream, thereby creating an area of reduced fluid pressure downstream of the turbine.

4. The fluid-powered energy conversion device of claim 2 further comprising a second set of hinged louvers positioned in the openings between the second set of baffles and encircling a downstream central vortex chamber cantered around the central longitudinal axis of the device, said second set of louvers being operable to permit entry of the moving fluid into the downstream central vortex chamber only when the fluid is rotating in the direction opposite to the first direction, and to prevent the fluid from exiting the downstream central vortex chamber through the sides of the device.

5. The fluid-powered energy conversion device of claim 4 wherein said first set of baffles are curved to form a toroidal pattern in the first direction, and said second set of baffles are curved to form a toroidal pattern in the direction opposite to the first direction.

6. The fluid-powered energy conversion device of claim 5 wherein said turbine comprises a set of rotating blades, each of said blades having a cross-sectional shape of a curved airfoil that generates a lift force, said lift force being directed in the direction of rotation of the turbine.

7. The fluid-powered energy conversion device of claim 1 further comprising a flywheel mounted on the drive shaft, said flywheel having sufficient mass to operate as an internal energy storage device due to its angular momentum.

8. The fluid-powered energy conversion device of claim 7 wherein said flywheel is a permanent magnet.

9. The fluid-powered energy conversion device of claim 7 wherein said flywheel is a fluid-filled flywheel that rotates with the drive shaft in a direction of rotation, said fluid-filled flywheel comprising: a hollow disk-shaped shell filled with fluid; and a set of radial bulkheads that separate the interior of the shell into separate sections, each of said bulkheads having at least one gate pivotally mounted thereon to open in a direction opposite to the direction of rotation, said gate covering an aperture in the bulkhead when the gate is pivoted to a closed position, and said gate opening the aperture when the gate is pivoted to an open position; whereby the gates are opened by the fluid when the flywheel accelerates in the direction of rotation, thus allowing the fluid to flow through the apertures in the bulkheads and reduce start-up inertia of the flywheel, and whereby the gates are closed by the fluid when the flywheel decelerates, thus preventing the fluid from flowing through the apertures, and causing the flywheel to maintain angular momentum like a solid flywheel.

10. The fluid-powered energy conversion device of claim 9 wherein the hollow disk-shaped shell includes: an annular compartment filled with the fluid; and a cooling fan mounted in a central hub section of the shell.

11. The fluid-powered energy conversion device of claim 1 further comprising an electrical generator mounted on the drive shaft, said generator converting mechanical energy from the rotation of the shaft into electrical energy.

12. The fluid-powered energy conversion device of claim 11 further comprising a cooling fan mounted on the drive shaft, said cooling fan directing cooling air through the generator.

13. A wind-powered energy conversion device for converting wind energy into mechanical energy, said device comprising: a rigid cylindrical frame having an upstream annular chamber, a downstream annular chamber, and an annular central divider between the upstream chamber and the downstream chamber, each of said chambers having sides that are open to allow entry of ambient wind, and said annular central divider having a central aperture therein and having a downstream surface that slopes downstream as it approaches a central longitudinal axis of the device; a first set of baffles longitudinally mounted in the upstream chamber and curved to form a toroidal pattern that operates to create in an upstream central vortex chamber cantered around a central longitudinal axis of the device, an upstream drive vortex rotating in a first direction when the ambient wind enters the upstream chamber through the upstream chamber's open sides and through openings between the baffles; a first set of hinged louvers positioned in the openings between the first set of baffles and encircling the upstream central vortex chamber, said first set of louvers being operable to permit entry of the wind into the upstream central vortex chamber only when the wind is rotating in the first direction, and to prevent the wind from exiting the upstream central vortex chamber through the sides of the device; a second set of baffles longitudinally mounted in the downstream chamber and curved to form a toroidal pattern operable to create in a downstream central vortex chamber cantered around the central longitudinal axis of the device, a downstream extraction vortex rotating in a direction opposite to the first direction when the ambient wind enters the downstream chamber through the downstream chamber's open sides and through openings between the baffles; a second set of hinged louvers positioned in the openings between the second set of baffles and encircling the downstream central vortex chamber, said second set of louvers being operable to permit entry of the wind into the downstream central vortex chamber only when the wind is rotating in the direction opposite to the first direction, and to prevent the wind from exiting the downstream central vortex chamber through the sides of the device; a floor of the upstream annular chamber that slopes downstream as the floor approaches a central longitudinal axis of the device, said floor causing the drive vortex to flow downstream and pass through the central aperture in the annular central divider; a longitudinal drive shaft centrally mounted in the central aperture; and a turbine mounted on the drive shaft in the central aperture, said turbine comprising a set of rotating blades, each of said blades having a cross-sectional shape of a curved airfoil that generates a lift force, said lift force being directed in the direction of rotation of the turbine, said turbine being rotated by the drive vortex as the drive vortex passes through the turbine and reverses direction to match the direction of the extraction vortex.

14. The wind-powered energy conversion device of claim 13 further comprising a flywheel mounted on the drive shaft, said flywheel having sufficient mass to operate as an internal energy storage device due to its angular momentum.

15. The wind-powered energy conversion device of claim 13 further comprising an electrical generator mounted on the drive shaft, said generator converting mechanical energy from the rotation of the shaft into electrical energy.

16. The wind-powered energy conversion device of claim 13 wherein the extraction vortex rotates in a counter-cyclonic direction so that the extraction vortex dissipates after it exits the downstream chamber.

17. A wind-powered energy conversion device for converting high-speed wind energy into mechanical energy, said device comprising: a rigid cylindrical frame having an upstream annular chamber and a downstream annular chamber, each of said chambers having sides that are open to allow entry of the high-speed wind; a first set of baffles longitudinally mounted in the upstream chamber that create in an upstream central vortex chamber, an upstream drive vortex rotating in a first direction when the high-speed wind enters the upstream chamber through the upstream chamber's open sides and through openings between the baffles; a first set of hinged louvers positioned in the openings between the first set of baffles and encircling the upstream central vortex chamber, said first set of louvers being operable to permit entry of the wind into the upstream central vortex chamber only when the wind is rotating in the first direction, and to prevent the wind from exiting the upstream central vortex chamber through the sides of the device; a second set of baffles longitudinally mounted in the downstream chamber that create in a downstream central vortex chamber, a downstream extraction vortex rotating in the first direction when the high-speed wind enters the downstream chamber through the downstream chamber's open sides and through openings between the baffles; a second set of hinged louvers positioned in the openings between the second set of baffles and encircling the downstream central vortex chamber, said second set of louvers being operable to permit entry of the wind into the downstream central vortex chamber only when the wind is rotating in the first direction, and to prevent the wind from exiting the downstream central vortex chamber through the sides of the device; a floor of the upstream annular chamber that slopes downstream as the floor approaches a central longitudinal axis of the device, said floor causing the drive vortex to flow downstream and pass through a central aperture located between the upstream annular chamber and the downstream annular chamber; a longitudinal drive shaft centrally mounted in the central aperture; and a turbine mounted on the drive

shaft in the central aperture, said turbine being rotated by the drive vortex as the drive vortex passes through the turbine.

18. The wind-powered energy conversion device of claim 17 further comprising a fluid-filled flywheel mounted on the drive shaft that rotates with the drive shaft in a direction of rotation, said fluid-filled flywheel comprising: a hollow disk-shaped shell filled with fluid; and a set of radial bulkheads that separate the interior of the shell into separate sections, each of said bulkheads having at least one gate pivotally mounted thereon to open in a direction opposite to the direction of rotation, said gate covering an aperture in the bulkhead when the gate is pivoted to a closed position, and said gate opening the aperture when the gate is pivoted to an open position; whereby the gates are opened by the fluid when the flywheel accelerates in the direction of rotation, thus allowing the fluid to flow through the apertures in the bulkheads and reduce start-up inertia of the flywheel, and whereby the gates are closed by the fluid when the flywheel decelerates, thus preventing the fluid from flowing through the apertures, and causing the flywheel to maintain angular momentum like a solid flywheel.

19. A water-powered energy conversion device for converting energy in a moving stream of water into mechanical energy, said device comprising: a rigid cylindrical frame having an upstream annular chamber and a downstream annular chamber, each of said chambers having sides that are open to allow entry of the stream of water; a first set of baffles longitudinally mounted in the upstream chamber that create in an upstream central vortex chamber, an upstream drive vortex rotating in a first direction when the stream of water enters the upstream chamber through the upstream chamber's open sides and through openings between the baffles; a first set of hinged louvers positioned in the openings between the first set of baffles and encircling the upstream central vortex chamber, said first set of louvers being operable to permit entry of the water into the upstream central vortex chamber only when the water is rotating in the first direction, and to prevent the water from exiting the upstream central vortex chamber through the sides of the device; a second set of baffles longitudinally mounted in the downstream chamber that create in a downstream central vortex chamber, a downstream extraction vortex rotating in the first direction when the stream of water enters the downstream chamber through the downstream chamber's open sides and through openings between the baffles; a second set of hinged louvers positioned in the openings between the second set of baffles and encircling the downstream central vortex chamber, said second set of louvers being operable to permit entry of the water into the downstream central vortex chamber only when the water is rotating in the first direction, and to prevent the water from exiting the downstream central vortex chamber through the sides of the device; a floor of the upstream annular chamber that slopes downstream as the floor approaches a central longitudinal axis of the device, said floor causing the drive vortex to flow downstream and pass through a central aperture located between the upstream annular chamber and the downstream annular chamber; a longitudinal drive shaft centrally mounted in the central aperture; and a turbine mounted on the drive shaft in the central aperture, said turbine being rotated by the drive vortex as the drive vortex passes through the turbine.

20. The water-powered energy conversion device of claim 19 further comprising a fluid-filled flywheel mounted on the drive shaft that rotates with the drive shaft in a direction of rotation, said fluid-filled flywheel comprising: a hollow disk-shaped shell filled with fluid; and a set of radial bulkheads that separate the interior of the shell into separate sections, each of said bulkheads having at least one gate pivotally mounted thereon to open in a direction opposite to the direction of rotation, said gate covering an aperture in the bulkhead when the gate is pivoted to a closed position, and said gate opening the aperture when the gate is pivoted to an open position; whereby the gates are opened by the fluid when the flywheel accelerates in the direction of rotation, thus allowing the fluid to flow through the apertures in the bulkheads and reduce start-up inertia of the flywheel, and whereby the gates are closed by the fluid when the flywheel decelerates, thus preventing the fluid from flowing through the apertures, and causing the flywheel to maintain angular momentum like a solid flywheel.

21. A fluid-powered energy conversion device for converting energy in a moving fluid into mechanical energy, said device comprising: a rigid cylindrical frame having an upstream annular chamber and a downstream annular chamber cantered around a longitudinal axis, each of said chambers having sides that are open to allow entry of the moving fluid in a direction approximately perpendicular to the longitudinal axis, said upstream and downstream chambers being separated by an annular divider having a central aperture therein; a longitudinal drive shaft centrally mounted along the longitudinal axis and passing through the central aperture; a turbine mounted on the drive shaft in the central aperture; means for creating in the upstream chamber an upstream drive vortex rotating in a first direction when the moving fluid enters the upstream chamber through the upstream chamber's open sides: means for creating in the downstream chamber, a downstream extraction vortex rotating in a second direction opposite to the first direction when the moving fluid enters the downstream chamber through the downstream chamber's open sides; end means for causing the drive vortex to flow downstream and pass through the turbine, said turbine being rotated by the drive vortex as the drive vortex passes through the turbine and reverses direction to match the direction of the extraction vortex.

22. The fluid-powered energy conversion device of claim 21 wherein the means for creating an upstream drive vortex in the upstream chamber includes a first set of longitudinally mounted baffles having openings between

them through which the moving fluid enters the upstream chamber, said first set of baffles being curved to form a toroidal pattern in the first direction.

23. The fluid-powered energy conversion device of claim 22 wherein the means for creating an upstream drive vortex in the upstream chamber includes a first set of hinged louvers positioned in the openings between the first set of baffles and encircling the upstream chamber, said first set of louvers being operable to permit entry of the moving fluid into the upstream chamber only when the fluid is rotating in the first direction, and to prevent the fluid from exiting the upstream chamber through the sides of the device.

24. The fluid-powered energy conversion device of claim 23 wherein the means for creating a downstream extraction vortex in the downstream chamber includes a second set of longitudinally mounted baffles having openings between them through which the moving fluid enters the upstream chamber, said second set of baffles being curved to form a toroidal pattern in the second direction.

25. The fluid-powered energy conversion device of claim 24 wherein the means for creating a downstream extraction vortex in the downstream chamber includes a second set of hinged louvers positioned in the openings between the second set of baffles and encircling the downstream chamber, said second set of louvers being operable to permit entry of the moving fluid into the downstream chamber only when the fluid is rotating in the second direction, and to prevent the fluid from exiting the downstream chamber through the sides of the device.

26. The fluid-powered energy conversion device of claim 25 wherein the means for causing the drive vortex to flow downstream includes means for creating a pressure differential in which the fluid pressure in the downstream chamber is less than the fluid pressure in the upstream chamber.

27. The fluid-powered energy conversion device of claim 26 wherein the means for creating a pressure differential includes a downstream surface of the annular divider that slopes downstream as it approaches the central longitudinal axis of the device, said downstream surface causing the extraction vortex to flow downstream, thereby creating an area of reduced fluid pressure downstream of the turbine.

28. The fluid-powered energy conversion device of claim 27 wherein the means for causing the drive vortex to flow downstream includes a floor of the upstream annular chamber that slopes toward the downstream chamber as the floor approaches the central longitudinal axis of the device, said floor causing the drive vortex to flow downstream and pass through the turbine.

29. The fluid-powered energy conversion device of claim 21 further comprising a fluid-filled flywheel that rotates with the drive shaft in a direction of rotation, said fluid-filled flywheel comprising: a hollow disk-shaped shell filled with fluid: and a set of radial bulkheads that separate the interior of the shell into separate sections, each of said bulkheads having at least one gate pivotally mounted thereon to open in a direction opposite to the direction of rotation, said gate covering an aperture in the bulkhead when the gate is pivoted to a closed position, and said gate opening the aperture when the gate is pivoted to an open position; whereby the gates are opened by the fluid when the flywheel accelerates in the direction of rotation, thus allowing the fluid to flow through the apertures in the bulkheads and reduce start-up inertia of the flywheel, and whereby the gates are closed by the fluid when the flywheel decelerates, thus preventing the fluid from flowing through the apertures, and causing the flywheel to maintain angular momentum like a solid flywheel.

ELECTRIC ENERGY GENERATION SYSTEM WITH FEEDBACK

Note: These three patents are in Portuguese and what is shown here is a low-quality attempt at translation into English using a translation program. The originals can be downloaded free from: http://worldwide.espacenet.com/singleLineSearch?locale=en_EP.

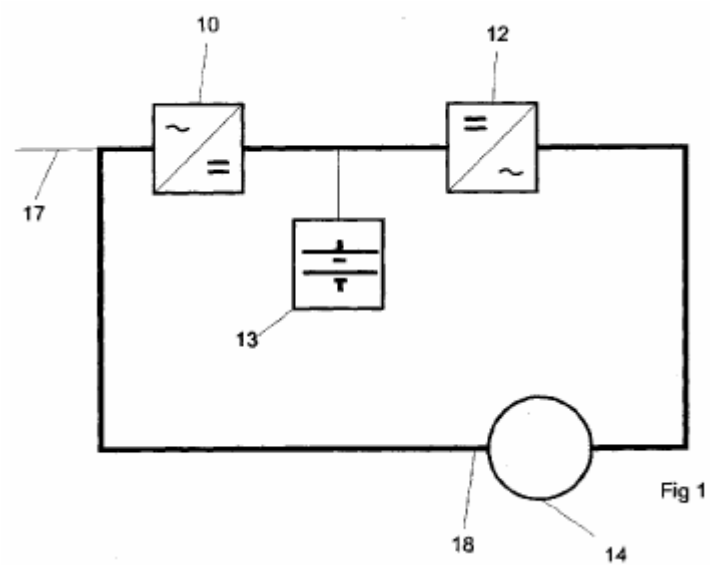

Fig 1

Abstract:
The present invention relates to electric energy generation equipment comprising a basic circuit formed by a rectifier (**10**), for example, an AC/DC converter connected in series to an inverter (**12**), for example, a DC/AC converter, and a bank of batteries (**13**) connected in series between the rectifier (**10**) and the inverter (**12**). An electron-capturing element (**14**), which can be either a free space electron-capturing element or, alternatively, an earth electron-capturing element, is connected in series to the basic circuit formed by the rectifier (**10**), the inverter (**12**) and the battery assembly (**13**). The bank of batteries (**13**) powers the basic circuit because it is connected to the system. Consequently, the inverter (**12**) converts direct current into alternating current and supplies this current to the electron-capturing element (**14**). After receiving the electric current from the inverter (**12**), the electron-capturing element (**14**) starts capturing electrons from the alternating current and powering the rectifier (**10**), which converts the alternating current into a direct current in order to recharge the bank of batteries (**13**) and power the inverter (**12**) which powers the electron-capturing element, closing the feedback loop, and also providing electric energy for consumption by external loads.

SELF-POWERED ELECTRICITY GENERATOR.

Technical field
The present invention relates to a device for generating electricity, in particular self-powered equipment for generating electricity.

Description of the Related Art
There are many methods for generating electricity using electromagnetism, but all of these are electromechanical devices using magnets and have limited generating capacity and an ecological impact which makes them unsuited to large scale projects.

Objectives of the Invention

The aim of this invention is the sustainable generation of electricity, using a generator which is able to produce large amounts of electricity from an extremely low input current, which initially is supplied by a bank of batteries, but subsequently is supplied by the output from the generator which is also able to power external loads.

The above objective, and other objectives, are achieved by the present invention through the use of a typical Uninterruptible Power Supply circuit comprising of an AC/DC rectifier feeding a battery bank which powers a DC/AC inverter, which is connected to a device to trap electrons from space (as described in Brazilian patent application No. BR1020120008378 of 13th January 2012) or alternatively, a device which extracts electrons from the Earth (as described in Brazilian patent application No. BR1020120008386 of 13th January 2012), which then passes the extracted electrons to the AC/DC rectifier, charging the battery bank, thus closing the loop as well as providing electricity to power external loads.

The self-powered system for generating electricity from the present invention can be fixed or mobile. It is fixed when using electron capture from the earth due to the ground connection, or mobile when using electron capture from space.

The self-powered electricity generating system of this invention may be configured in several different ways, each using the same inventive concept but using different arrangements of components. Different versions include single-phase, two-phase or three-phase versions, producing outputs of any power and voltage.

Brief Description of the Drawings

The present invention will now be described with the aid of drawings, but this patent is not limited to the versions and details shown in these drawings, although they show additional details and advantages of the present invention.

The drawings:

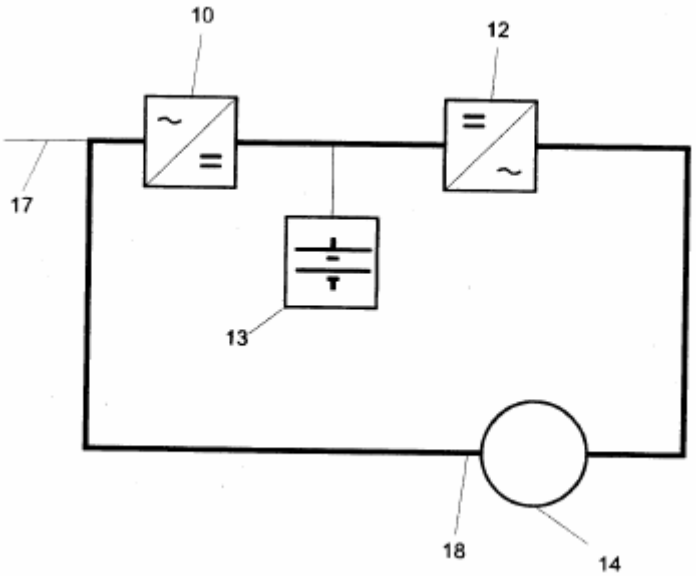

Figure 1 - shows a basic circuit system for self-powered electricity generation of the present invention

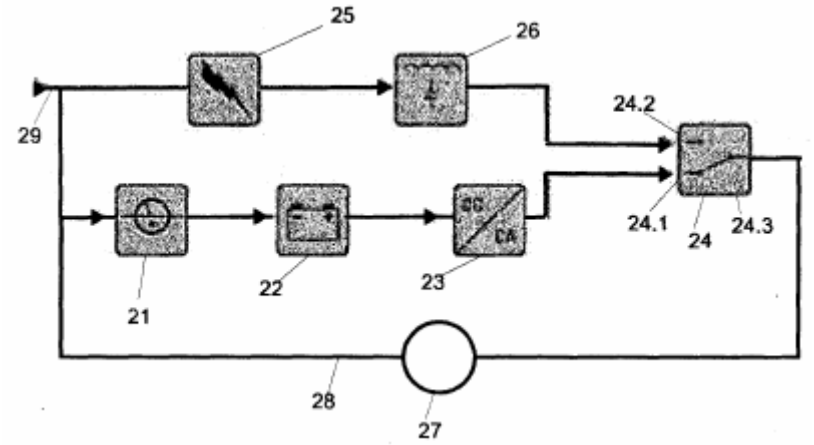

Figure 2 - shows a first embodiment of the constructive system for self-powered electricity generation of the present invention;

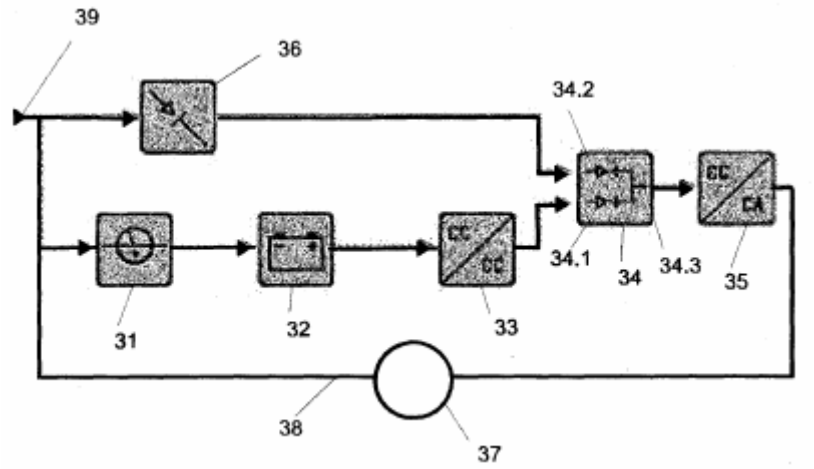

Figure 3 - shows a second embodiment of the self-powered system for generating electricity of the present invention;

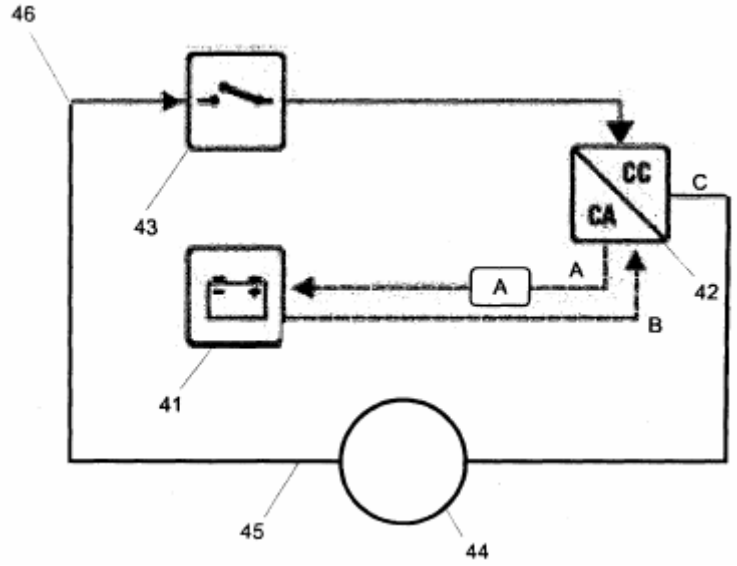

Figure 4 - shows a third embodiment of the self-powered system for generating electricity of the present invention;

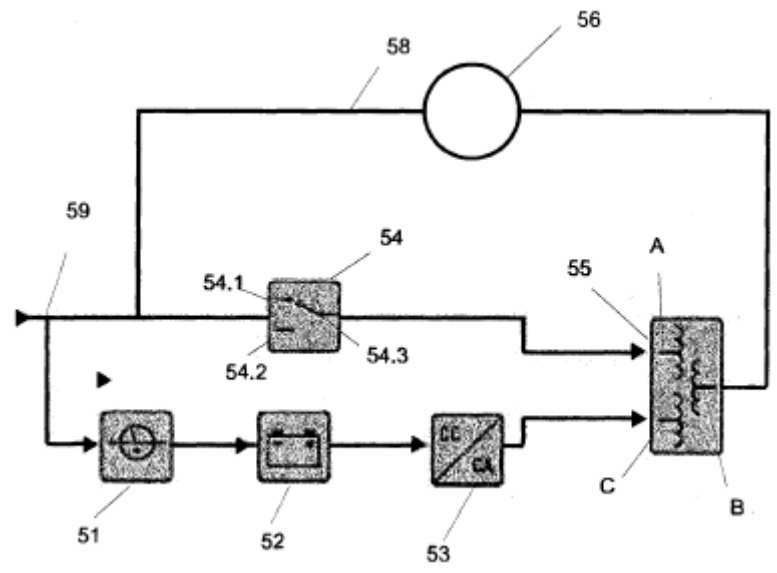

Figure 5 - shows a fourth embodiment of the self-powered system for generating electricity of the present invention;

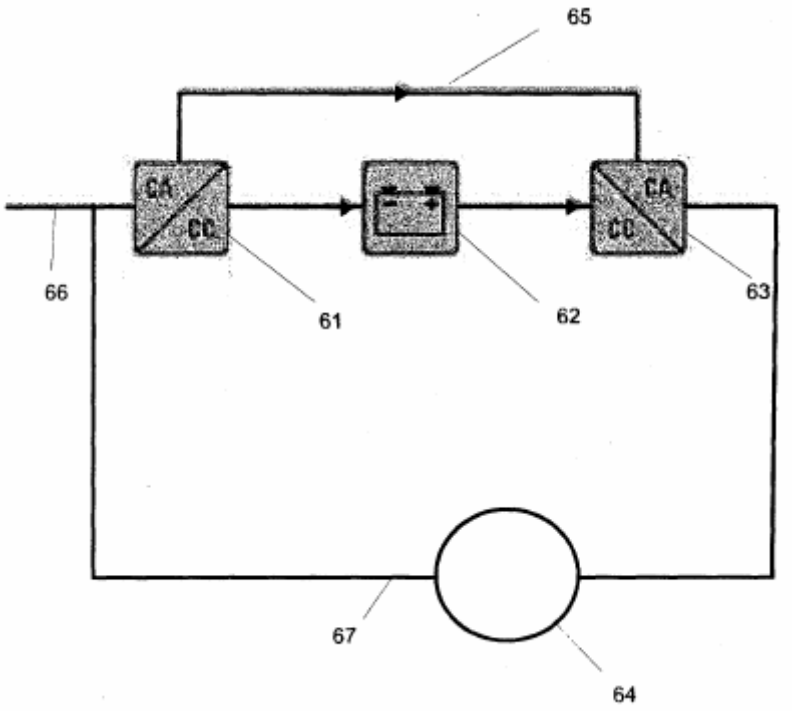

Figure 6 - shows a fifth embodiment of the self-powered system for generating electricity of the present invention;

Detailed description of the Invention:
There are different ways of closing the self-feeding cycle depending on the circuit configuration chosen. Some of these arrangements are shown in **Figures 2** to **6**, wherein the main circuitry continues to oscillate, continuously generating instant electricity.

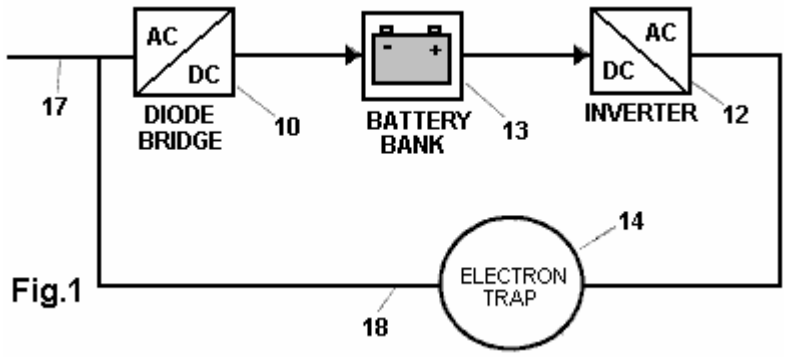

Fig.1

As shown in **Fig.1**, the self-powered system for generating electricity comprises a basic circuit consisting of a rectifier (AC/DC converter) **10** which is connected in series to an inverter (DC/AC) **12**. A bank of batteries **13** is connected between the rectifier **10** and the inverter **12**. The output from the DC/AC inverter **12**, connects to an electron-trap **14** which can extract electrons from space (as described in Brazilian patent application No. BR1020120008378 of 13th January 2012) or alternatively, extracts electrons from the Earth (as described in Brazilian patent application No. BR1020120008386 of 13th January 2012).

When connected, the battery bank **13** provides power to the DC/AC inverter **12** which converts the direct current into alternating current and provides current to the electron-trap **14**. The output of the electron trap **14** is passed through wire **18**, to the AC/DC bridge rectifier **10**, which keeps the battery bank charged as well as powering the DC/AC inverter **12**. Additional power is passed to external equipment through wire **17**.

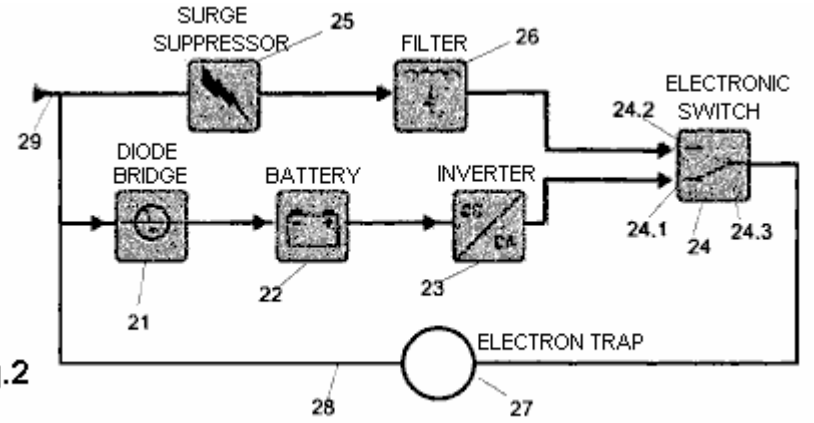

Fig.2

Fig.2, shows another embodiment of the system of this self-powered electric power generation equipment. It comprises a typical Uninterruptible Power Supply circuit of a battery charger (AC/DC converter) **21** connected to a drive device (a DC/AC inverter) **23** and between them, a battery bank **22** forming the basic circuit. Additional devices are an electron-trap **27** which may collect free electrons from space (as defined in Brazilian patent application No. BR1020120008378 of 13th January 2012) or, alternatively, collects electrons from the Earth (as described in Brazilian patent application No. BR1020120008386 of 13th January 2012). The 3-phase electronic switch **24** normally connects **24.1** to **24.3** connecting the electron trap **27** to inverter **23**. Connected in parallel is the surge suppressor **25**, which, when activated, via filter **26**, causes switch **24** to disconnect the **24.3** to **24.1** link and instead, connect **24.3** to **24.2**.

An alternative arrangement for use in emergency situations, is to use the system no longer self-powered. For this, the system is comprised of a power input from an external power source, directly to the interconnection point **29** to provide power to surge suppressor **25**, which provides power to feed the power output point **28** in order to power external loads. When the electron-trap **27** is turned off, the electronic transfer switch **24** reverts to its default position which connects point **24.1** to point **24.3** causing the circuit to function, once again, in its self-feeding mode. As soon as the electron sensor **27** provides sufficient power to the over-voltage sensor **25**, it operates the transfer switch **24** through filter **26**, ending the self-feeding phase and supplying energy directly to the power output point **28**, in order to feed external loads.

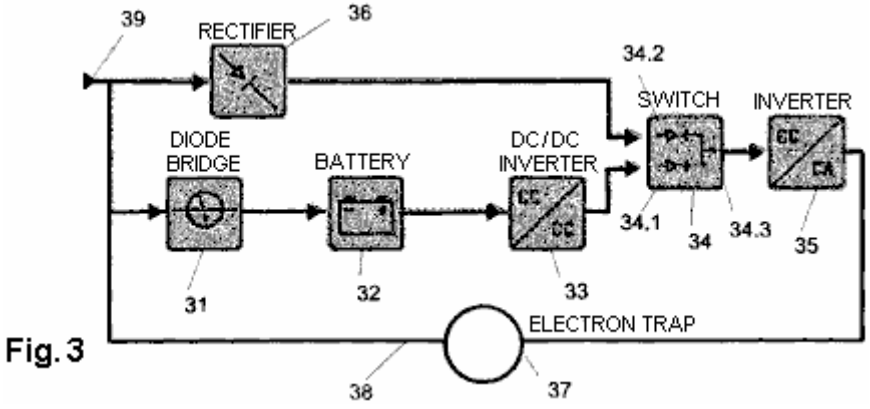

Fig. 3

Fig.3 shows another embodiment of the self-powered system for generating electricity, comprising a device which includes the basic circuit of a typical Uninterruptible Power Supply, consisting of a battery charger (AC/DC converter) **31** connected to a drive device (inverter DC/AC) **35** and attached to them, a battery bank **32**. This basic circuit together with other devices is connected to an electron-trap **37** for collecting free electrons from surrounding space or, alternatively, an Earth-connected electron trap **37**. We have then, a bank of batteries **32** connected to the DC/DC converter **33**, which is connected to the phase transfer switch **34 / 34.1** which is connected to point **34.3**, which connects to the inverter **35**, and so, the electron-trap **37**.

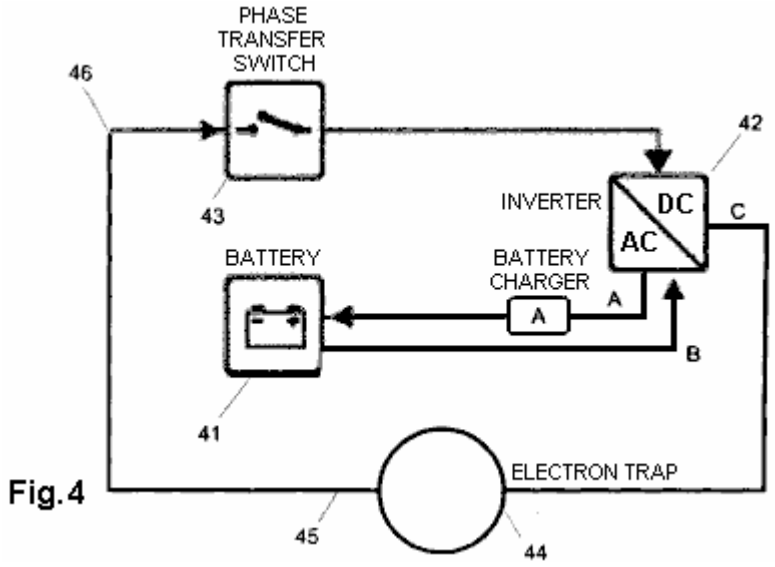

Fig. 4

Fig.4 shows another embodiment of the system for self-powered electricity generation which is comprised of a basic circuit of a typical uninterruptible power supply, consisting of a battery charger (AC/DC converter) **A** connected to an inverter (DC/AC) **42** and attached to them, battery bank **41**, and this basic circuit together with other devices are connected to a free space electron-capture device **44** or an earth-connection electron-trap **44**. Comprising thus, a battery charger **A** connected to a battery bank **41**, which is connected in series with inverter **42** at point **B** which is in series with point **C** of inverter **42** which is in series with the electron sensor **44**, which is in series with the phase transfer switch **43** via the three-phase load output connection point **45**. The phase transfer switch **43** is in series with the inverter **42**, which is connected in series the (AC/DC converter) battery charger **A** feeding the battery bank **41**.

An alternative construction for use in emergency situations, in which the system ceases to be self-powered, the system may include power input from an external power source, via the interconnection point **46**, thus providing electricity output **45**, to power external loads. The battery bank **41** provides power to the inverter **42** which converts the direct current into alternating current and feeds the electron trap **44**. The phase transfer switch closes when the batteries need recharging.

Sensor **44** captures electrons, producing alternating current, which feeds the phase transfer switch **43** with alternating current input power. The phase transfer switch **43** feeds the inverter **42** which charges the batteries, closing the self-powering loop which provides power at the output **45**, feeding both the power input and any external loads.

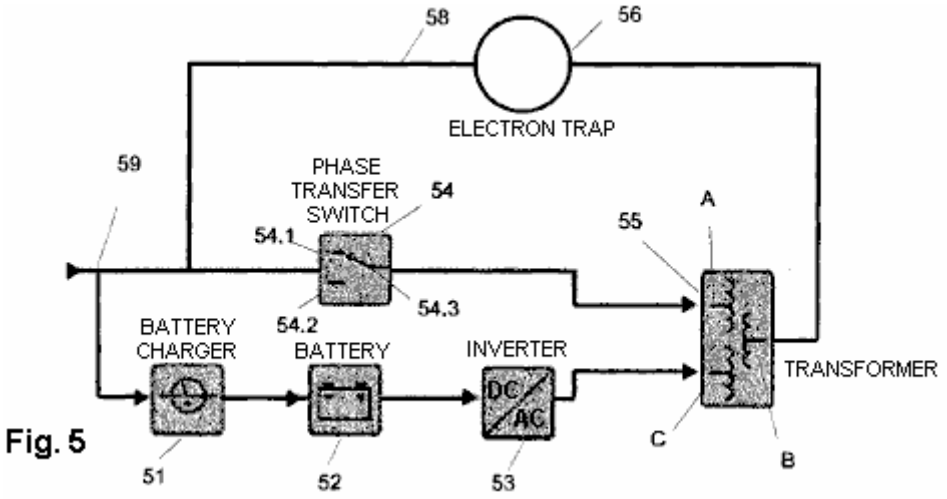

Fig. 5

Fig.5 shows another embodiment of the system for self-powered electric power generation equipment comprising a circuit which includes a typical uninterruptible power supply comprising a battery charger (AC/DC converter) **51** connected to a DC/AC inverter **53** and attached to them, a battery bank **52**. This basic circuit together with other devices are connected to a space free-electron capture device **56** (as defined in Brazilian patent application No. BR1020120008378 of 13/1/12) or, alternatively, an earthed free-electron collector **56** (as defined in Brazilian patent application No. BR1020120008386 of 13/1/12). This then comprises a battery charger **51** which is connected in series with a battery bank **52**, which is connected in series with the inverter **53**, which is connected in series with the transformer **55** at its point **C**, which is in series with its point **B** which is in series with the electron collector **56**, which is in series with the battery charger **51** which is connected to the load exit point **58**, which is also the circuit entry point **59**, which is in series with the phase transfer switch **54** section **54.1**, which is connected to terminal **54.3**, which is in series with point **A** of the transformer **55** which exits at point **B**. Points **A** and **54.3** as well as the parallel points **54.1** and **54.2**, are all parallel to the battery charger **51**, the battery bank **52**, the inverter **53** and to point **C** of the transformer **55**.

An alternative construction for use in emergency situations, in which the system ceases to be self-powered, the system may include an external power input point **59**, allowing phase transfer switch **54** to provide power output **58**, to feed external loads. Battery bank **52** provides power to the inverter **53**, which converts the direct current into alternating current, feeding point **C** of the transformer, which comes out at points **B** and **A** of the transformer **55**. Point **B** of the transformer feeds the electron-trap **56** producing alternating current which feeds the battery charger **51**, recharging the battery bank **52**.

The battery charger **51** is connected in parallel with the transfer switch **54** via connection points **54.1** and **54.3**, feeding point **A** of the transformer, which comes out at point **B**. Point **A** of the transformer and the switch transfer points **54.3** and **54.1** are in parallel to the battery charger **51**, the battery **52**, the inverter **53** and point **C** of the transformer **55**.

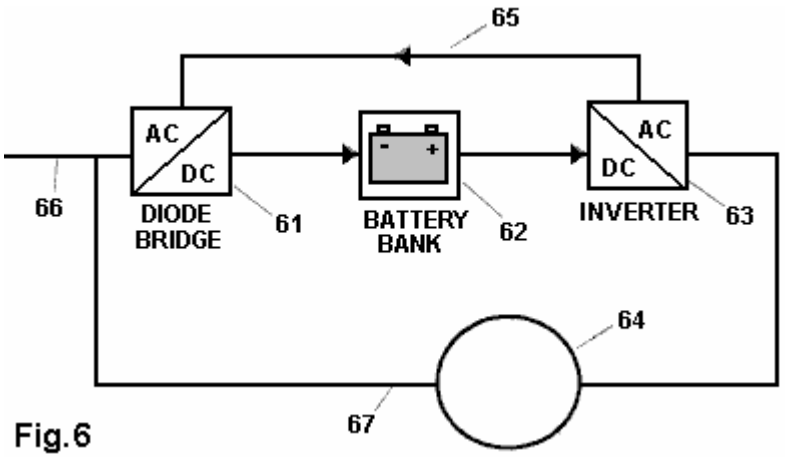

Fig.6

Fig.6 shows another embodiment where a rectifier **61** is connected to an inverter **63** and a battery bank **62**, and to a space free-electron trap **64** or alternatively, an earth electron trap **64** comprising thus, a delta (AC/DC) converter **61**, which is connected in series to a battery bank **62**, which is connected in series with the (DC/AC)

inverter **63**, which is in series with the electron collector **64** which is connected in series with the delta converter (AC/DC) **61** whose AC part is in series with the alternating AC current inverter **63** via a connecting wire **65** which is in parallel with the DC part of the delta converter **61** with the battery bank **62** and the DC part of inverter **63**. An alternative construction for use in emergency situations, in which the system ceases to be self-powered, the system may comprise a power input from an external power source, via the interconnection point **66** connected to the delta converter **61**, the output **67** supplying power, to the external loads.

Battery bank **62** provides power to the inverter **63**, which converts the direct current into alternating current, powering the free-electron collector **64**. The captured electrons from collector **64** form an alternating current which feeds the delta converter **61** via an output power load wire **67**.

The alternating part of the three-phase delta converter **61** is fed with alternating current from inverter **63** via connecting wire **65**, which is connected in parallel to the continuous DC delta converter **61**, which feeds the battery bank **62** and with the continuous portion the inverter **63**, closing the cycle of self-feeding and supplying power at the output **67**, which is the output power point.

Having described examples of preferred embodiments, it should be understood that the scope of the present invention encompasses other possible forms of construction, using the electron collectors connected to a basic circuit of a typical uninterruptible power supply of energy, known as a UPS, comprising a rectifier device (an AC/DC converter) **10**, connected to one inverter (DC/AC converter) **12**, and attached between them, an energy storage device (typically, a battery bank).

A very important part of the above patent is the device described as a “collector of free-electrons”, either from the earth or from space. We have to go to the patent applications mentioned above to find the details of these designs:

ELECTROMAGNETIC ELECTRON TRAP FOR ELECTRIC POWER GENERATION

Technical Field

The present invention refers to electromagnetic equipment for electric power generation or alternatively for thermal power generation. More specifically equipment capable of producing abundant electricity and thermal energy from a tiny amount of input electrical energy

Description of the Related Art

According to Lenz's law, any induced current has a direction such that the magnetic field it generates opposes the change in magnetic flux which produced it. Mathematically, Lenz's Law is expressed by the negative sign (-) that appears in the formula of Faraday's Law, as follows.

The magnitude of the induced emf (ε) in a conducting loop is equal to the rate of change of magnetic flux (Φ_B) with time:

$$\varepsilon = -\frac{d\Phi_B}{dt} \qquad \text{Equation 1}$$

As an example of application of Faraday's Law, we can calculate the electromotive force induced in a rectangular loop that moves in or out, with constant speed, a region of uniform magnetic field. The magnetic field flux through the surface limited by the loop is given by:

$$\phi = xLB \qquad \text{Equation 2}$$

and its variation in time:

$$\frac{\Delta\phi}{\Delta t} = \left(\frac{\Delta x}{\Delta t}\right)LB = vLB \qquad \text{Equation 3}$$

So:

$$\varepsilon = vLB \qquad \text{Equation 4}$$

and if the coil has a resistance (R) and the induced current:

$$i = \frac{\varepsilon}{R} = \frac{vLB}{R} \qquad \text{Equation 5}$$

A conductor traversed by an electric current immersed in a magnetic field undergoes the action of a force given by:

$$F = IL \times B \qquad \text{Equation 6}$$

Thus, the effect of the current induced in the loop appears as forces Ff, and F - FM. The first two cancel each other out and the third is cancelled by an external force P_{EXT} needed to maintain the constant speed loop.

As the force FM must oppose the force F_{EXT}, current (i) induced in the loop by varying the magnetic flux must have the meaning indicated in **Fig.3**. This fact is a particular example of Lenz's Law.

Considering the experimental activities discussed with Faraday's law, when a magnet approaches a coil, the induced current in the coil has a direction as shown in **Fig.1**. This generates a magnetic field whose north pole is facing the north pole of the magnet, that is, the field generated by the induced current opposes the motion of the magnet.

When the magnet is moved away from the coil, the current induced in the coil has a direction opposite to that shown in **Fig.1**, thereby generating a magnetic field whose south pole is facing the north pole of the magnet. The two poles attract each other, that is, the field generated by the induced current opposes the movement of the

magnet away from the coil. This behaviour is present in all current power generators, and known as ‘engine brake’ is highly undesirable as it increases the resistance and so, the energy loss.

When two electromagnetic coils are placed facing each other, as shown in **Fig.2**, there is no current in either of them. At the instant of power-up of one of the coils, the current in the coil, generates an induced current in the second coil. When powered up, the current in the coil goes from zero to its maximum value, and then remains constant.

Thus, when the current is changing, the magnetic field generated by it, (whose north pole faces the second coil) is also changing and so the magnetic flux of this field through the second coil is also changing. Then there is a current induced in the second coil whose sense is such that the magnetic field it generates tends to decrease the flow mentioned above, that is, its north pole confronts the north pole of the first field coil.

When the power switch is opened, the current in the first coil drops from its maximum value to zero, and correspondingly its magnetic field decreases. The flux of the magnetic field in the second coil also decreases, and the induced current now flows in the opposite direction. This current flow direction produces an enhancing magnetic field, that is, it has a south pole facing the north pole of the field of the first coil.

Thus, there is a realisation of the principle of conservation of energy, expressed by Lenz's law, wherein any induced current has an effect which opposes the cause that produced it. Assuming that the induced current acts to favour the variation of the magnetic flux that produced the magnetic field of the coil, it would have a south pole facing the north pole of the approaching magnet, causing the magnet to be attracted towards the coil.

If the magnet were then released, it would experience an acceleration toward the coil, increasing the intensity of the induced current and thus create an enhanced magnetic field. This field, in turn, would attract the magnet with increasing force, and so on, with a continuing increase in the kinetic energy of the magnet.

If energy were to be withdrawn from the magnet-coil system at the same rate at which the kinetic energy of the magnet increases, then there would be an endless supply of energy. So it would be a perpetually operating motor, which would violate the principle of conservation of energy. Therefore, it can be concluded that current generators feature a large energy loss during the generation of electricity.

Objectives of the Invention

An objective of the present invention is to contribute to the generation of sustainable energy, proposing an electromagnetic machine capable of producing abundant electricity from an extremely low input of electrical energy.

The above objective and other objectives are achieved by the present invention by a device comprised of at least one electromagnetic field-generating device (without a core or with at least one core) powered by an electrical power source (without a core or with at least one core) having their coils, or sets of coils, wound on at least one common conductive member in a closed circuit which itself has a polarised voltage which is connected to at least one conductive interconnection element which is connected to a grounding grid, these interconnections creating a new technical effect, namely, the appearance of an electric current which keeps circulating in a closed conductive loop, and which can therefore be used to power external loads.

The device which is the object of the present invention operates as follows: the electromagnetic field generating device, powered by a power source, produces an electromagnetic field which induces an electric current in a closed conductive circuit, creating an interaction between the magnetic poles of the equipment and the magnetic poles of the earth - through both electromagnetic attraction and repulsion. An endless supply of electrons is drawn from the earth into the conductive closed loop, which is connected to the ground through a conductive interconnected grid. Attracted electrons add to the current already flowing in the conductive closed loop, making power available for driving high-power loads, although the device itself is only supplied with a small amount of power. Thus, advantageously, the device which is the object of the present invention, acts as a trap for electrons from the earth and this allows the generation of electricity.

Advantageously, the present electromagnetic equipment generates either electricity or thermal energy, providing access to this new source of energy is through an electromagnetic field. The interconnections of the components of the electron-trap of the present invention, cause an advantageous new technical effect, namely, the appearance of an electric current which keeps circling in the conductive closed circuit, with or without voltage being applied and even without a load being connected to the loop - provided that the electron-trap is connected.

The proposed sensor can also be used to generate thermal power, depending on the form in which you want to use the effect of the flow of electrical current produced in this electromagnetic equipment.

For the generation of thermal energy in amounts proportional to the power of the electron-trap, through the movement of electrons in the conductive closed loop itself, the resistance should be increased by increasing the number of turns around the cores in the conductive element of the closed circuit, and in that instance, the coils of the electromagnetic field generating device, will then be made of heat-insulated electrical circuit components, bearing in mind the required temperature which is to be produced. The thermal energy generated by the electron-trap can be used in any application from domestic to industrial applications.

This technology can also be used for various technical purposes in electric machines. By "electrical machines", it should be understood to include: static electrical machines, transformers, ballasts, rotating electrical machines, synchronous machines, dual power supply machines, current rectifiers in synchronous cascade, external pole machines, synchronous current machines alternating current machines and/or direct current machines, electronic equipment and electrical resistances. The capture of electrons can provide single-phase, two-phase or three-phase supplies, operating at low, medium or high voltage.

The capture of electrons by induction, does not impact on the environment. The fact is that we use as the capturing force, only a negligible amount of electricity relative to the current captured by the sensor. The relationship between power input and the quantity of electricity generated by the electron-trap is at least 1 to 100, that is, for each 1 watt provided to the sensor, there is at least 100 watts of power available for external loads. This relationship, however, is not limited, as it depends on the mounting of the electron-trap and the objectives of the circuit, and so, the generated power can be greater than 100 times the input power.

Another advantage of the earthed electron- trap proposed in the present invention is that the electron-trap can transport electrons from point "A" to point "B" without a voltage drop across the closed-loop conductive element - if it is biased with a voltage - regardless of the distance between the points depending on the strength and quantity of the electromagnetic field generating devices. It is also possible to transport electrons when the conductive element in a closed circuit is itself not polarised. Thus, the electric current is transported without voltage, just by the magnetic field formed between the device and the generator of the electromagnetic field.

Brief description of the Drawings

The present invention will now be described with the aid of drawings, but the design is not limited to the implementations shown in these drawings, although they show other details and advantages of the present invention.

The figures show:

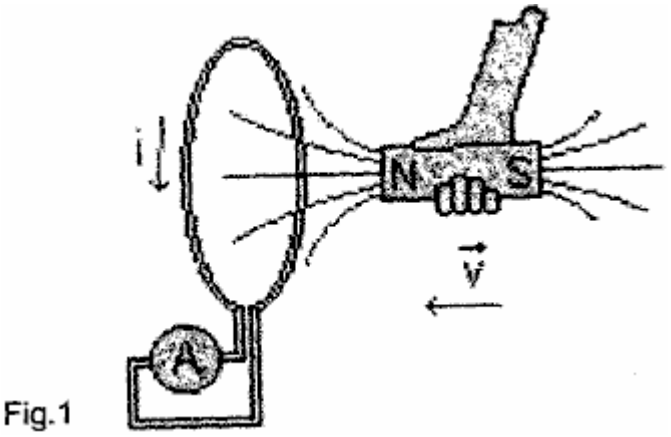

Fig.1

Detailed Description of the Drawings

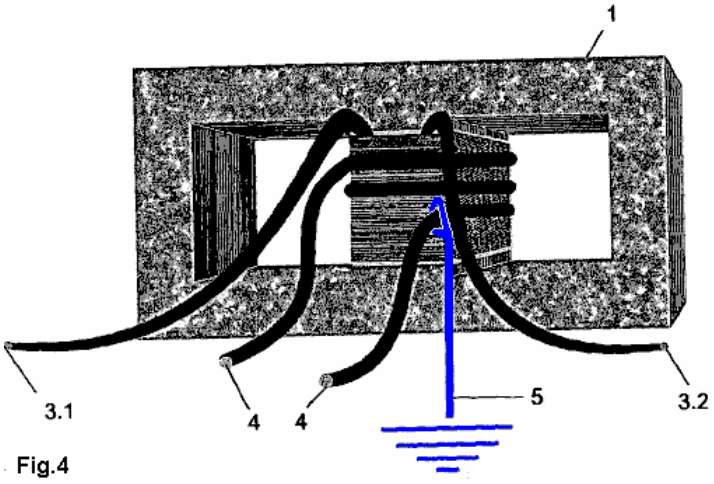

Fig.4 shows one of several types of electron-trap proposed by the present invention, where the electron-trap is single-phase and consists of at least one electromagnetic field-generating device with at least one set of coils, in this case it happens to be an electromagnetic type coil with one common magnetic core, but it could alternatively have any number of windings of any kind and shape. However, the electron-trap proposed by the present invention can be constructed with a different type of electromagnetic field generating device, such as an electromagnetic inductor or magnet of any type or shape, or any combination of them, and in unlimited numbers for each phase of the electron trap.

When winding these coils, for example, coil **4-4**, each coil must have at least one complete turn, preferably two turns if the objective is to generate electricity, and preferably four turns if the objective is provide thermal energy. The number of turns in the coils wound around the common core, is directly related to the amount of current to be generated.

At least one conductive interconnection element, in this case the driving member **5** - which can be copper or any other suitable conductive, material whether insulated or not insulated, connects or loop-links wire **4** to the ground grid. The connection between the conductor **5** and wire **4** is by electromagnetic induction. Winding **4** is also the power supply for the loads which are to be powered by the captured electrons.

Also in **Fig.4**, the power wires **3.1** and **3.2** (live phase and neutral) have an input from an external power coil **1** which can be energised from any external source of electricity such as a power grid. The trapped electrons can be configured to supply DC or AC current. Thus, if the coil **1** power source is alternating electrical current - AC, then the electron-trap provides alternating electrical current. If the power source is continuous electrical current - DC, then the electron-trap provides continuous electrical current - DC. The electrical supply provided by the trapped electrons can be single-phase, two-phase or three-phase, and at low, medium or high voltage.

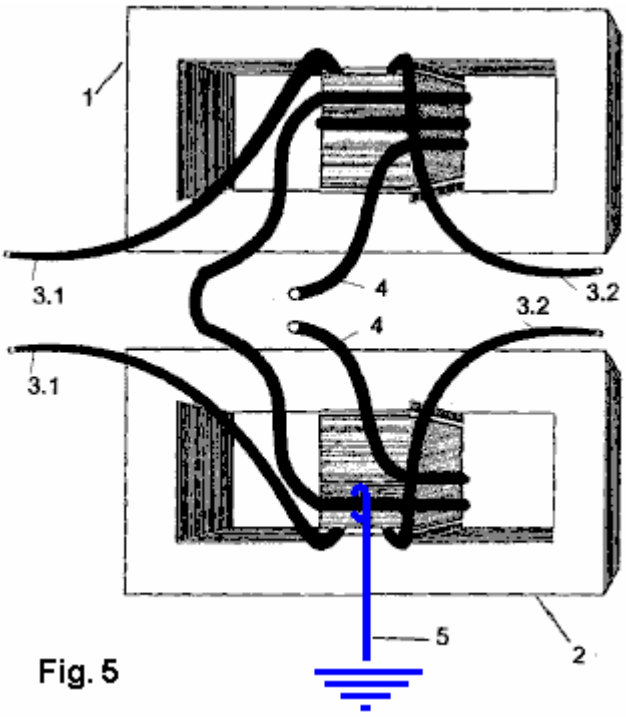

Fig. 5

Fig.5 shows an electron-trap with two single-core phase coils: **1** and **2**, although these coils may be of any type and shape. However, the electron-trap proposed by the present invention can be constructed with other types of electromagnetic field generating device, with at least one electromagnetic inductor or electromagnet which can be of any type and shape, with any combination of them, and in unlimited quantities in each phase of the electron-trap.

The coils on frames **1** and **2** may have other shapes, but they must each have at least one complete turn, particularly in coil **4**. The number of turns in this winding are directly related to the amount of current to be generated. This coil also makes the interconnection between the coils **1** and **2** forming the link between their two cores.

At least one conductive interconnection element, in this case the driving member **5** - which can be copper or any other suitable conductive, material whether insulated or not insulated, connects or loop-links wire **4** to the ground grid. The connection between the conductor **5** and wire **4** is by electromagnetic induction.

In electron-traps which have numerous sets of coils **1** and **2**, the ends of all of the power-supply conductors **3.1** can all be connected to each other, and all of the **3.2** conductor ends may be connected together. Thus, all of the coils **1** and **2** can be fed exactly the same voltage. The power to energise coils **1** and **2** can be provided from any external source of supply of electricity such as a power grid.

In electron-traps which have numerous coils **1** and **2**, a single coil winding **4** connects the cores of all of the coils **1** and **2**.

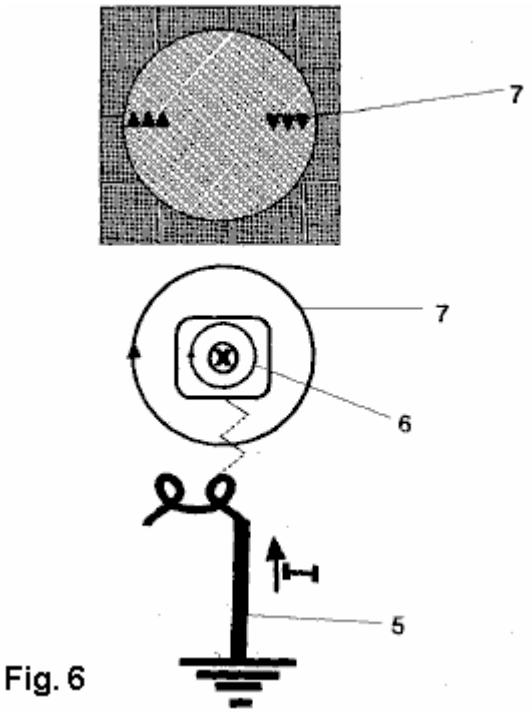

Fig. 6

The diagram shown in **Fig.6**, illustrates the magnetic induction **6** around the core "**X**" of the coil **1**. This induction causes electrical current flow in the conductor coil link **7/4**, attracting electrons from the earth, through the conductive member **5**, to the magnetic field of the electron-trap, where those electrons are added to the current generated by induction in the link coil **4** conductor loop circulating between north and south magnetic poles.

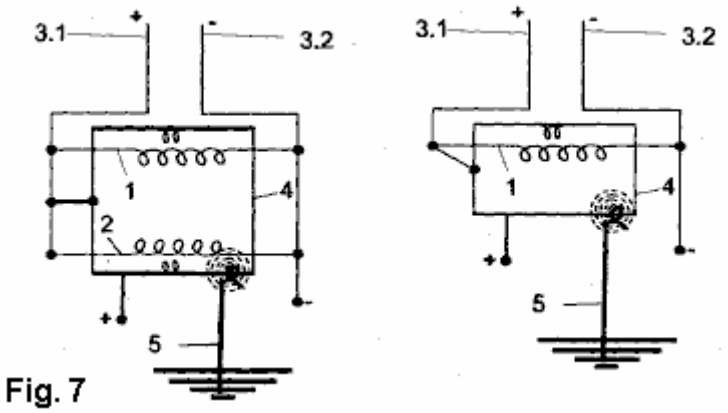

Fig. 7

Fig.7 shows how the connections should be made in one version of the electrical circuit of the electron-trap proposed in this invention. The diagram shows the electrical circuit of an electron-trap where the link/coil driver **4** is polarised with a voltage. This is one form of construction for an electron-trap which has two coils **1** and **2**, where a link/coil loop conductor **4** is biased with a voltage, that is, there is a link connecting the coil conductors **4** of a power supply **3.1** or **3.2**, whatever the stage.

In this way, earth electron-traps, by adopting this circuit, that is, with the link/conductor loop **4** and polarised voltage on coils **1** and **2**, besides being used as a power source for external loads, can also be used for thermal power generation.

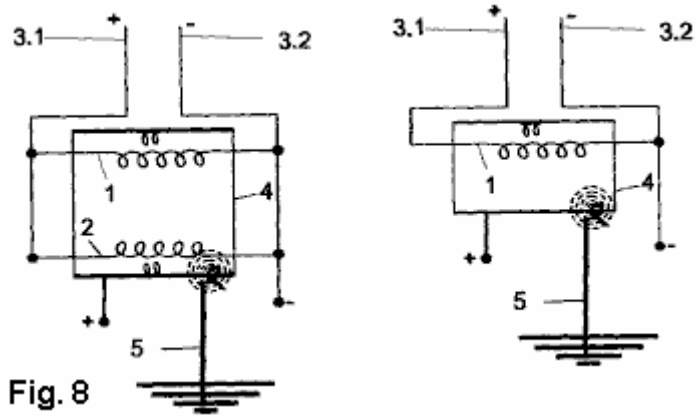

Fig. 8

Fig.8 shows how connections should be made in another electric circuit electron-trap proposed in this invention. the circuit illustrates a circuit of an electron-trap with a non-polarised link / coil driver **4**. This is one form of construction of the electron-trap where a link / coil conductor **4** of the spiral conductor coils **1** and **2** is not polarised, that is, there is no such link connecting conductor / conductor coil conductors **4** of a coil **3.1** or **3.2**.

Thus, earth electron-traps adopting this circuit, that is, with the link coil not polarised, the current flows without there being voltage in the link/coil conductor **4** joining the first and second coils by electromagnetic induction. They can also be used for generating thermal energy.

The structure of the circuit - in the open or closed coils **1** and **2**, and always in the closed link / loop lead **4** - makes it possible to generate current by induction and electron capture by electromagnetism on the link conductor **4** - where current is generated and stays in motion with or without voltage, as the coils **1** and **2** are being fed. Thus, the present invention provides a new concept for electrical energy generation, since it is obtained from an electric current circling without consumption and even without an output load being attached to it.

Additionally, because the induced electrical current flows regardless of the voltage present, it can be used as a current stabiliser for electrical networks whether they be single-phase, two-phase or three-phase, with low, medium or high voltage.

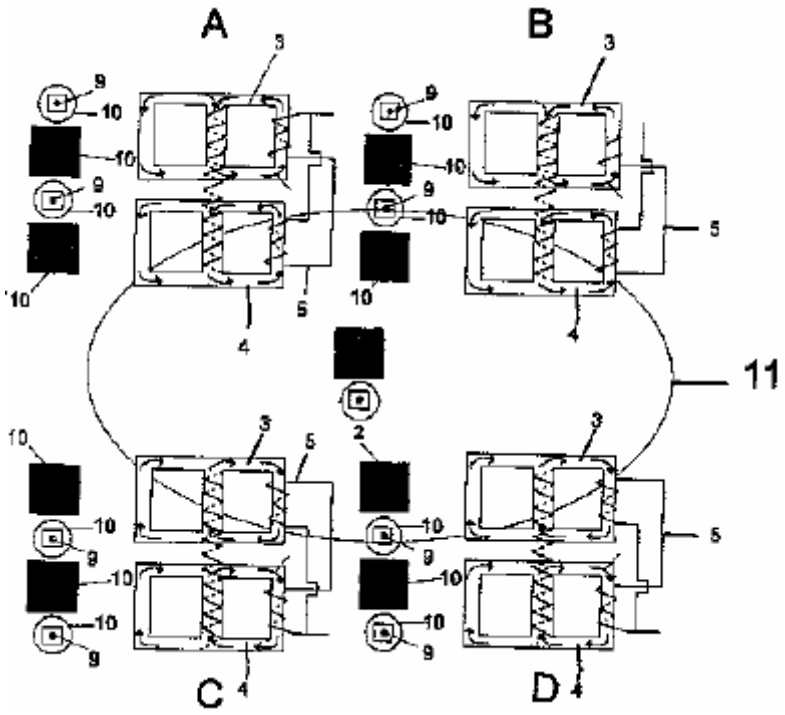
ELECTROMAGNETIC DEVICE FOR CAPTURING FREE SPACE ELECTRONS TO GENERATE ELECTRICITY

Application Number: BR2013/000014

Publication Date: 07/18/2013

Filing Date: 01/11/2013

Assignee: EVOLUÇÕES ENERGIA LTDA (Rua Santa Tereza 1427-B Centro - Imperatriz -, MA - CEP -470 - Maranhão, 65900, BR)



Abstract:

The invention relates to a device that comprises at least three sets (**A, B, C, D**) of at least one device for generating an electromagnetic field (**3**) and (**4**), powered by an electricity source (without a core or with at least one core) the cores thereof or any extension thereof, preferably the windings or sets of windings thereof, being surrounded by at least a single conductive element forming a polarised and energised closed-circuit (**5**), the sets of electromagnetic-field generating devices (**3**) and (**4**) being linked together by their opposing poles to encourage the interaction of their electromagnetic fields, which ideally, are located between two hollow metal hemispheres (**1**) so as to concentrate and enhance the electromagnetic fields, these interconnections causing, as a novel technical effect, the emergence of an electrical current that circulates, with or without voltage, in the conductive element forming a closed-circuit (**5**) - even if no load is connected.

Description:

"ELECTROMAGNETIC EQUIPMENT FOR FREE ELECTRON-CAPTURE FROM SPACE, FOR ELECTRICITY GENERATION".

Technical Field

The present invention relates to electromagnetic equipment for electrical power generation and/or thermal power generation. More specifically, equipment capable of producing abundant electricity and thermal energy from a tiny input of electrical energy.

Description of the Related Art

According to Lenz's law, any induced current has a direction such that the magnetic field it generates opposes the change in magnetic flux that produced it. Mathematically, Lenz's Law is expressed by the negative sign (-) that appears in the formula of Faraday's Law, as follows.

The magnitude of the induced emf (ε) in a conducting loop is equal to the rate of change of magnetic flux (Φ_B) with time:

$$\varepsilon = -\frac{d\Phi_B}{dt} \qquad \text{Equation 1}$$

As an example of application of Faraday's Law, we can calculate the electromotive force induced in a rectangular loop that moves in or out, with constant speed, a region of uniform magnetic field. The magnetic field flux through the surface limited by the loop is given by:

$$\phi = xLB \qquad \text{Equation 2}$$

and its variation in time:

$$\frac{\Delta\phi}{\Delta t} = \left(\frac{\Delta x}{\Delta t}\right)LB = vLB \qquad \text{Equation 3}$$

So:

$$\varepsilon = vLB \qquad \text{Equation 4}$$

and if the coil has a resistance (R) and the induced current:

$$i = \frac{\varepsilon}{R} = \frac{vLB}{R} \qquad \text{Equation 5}$$

A conductor traversed by an electric current immersed in a magnetic field undergoes the action of a force given by:

$$F = I\vec{L} \times B \qquad \text{Equation 6}$$

Thus, the effect of the current induced in the loop appears as forces Ff, and F - FM. The first two cancel each other out and the third is cancelled by an external force P_{EXT} needed to maintain the constant speed loop.

As the force FM must oppose the force F_{EXT}, current (i) induced in the loop by varying the magnetic flux flux must have the meaning indicated in **Fig.1**. This fact is a particular example of Lenz's Law.

Considering the experimental activities discussed with Faraday's law, when a magnet approaches a coil, the induced current in the coil has a direction as shown in **Fig.2**. This generates a magnetic field whose north pole is facing the north pole of the magnet, that is, the field generated by the induced current opposes the motion of the magnet.

When the magnet is moved away from the coil, the current induced in the coil has a direction opposite to that shown in **Fig.2**, thereby generating a magnetic field whose south pole is facing the north pole of the magnet. The two poles attract each other, that is, the field generated by the induced current opposes the movement of the magnet away from the coil. This behaviour is present in all current power generators, and known as ‘engine brake’ is highly undesirable as it increases the resistance and so, the energy loss.

When two electromagnetic coils are placed facing each other, there is no current in either of them. At the instant of power up one of the coils, the current in the coil, generates an induced current in the second coil. When powered up, the current in the coil goes from zero to its maximum value, and then remains constant.

Thus, when the current is changing, the magnetic field generated by it, (whose north pole faces the second coil) is also changing and so the magnetic flux of this field through the second coil is also changing. Then there is a current induced in the second coil whose sense is such that the magnetic field it generates tends to decrease the flow mentioned above, that is, its north pole confronts the north pole of the first field coil.

When the power switch is opened, the current in the first coil drops from its maximum value to zero, and correspondingly its magnetic field decreases. The flux of the magnetic field in the second coil also decreases,

and the induced current now flows in the opposite direction. This current flow direction produces an enhancing magnetic field, that is, it has a south pole facing the north pole of the field of the first coil.

Thus, there is a realisation of the principle of conservation of energy, expressed by Lenz's law, wherein any induced current has an effect which opposes the cause that produced it. Assuming that the induced current acts to favour the variation of the magnetic flux that produced the magnetic field of the coil, it would have a south pole facing the north pole of the approaching magnet, causing the magnet to be attracted towards the coil.

If the magnet were then released, it would experience an acceleration toward the coil, increasing the intensity of the induced current and thus create an enhanced magnetic field. This field, in turn, would attract the magnet with increasing force, and so on, with a continuing increase in the kinetic energy of the magnet.

If energy were to be withdrawn from the magnet-coil system at the same rate at which the kinetic energy of the magnet increases, then there would be an endless supply of energy. So it would be a perpetually operating motor, which would violate the principle of conservation of energy. Therefore, it can be concluded that current generators feature a large energy loss during the generation of electricity.

Objectives of the Invention

The present invention aims to contribute to the generation of sustainable energy, proposing electromagnetic equipment capable of producing abundant electricity from an extremely low input of electrical energy.

The above objective and other objectives are achieved in the present invention by a device comprising at least three sets of at least one electromagnetic field generating device (without a core or with at least one core) powered by an electrical power source, having their cores or any extension of them, with their coils or sets of coils, wound on at least one common conductive member in a closed circuit which is polarised by a voltage source, and these sets of electromagnetic field generating devices are arranged with their poles in confrontation, to promote the interaction of electromagnetic fields, and, preferably, positioned between two hollow metallic hemispheres, in order to focus and enhance their electromagnetic fields - these interactions cause a new technical effect - the emergence of an electric current which keeps flowing in a closed loop, with or without voltage being applied to that closed loop, current which is capable of powering external loads - even if no load is attached to it.

The device which is the object of the present invention operates as follows: Sets of electromagnetic field generating devices to be powered by an electrical power source, produce an electromagnetic field which induces an electric current in a closed conductive circuit, creating an interaction between the magnetic poles, and through repeated electromagnetic attraction and repulsion, provides an endless supply of electrons to the conductive closed loop itself.

The electrons attracted by this technique, augment the current flowing in the closed conductive loop, which provides the current to power external loads of high power, in spite of the fact that the device itself is supplied with only a small level of power. Thus, advantageously, the device which is disclosed in the present invention forms a trap for electrons from space, resulting in the generation of electricity. The interconnections of the components of the electron-trap cause, a new technical effect, namely, the appearance of an electric current which keeps circling in a closed circuit, even without any voltage being applied to the closed circuit, and even without a load being connected to it. The present electromagnetic equipment generates electricity or thermal energy, providing access to this new source of energy through the use of an electromagnetic field.

The proposed sensor can also be used for the generation of thermal energy depending on the form of circuit which is to be used, resulting from the flow of electric current produced by this electromagnetic equipment.

This field generates a flow of electric current induced by electromagnetic coils, which appears in the linking interconnecting devices generating electromagnetic fields with electromagnets, inductors or magnets. This chain operates in a manner favourable to the variation of the magnetic flux produced by the magnetic field in the electron-trap. Thus, it creates a north pole and a south pole, providing an endless supply of electric current without resistance between the links which interconnect the devices which are generating the electromagnetic fields. So, induced electric current is generated with or without voltage in the interconnection links of electromagnetic field-generating devices, depending on the connection method of the electrical circuit of the electron-trap.

The free-electrons collected by the space electron-trap can form alternating current (AC) or direct current (DC). The ratio of input power to output power is 1 to 100, that is, the generated power can be 100 times greater than the input power when there is at least one link / coil driver between the coils and the inductors or electromagnets. This relationship, however, is not limited to a factor of 100, as it depends on the shape of the electron-trap and its objective.

Another advantage of the free space electron-trap of the present invention is that, with thermal insulation of the components in the electric circuit, it is possible to produce thermal energy at low, medium or high temperature, through the movement of the electrons in the conductors, coils and/or electromagnets. The temperature generated is linked directly to the number of turns in the coils.

Thermal power generation performed by the sensor can be used for boiling and/or evaporation of liquids to be used in other types of energy generation, for example, replacing the use of coal and natural gas.

Another advantage of the proposed electron-trap of the present invention is that the electron-trap can transport electrons from one point "A" to a point "B", without a voltage drop in the link - if it is polarised - regardless of the distance between the points, depending on the strength and quantity of the electromagnetic field-generating devices. It is also possible to transport the electrons when the link devices generating the electromagnetic field are not polarised. In this way, the electric current is conveyed without voltage but only by the magnetic field formed between the coils. This methodology can be used in various fields.

Because of its simple construction, the electron-trap is a simple device which is compact, and performs low-cost power generation which can be used in all types of machinery, equipment and devices of all kinds, and many areas of application which require electricity in order to operate. The electron-trap can have single-phase, two-phase or three-phase output, and can generate electric current at low, medium or high voltage.

Brief description of the Drawings

The present invention will now be described with the aid of drawings, but the design is not limited to the implementations shown in these drawings, although they show other details and advantages of the present invention.

Detailed Description of the Drawings

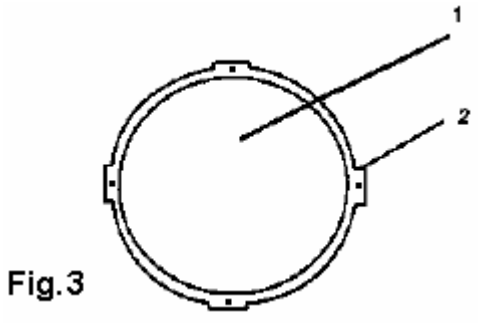

Fig.3 is a top view of one of the two hollow metallic hemispheres **1** which is part of the electron trap of free space proposed in this invention. Hemisphere **1** is preferably made from, but not limited to, aluminium, and it has mounting tabs **2**.

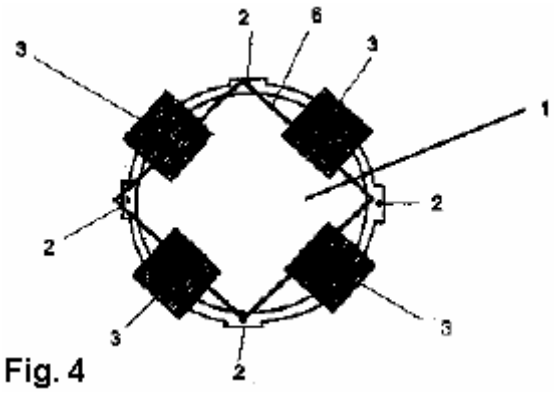

Fig.4 is a bottom view of metallic hemisphere **1**. It has four electromagnetic field generating devices **3**, positioned around the hemisphere and fixed to support **6** which is attached to hemisphere **1** by mounting tabs **2**.

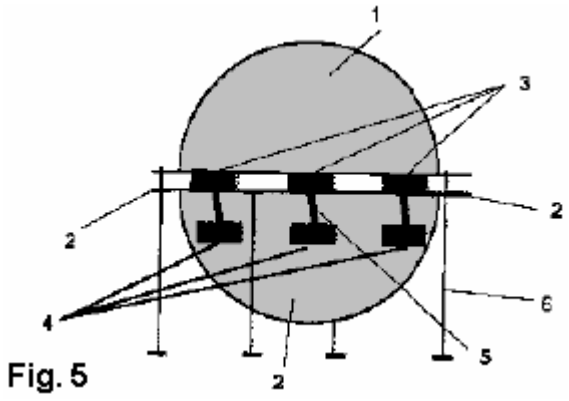

Fig. 5

Fig.5 is a side view of the free space electron-trap. It shows the two metallic hemispheres **1** and **2** (which form an imperfect sphere), and three of the coils **3** which are attached to the mounting tabs **2** and three inductors **4** which form the closed circuit itself, and which are attached by conductors **5**, and support member **6** on which are mounted coils **3** and their components.

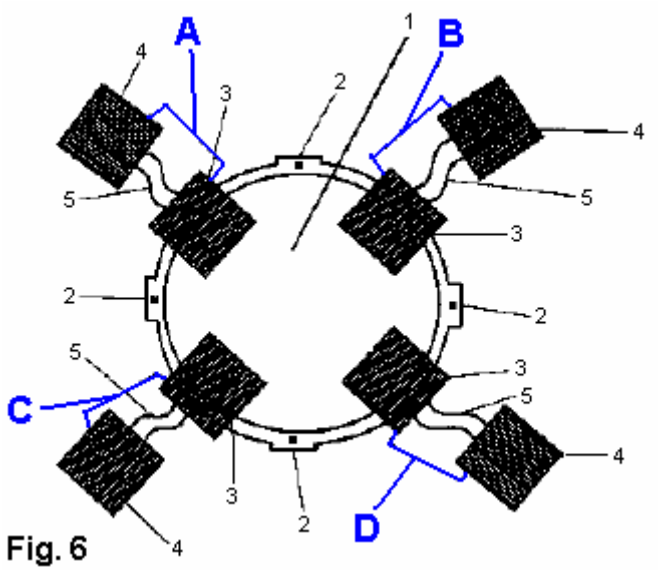

Fig. 6

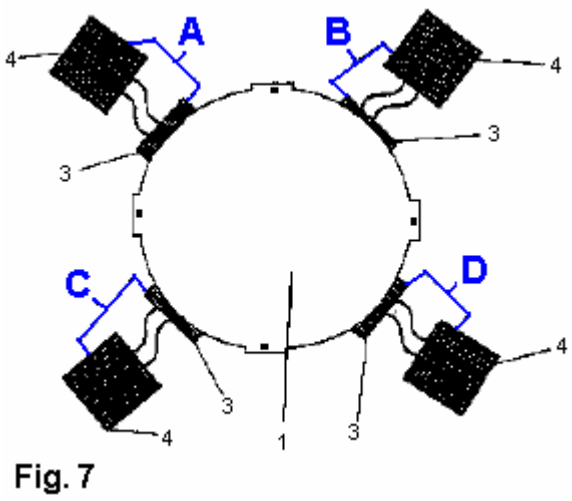

Fig. 7

Fig.6 and **Fig.7** show the top and bottom views of the metallic hemisphere **1** which accommodates four coils **3** attached to the holder **6** (not shown) which is secured to the hemisphere **1** by its mounting tabs **2**. **Fig.6** also shows the inductors or electromagnets **4** their corresponding coils **3** and their interconnecting conductors **5**. Each coil **3** and its linked inductor **4** forms a set. In **Figures 6** and **7** there are four such sets, marked **A, B, C** and **D**. The coils **3**, connected by their links **5**, each have at least one turn, and if the objective is to generate electricity, then preferably two turns, and if the objective is thermal energy, then four turns. The coils **3** may have various different shapes. The number of turns in the coil **3** are directly related to the amount of current to be generated, and the connecting links **5** may be either a single conductor or more than one conductor, the cross-sectional area of conductor **5** being selected to carry the current which is to be generated.

In sets **A, B, C** and **D**, the link conductors **5** have at least one turn around coils **3**. This winding is connected to the respective electromagnets **4** of each set (**A, B, C** and **D**) as shown in **Figures 6** and **7**. Please note that the inductors and electromagnets **4** can be any type of inductor, and other types of coil may be used.

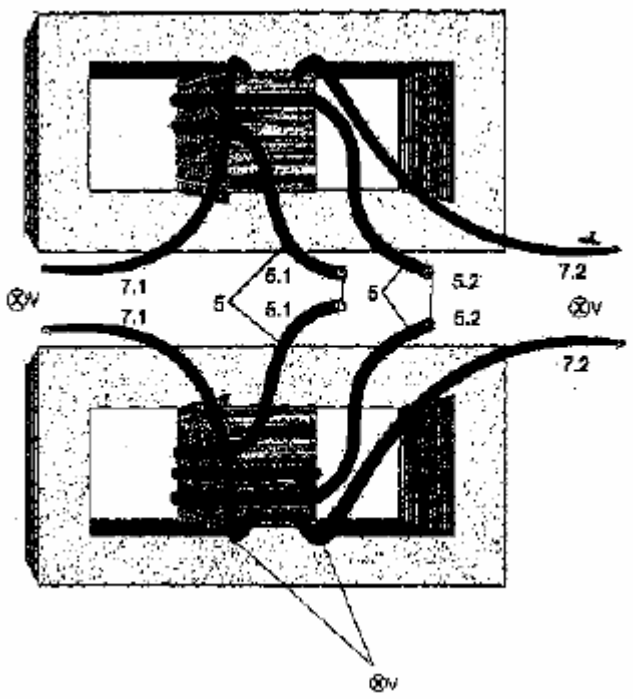

Fig.8 shows the inter-connecting coils **5** for each of the five sets **A, B, C** or **D** linking between coils **3** and **4** in each set. As shown in **Fig.6** and **Fig.7**, the link **5** makes the connection between coils **3** and **4**. This means that the wires marked **5.1** are all connected together, and the wires marked **5.2** are all connected together. Doing this, establishes the interconnection links **5** shown in the drawings. The power supply wires marked **7.1** are connected together as are the wires marked **7.2**. The wires marked **7.1** are connected to the live phase of the external power supply, while the other ends marked **7.2** are connected to the neutral of the external power supply.

In the space free-electron trap of the present invention, the coils **3** can be either single-phase, two-phase or three-phase. Also, the coils **3** may be powered by any voltage (V). The power coil **3** can be energised by any source of electrical energy such as a power grid. The electron-trap can be configured to produce alternating current or direct current. So, if the external power supply is alternating electrical current - AC, then the electron-trap provides an alternating electrical current output. If the power supply is DC, then the electron-trap provides an output of continuous electrical current - DC. The electron-trap can be configured for single-phase, two-phase or three-phase operation, with low, medium or high voltage outputs.

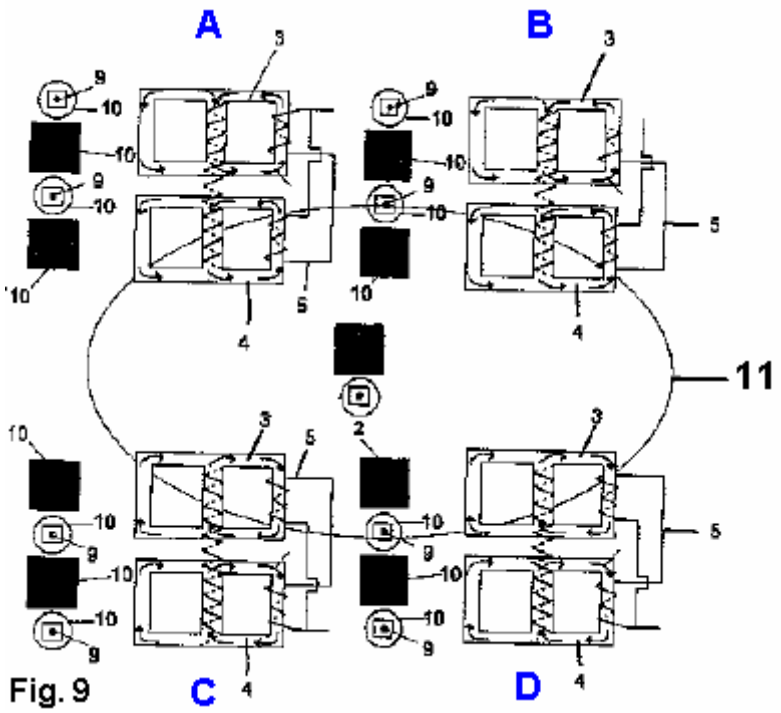

Fig.9 shows an electron-trap circuit diagram with four sets **A, B, C** and **D** of inductor coils **3** and **4**. Induction is produced around core **9** of the three sets of coils **A, B, C** and **D**. The effect of the interaction of the

electromagnetic fields **11** is shown. The induction via core **9**, causes the circulation of electric current in the links **5**, attracting the free electrons through the electromagnetic field of the trap. Then, the electrons join with the current generated by induction on link **5**, circulating between the magnetic poles north-south and south-north.

By way of example, the coils **3** are shown wound on a single phase column type core, but these can also be of any kind or shape. The electron-trap proposed by the present invention can be constructed with another type of electromagnetic field generating device which has at least one electromagnetic coil or magnet or electromagnetic inductor which can be of any kind or shape, or any combination of those, and with any number in each phase of the electron-trap.

The electron capture occurs through an electromagnetic field which is formed with the connection of coils **3** with the electromagnets or inductors **4** through the links **5** between the eight components.

This closure produces the displacement of the electrons in the coil **3** set (**A**) (for simplicity, referred to as coil **3A**), these electrons are attracted by the protons of coil **3D**, and are repelled by the electrons of the electromagnetic field of the coil **3D** itself. These coil **3D** electrons are attracted by the protons of the coil **3B**, and are repelled by the electrons of the electromagnetic field of coil **3B**. These electrons of coil **3B** are attracted by the protons of coil **3C**, and are repelled by the electrons of the electromagnetic field of the coil **3C** itself. Similarly, the **3C** coil electrons are attracted by protons of the **3A** coil, and are repelled by the electrons of the electromagnetic field of the coil **3A** itself. These coil **3A** electrons are attracted by the protons of the **3D** coil, and are repelled by the electrons of the electromagnetic field of the **3D** coil itself. Analogously, the coil **3D** electrons are attracted by the protons of the coil **3B**, and are repelled by the electrons of the electromagnetic field of the coil **3B** itself. These **3B** coil electrons are attracted by the protons of coil **3C**, and are repelled by the electrons of the coil itself induced **3C**, and then the coil **3C** electrons are attracted by protons of coil **3A**, and are repelled by the electrons of the electromagnetic field of the coil **3A** itself. That cycle continues as the sets of coils **A, B, C** and **D** are being fed by a voltage. These endless attractions and repulsions generate an electric current in the link coil **5**.

In the electron-trap, the voltage is stable. Regardless of the amount of current generated-which can be very high, the voltage will be the same in the electric circuit of the sensor, because the current moves through the attraction and repulsion of the electrons, regardless of voltage.

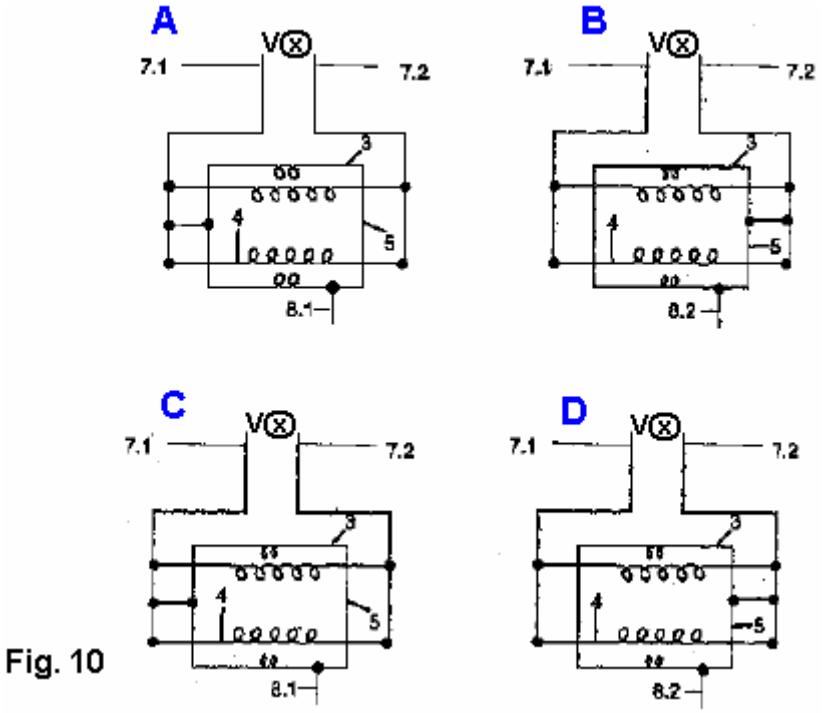

Fig. 10

Fig.10 illustrates a circuit diagram of the electrical connection between the coils **3** and **4** in sets **A, B, C** and **D**. It can be seen that the sets **A, B, C** and **D** are enclosed between the coils **3** and their associated inductors or electromagnets **4**. The supply conductors **7.1** and **7.2**, of sets **A, B, C** and **D** must be interconnected. When feeding power to the coils **3** and **4** the phase should be connected to **7.1** and the neutral to **7.2**.

The sets **A, B, C** and **D** after being fed with electric current, generate voltage through the attraction and repulsion of the electrons in the linking coil **5**, where there is at least one output load **8.1**, which should be connected joining sets **A** and **C**, and at least one load output **8.2**, which should be connected joining sets **B** and **D**. The output points **8.1** and **8.2** are the respective phases and neutral of power points **7.1** and **7.2**.

In this way, a singl-phase electron-trap is created by two pairs of sets of coils/inductors **3** and **4**.

The **3/4** electromagnet coil set can be replaced by a **3/3** coil set, without any disadvantage to the electron-trap.

Sets **A, B, C** and **D**, are inserted into a hollow metal hemisphere **1** preferably constructed from - but not limited to - aluminium. The hemisphere **1**, whose function is to concentrate and maximise their electromagnetic fields, simulating an electron cloud, has a fixed support **6** connected to attachment tabs **2**, and to which the coils **3** are fixed.

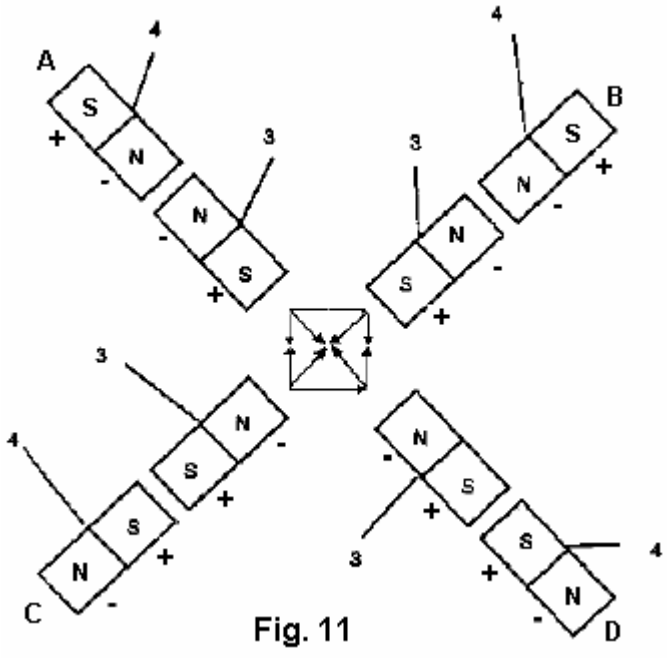

Fig. 11

Fig.11 is a diagram of the electromagnetic north and south poles of the inductor coils **3** and **4** of sets **A, B, C** and **D** of the electron-trap. The electromagnetic behaviour described for **Fig.9** is again demonstrated by the formation of the magnet assembly to the North Pole and South Pole being attracted and repelled by the lines of force of the magnet from the point "**A**" to point "**D**", point "**A**" to point "**B**", the point "**B**" to point "**C**", point "**C**" to point "**A**", and so on, as long as there is an electromagnetic field. The electromagnetic field of the space electron-trap provides that induced current in a direction similar to the variations of the magnetic flux that produced it. So, the magnetic field creates a north pole and a south pole in each of the sets **A, B, C** and **D**, as shown in **Fig.11**.

By feeding the coils **3** of the electron-trap with a desired voltage a magnetic field is generated in coils **3**, between the four sets **A, B, C** and **D**, which form a flow of electrons. This flow of electrons augments the electron flow which is circulating in the closed-loop link-coil **5**, thus implementing free electron capture from space. The electromagnetic field of the coil **3A** runs north to south, the electromagnetic field of the coil **3B** runs north to south, the electromagnetic field of the coil **3C** flows from south to north, and the electromagnetic field of the coil **3D** flows from south to north, as shown in **Fig.11**. It should be noted that the sets **A, B, C** and **D** can be formed by any combination of coil, magnet and electromagnet.

The south to north electromagnetic field induces current flow in the coil **3A**. The north to south electromagnetic field induces current flow in the coil **3B**. The north to south electromagnetic field induces current flow in the coil **3C** and The north to south electromagnetic field induces current flow in the coil **3D**. The induced current flow can have any power and it can be single-phase, two-phase or three-phase current.

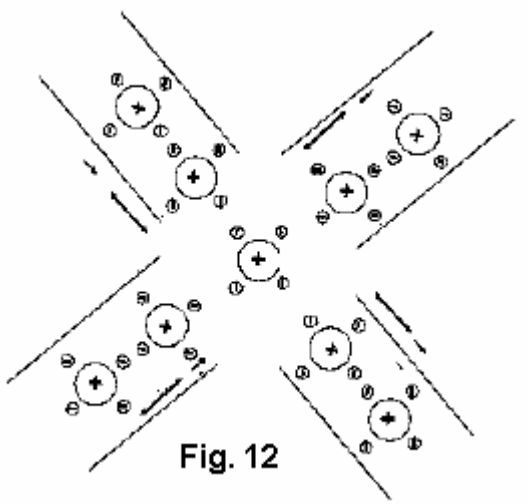

Fig. 12

Fig.12 shows the electrons being attracted and repelled by the induction coils **3** and **4**. Being repelled and attracted by electromagnetic induction, the electric current flows without resistance.

The electron-trap produces electromagnetic waves which can be used for various purposes, including signal transmission at any frequency and for any purpose. The capture is caused by these electromagnetic waves. The same physical effect can be achieved by the combination of the capture devices of other technologies, including electromechanical, electric, electronic, electromagnetic, or through the combination of a magnet or any other magnetised materials.

The space free electron-trap of the present invention is a renewable source of electrical power production and a new way of generating energy through the capture effect, generating flows of electrons, generating ordered movement of electrons - electric current - as shown in **Figures 9, 11,** and **12**. Electrons can move without any voltage difference in the continuous loop **5**. Alternatively, the loop may be biased with any chosen voltage.

THE IMPULSE GENERATOR

Dr. Evgeny Podkletnov on the Impulse Gravity-Generator

By Tim Ventura & Dr. Evgeny Podkletnov, April 10th, 2006

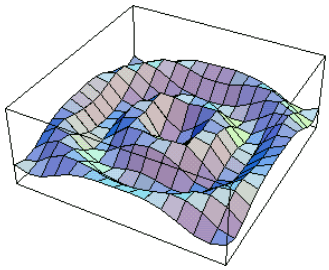
In 2001, Dr. Evgeny Podkletnov began publishing a series of scientific papers detailing the experimental results of what he called an "impulse gravity generator". The device reportedly produced hundreds of pounds of gravitational force in a non-diverging beam, capable of "punching holes through concrete and warping metal like hitting it with a sledgehammer". Podkletnov further added that this beam produced no recoil on the superconducting emitter itself, and that a radiation had been produced behind the device creating a molecular juxtaposition between plastics, metals, and living tissues similar to that described in the Hutchison Effect. This document is the result of 3 interviews between 2004 and 2006 that attempt to document and further clarify his remarkable experimental claims...

AAG: Thanks again for taking the time to speak with us about your research; it's truly been pioneering in the field of superconductive antigravity. A lot of the papers that I read online – and a lot of the references – date directly back to your research from the early 1990's, and more recently your experiments with Dr. Giovanni Modanese. Is there anything that you can tell us about what you've been up to lately?

Podkletnov: My research is based on the idea that it is possible to change or to modify the local gravitational field, and to consequently change the gravitational properties of objects within that field to make them lighter or heavier. This all can be done by creating special conditions in what might be described as the polarization of the ubiquitous vacuum, or by modifying the curvature of Einstein's space-time. There are several ways to do this – we can use high-voltages, large magnetic fields, and extremely high-speed rotation of various objects. We can also take advantage of topological effects in superconductive materials. Altogether, there are a number of possibilities, including potential combinations of some or all the parameters that I've just described.

Dr. Evgeny Podkletnov: Specialist in Type-II superconductive gravitomagnetic systems.

My latest experiment is a device called the "gravity impulse generator", which utilizes a Marx-Generator discharge through a superconducting emitter in a high-magnetic field to create a wave in time-space with properties very close to gravity-waves. The similarities are apparent enough we're almost positive that it actually is a form of gravity. These impulses can be directionally projected in any direction in space, and they exert a force on any object in the path of propagation. We haven't quite uncovered a detailed mechanism to explain how this force is generated, but we nonetheless have the technological possibility for industrial and commercial applications of these results, and this is the most important.



HFGW: A High Frequency Gravitational Wave model.

AAG: You'd mentioned that this effect generated hundreds of pounds of force in a very short period of time, and I'd wondered if

this effect has been able to punch holes through lightweight substances, or does it produce more of just a motion on them?

Podkletnov: The force of the impulse depends entirely on the structure of the superconducting emitter and the voltage that we apply to it. Given the materials & voltages we currently have available, we can obtain large impulses capable of deforming metal plates with a thickness of a couple of inches, and we've also been able to demonstrate punching holes in thick concrete walls. Obviously these effects are not limited to just lightweight substances – a concrete wall is something very solid. The impulse deforms metal in the way that a hydraulic press might do it, but the pulse-duration is very short in time, so we've been discussing a system utilizing several Marx-Generators to give a series of impulses that will definitely improve the overall effect. We've experimented with using the impulse-generator to treat a variety of materials, and we've also made another important find: the beam can hit a target over very large distances with a minimum of divergence and what appears to be zero loss in energy, even after passing through other objects in the beam-path.

By using extreme parameters we can create an even larger impulse forces. We discovered in the last year and a half that if we go to 5-million volts we can generate hundreds of pounds of force. At that time, we were also trying to measure the speed of propagation for these impulses. The results were extremely interesting, and hard for even us to believe, because to some extent it contradicts many aspects of modern physics. Nonetheless, we have experimental proof, and we're going to continue developing all of these experiments.

Marx Generator: An example 2 megavolt model constructed by Information Unlimited.

AAG: Oh, so these are all generated by Marx-Generator discharges?

Podkletnov: It is possible to use high-voltage discharges up to 5 million volts and specially prepared superconductors. These impulses are very short in time, we're talking about 1 millionth of a second and shorter, and they can be very powerful, and can be used for rocket propulsion in space. At the same time, they can be used for the correction of satellite orbits from the earth with minimum expense, making this a very promising technology.

AAG: In terms of putting holes through concrete, it makes sense that the holes would remain, but with metals, after the metal is deformed, do they snap back after the beam is gone, or do they remain deformed?

Podkletnov: No, they just remain deformed. It's just like a punch – very short in time, so it's close to an explosive action or something like that.

AAG: One of the things that I was wondering about is whether you've been able to do efficiency calculations for the force-beam.

Podkletnov: Well, Dr. Giovanni Modanese made some preliminary measurements that gave us the force in joules, but we did not try to make predictions – we wanted to simply see the results of how different objects reacted to the action of this impulse, so we didn't make any precise calculations.

AAG: The type-II YBCO emitter measured 47mm in diameter, if I remember correctly. Does changing the size or the shape change the beam output – maybe making it stronger or refocusing it?

Podkletnov: Well, in terms of the size of the superconducting emitter, there are some limitations. The diameter of the superconductor shouldn't be smaller than 4 inches, because of the Schwartzchild radius. Now to answer your question, in terms of the shape of the emitter, the superconductor can in fact have different shapes, and the projected impulse will maintain the emitter's cross-sectional shape, so is important.

Impulse Gravity Generator (initial setup)

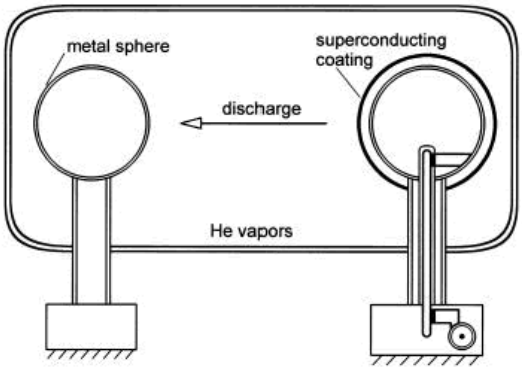


Fig. 1

AAG: The 4-inch minimum size for the superconductor seems to limit the public's ability to perform experimental replications. The largest commercial available superconductor that I've seen is a 1" superconductor – so it sounds like the emitters require custom fabrication?

Podkletnov: Well the size is very important – we didn't get any good results with smaller superconductors, and it's also more difficult to create the correct flat-glow discharge with smaller superconductors.

Impulse Gravity Generator (improved variant)

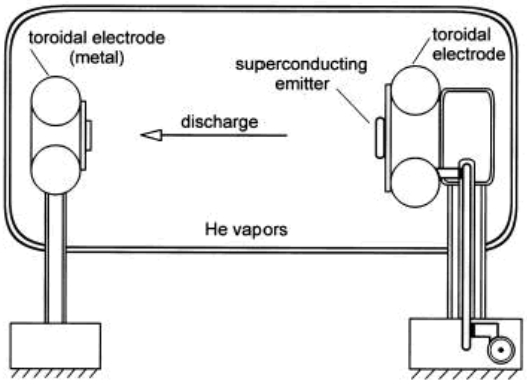

Fig. 2

Emitter Configuration: Schematic of two superconducting emitter apparatus designs.

AAG: Have you noticed any changes in the molecular structure, internal materials deformation, or maybe simple mechanical compression in the targets that you'd sent the beam through? You'd mentioned metals deforming and holes through concrete...

Podkletnov: We didn't see any compression effects or any change of the molecular structure – just a large scale deformation of the target material from the beam's force.

AAG: I should ask whether the beam loses energy as it penetrates materials. Does it naturally decrease or diverge with distance?

Podkletnov: That's an interesting question...and to our great surprise the beam practically does not lose energy when it meets the materials. It can pass through a brick wall or concrete, or metal-plates – very thick ones – or plastics also, and it seems that it doesn't lose energy at all. This is the consistent, long-term evidence from a lot of test discharges we performed at an installation I've been working at for about 4 years.

These results seem a bit strange, but we don't believe we're breaking any natural laws...simply that the system we're working in is not a closed one, and therefore the second law of thermodynamics is not applicable in the traditional sense.

In terms of action at a distance – and the dependence of distance on the beam energy – we don't have much experimental data, but what we do have is a first measurement at a distance of 1.2 kilometers without any loss in energy. Our latest experiment was conducted over a distance of 5 kilometers, and the beam penetrated through several houses made of concrete. We did not measure any loss of energy, but after closely evaluating some of the calculations that we've made, we should get some decrease in beam-energy at distances greater than 100 kilometers. This is research that awaits us in the future.

AAG: You'd mentioned 5 kilometers – did you notice any change in the focus of the beam. Did it widen or perhaps get smaller as it travels?

Podkletnov: If the main solenoid which is wound around the chamber is made in a good way, then we have a very good discharge and it effectively maintains a non-divergent cross-sectional pattern of the emitter it was projected from. However, at a distance of 5 kilometers, the beam begins to lose focus– it gets a bit wider than it was, indicating minor deviations in the shape of the impulse as it propagates.

AAG: I collected a few questions online, and one person wrote me, "Is it possible to generate more work along the path of the beam than energy put into the beam?" I think they were asking about potential "over-unity" applications.

Podkletnov: It's been surprising to find that the energy that we put into the discharge is much less than the energy that the impulse seems to generate, but it doesn't mean that it's an over-unity device, simply that we're creating a set of special space-time conditions through the interactions of the electromagnetic pulse-discharge with the bose-einstein condensate (superconductor). By manipulating these

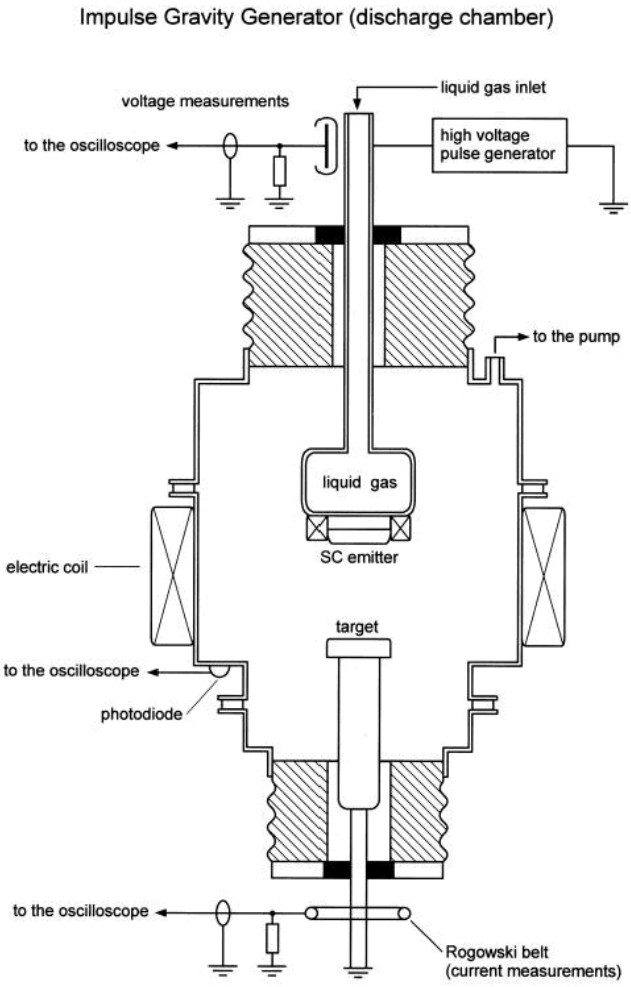

Fig. 3

Discharge Chamber: A complete layout-schematic of the chamber showing experimental components.

parameters we allow the interaction of electromagnetic fields with the sub-atomic field environment. We may call it zero-point energy or maybe even aether, but whatever it is, when normal matter interacts with it this special energy is obtained, and we can harness this energy. Our technology may be like a key that opens the door to the energy of the subatomic realm. This is at least our fervent hope...

AAG: Does the impulse-generator seem to defy conventional Relativity Theory? I'm wondering if you might have any specific examples or observations of things that Relativity Theory simply can't explain...

Podkletnov: I would never say that that our experiments defy conventional Relativity Theory because they don't. You know, people also suggested that about my earlier experimentation with the rotating disks, but in that case the rotations around the disk's own axis are absolute rotation. This is absolute movement, not relative, which is why relativity theory is not applicable to our rotating disks – it's a totally different thing. However, I don't think the force-beam experiment defies Relativity Theory either.

AAG: Does the inertia change in proportion to changes in mass? The reason that I wrote that down was really in relation to Fran De Aquino's research. He believes that inertial & gravitational mass are not equal, they just appear equal to us in our frame of reference.

Podkletnov: Well, based on our understanding and our experience, we didn't differentiate between gravitational and inertial mass, and we believe that they are equal. Experimentally, the pulse-width of the impulses is too short to notice any difference, and we never conducted any special experiments just to distinguish gravitational and inertial mass.

AAG: In Relativity Theory, gravitation and time are integral components of the "fabric of time and space" –and modifying one inherently changes the other. Given your description of the impulse-beam as being gravitational in nature, have you noticed any experimental time effects?

Podkletnov: It's difficult to say, because in a practical sense it's not truly a gravity-beam – it's a gravity-impulse with a very short time-duration, and because of this limitation -- because it has such a short pulse-width -- we didn't notice any time effects and didn't even try to measure them, but it's possible they are present. These effects were definitely present when we were experimenting with the rotating disks – definitely – and we had some experience with this, but with the gravity impulse-generator we simply didn't conduct any measurements.

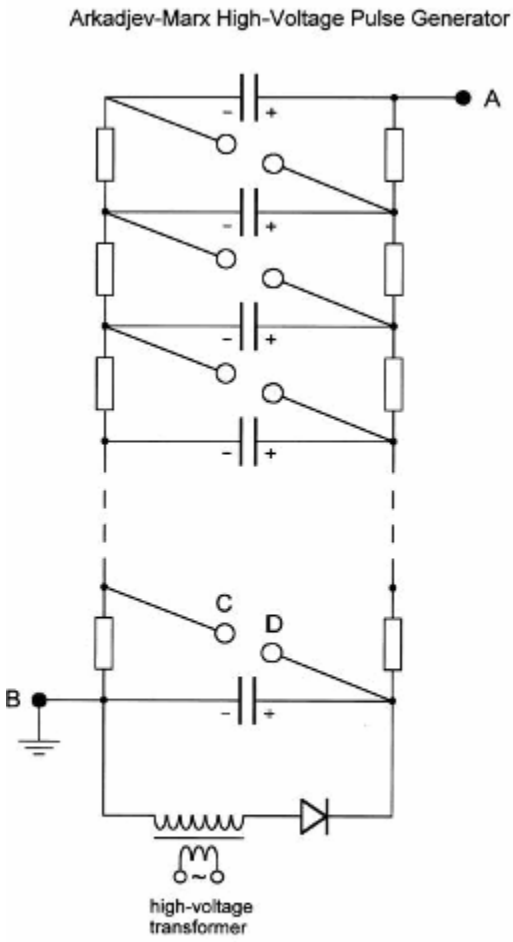

Fig. 4

Marx Circuitry: An overview of an idealized circuit for the Marx-Generator.

AAG: Now you've mentioned working on some scientific publications, and I'd like to find out more about what topics you plan on publishing about in the future, and what your schedule for publication might be?

Podkletnov: Well, of course there is a growing interest in the concept of manipulating gravity in a number of countries. For instance, we got a very interesting offer from China-- they have a very special project at the University of Beijing – and there's also been some interest from the private sector in the United States as well.

As soon as we get funding we'll try to publish on a variety of experiments in a more detailed manner, but at present we're extremely interested in attempting to measure the interaction of the impulse-beam with visible light, and we published some preliminary results about this in the journal of low-temperature physics in August of 2004. The details are all in my article with co-author Dr. Giovanni Modanese, and we're continue this research now, again with a focus on attempting to measure the propagation speed of the impulse.

We're very cautious about what we write, because we don't want to frighten the scientific community, and also we want to be absolutely sure that the results are checked and rechecked several tens of times-- but it seems that based on what we have now, and we've already been working for a year and a half, the speed of the impulse is much higher than the speed of light.

With the parameters that we use now – using our current emitter designs and a voltage of 3 and 5 million volts, the speed is about 63 to 64c – which means that the propagation speed of the impulse is close to 64 times the speed of light. Of course, we would like to measure all these parameters using different measurement systems and different approaches. At present we use two atomic clocks, and we think that our measurements were precise enough, but we would welcome the advice of the international community. It would help to have additional input on how to measure the speed of the impulse in a very specific way. As soon as we get a good confirmation of these results, we will try to publish all of this information.

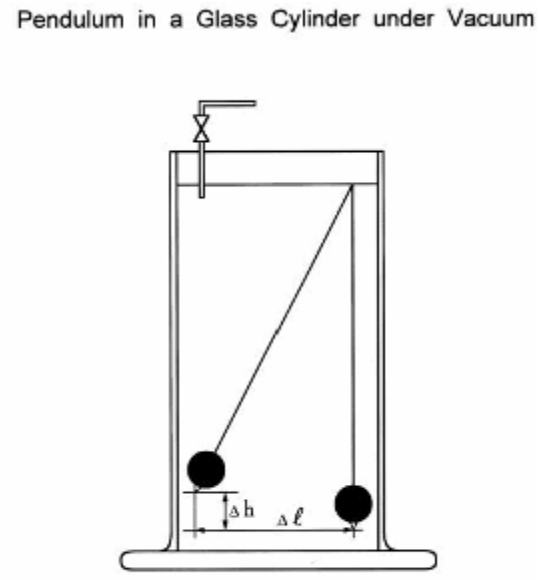

Fig. 5

Pendulum: Podkletnov's initial force-beam experimental measurement apparatus.

AAG: I was wondering about funding: you've mentioned that there was interest from the private sector in the United States and from China – do you know if there are any replication efforts underway by other groups to duplicate your research?

Podkletnov: I know that there was a lot of interest from Boeing, but I don't know the details. I also know that the Department of Defense in the United States is very interested in this technology, and that's why they invited Dr. Ning Li to lead the scientific laboratory funded by AMCOM, but at present I don't know of any official replication of my gravity experiments. This is because my research is rather hard to categorize, it's costly, and the official attitude of the

"politically correct" scientific establishment towards gravity-modification is negative, which creates a lot of difficulties.

However, I don't hide anything, and when people contact me directly or by email I usually try to give all the advice that I have and to share my experience with them. The problem is too complicated for one country or for one lab to succeed; gravity should be studied all over the world using the best forces and the brains of difference scientists. That's the key to success.

Dr. Modanese: Podkletnov's research partner, physicist, and force-beam co-author.

AAG: I think we've already agreed that one of the chief obstacles to a successful replication is the 4-inch superconductor – do you know if those are manufactured and sold anywhere, or is that a process that everyone has to go through to build their own?

Podkletnov: Frankly speaking, in the case of extremely effective emitters that's a part of my professional know-how, but if you're only talking about emitters that allow you to generate small effects, then it's not a problem. I believe that American Superconductor can help to easily make emitters of this kind, and also there is a nice firm called "Superconductive Components" in Columbus, Ohio – they're more or less familiar with my technology, and I think that they are up to the task of building emitter components.

AAG: So essentially, by using a smaller superconductor you have a smaller effect, but that can be tested by using more sensitive equipment.

Podkletnov: The diameter of the disk should still not be less than 4-inches, but I'm talking about the physical structure of the ceramic itself. The structure for efficient emitters is very difficult to build, and requires a lot of experience to build correctly, so even if I provided a detailed description, it would be difficult to construct without my help. Normal emitters which allow you to push a thick book away from a table are possible to construct, as they aren't quite so complicated.

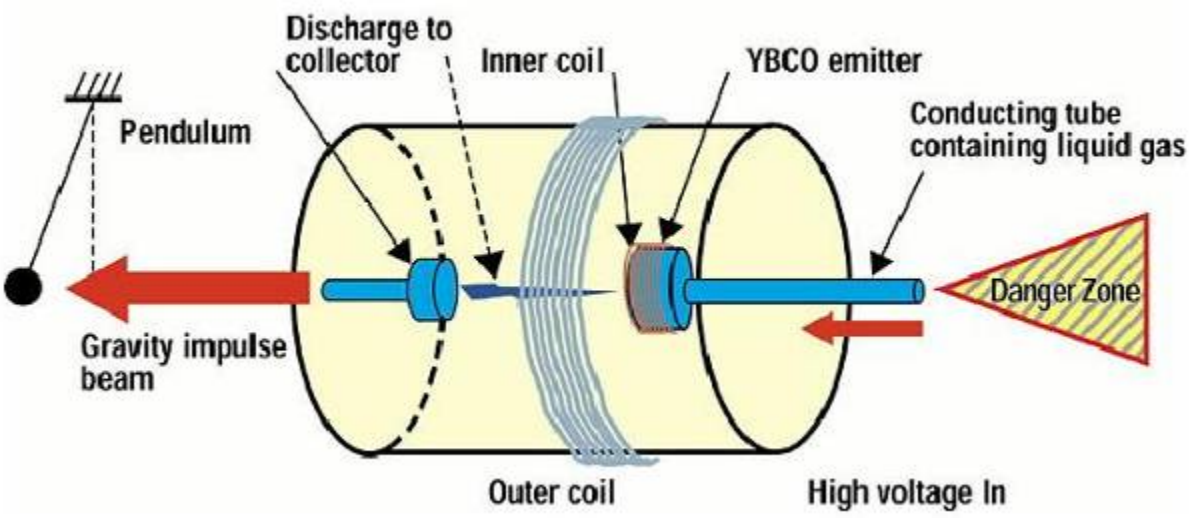
Dr. Ning Li: A colleague of Podkletnov's and specialist in gravitomagnetic coupling effects.

AAG: I had a question from another person who was asking about video, but they were also asking about a flat-glow discharge.

Podkletnov: Well, in order to make a video for the flat-glow discharge, we should use a high-speed video camera that we don't presently have, so we typically have to rely on our keen sight, but it's a bit difficult. We're planning to film it, but even with a normal discharge – a spark, as in a van de graaf generator, or in a flat-glow discharge, which repeats the configuration of the emitter, it's possible to see it with your own eyes -- you don't need a camera for that.

AAG: Now in terms of experimental setup, because I'm getting ready to buy parts...it looks like, from reading through your experimental setup, that essentially you're discharging a high-voltage onto a superconductor – that, and the superconductor itself is inside a magnetic field. It looks in some ways deceptively simplistic, but I understand that there is a definite challenge involved with it. Have you found any real tricks to testing with this?

Podkletnov: Well, this technology is really nothing special, but I work with a team of experienced people who are experts in high-voltage discharges, experts in ceramic materials & superconductors, and experts in magnetic fields, and only by combining the knowledge different fields and people from different countries can we reach something positive. This international collaboration becomes inevitable, and becomes the key to success.



Emitter Experimental Setup: An overview of the emitters subjected to a high-voltage discharge.

AAG: Dr. Bob Baker is working on putting together a 2006 High-Frequency Gravity-Wave Conference as a follow-up to the earlier one in 2003. Has he contacted you about this, and would you be open to attending?

Podkletnov: No, he hasn't sent me anything. You know, I have a job here and I don't want to risk it, especially without firm opportunities for funding. I'm hoping to find investors wise enough to see how much money this research can generate. Unfortunately, up to now they don't understanding it – if I release this technology, if they put money in it – then we will definitely succeed in it, and in 2 or 3 years they will be richer than Bill Gates, but this understanding comes very slowly. We've been hoping for commercial funding, because the impulse generator is basically a gravity-gun, and I'm not really interested in providing a weapon of strategic importance to the United States. If we're talking about new propulsion systems, though, I'm eager to share my knowledge. Of course the gravity-beam can also used for propulsion, but the rotating superconductor can be used only for creating propulsion – a vertical column to help lift a craft off the surface of the earth.

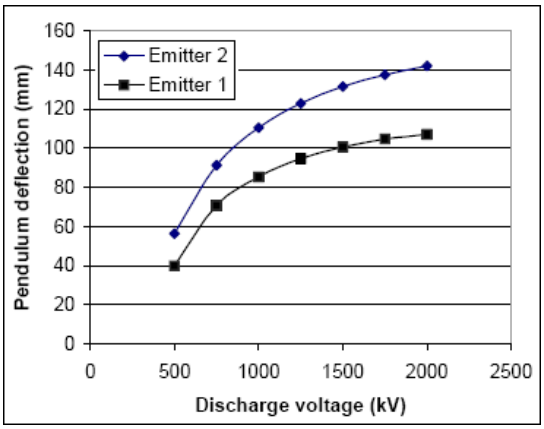
AAG: The force-beam that you'd mentioned coming out of the back of the impulse generator had a negative effect on living organisms, right?

Podkletnov: Yes, it produced a strange kind of non-focused radiation that was very harmful to biological tissue -- fortunately for us; the impulses were very short in time. It was very harmful to living organisms; we also observed a melting or molecular-juxtaposition effect of biological tissues with plastic materials, and even with metals to some extent.

AAG: So this was a very different force than the impulse coming out of the front of the generator?

Podkletnov: Yes, it was an entirely different force, and it was not focused like the gravity-beam.

AAG: In "The Hunt for Zero Point", Nick Cook described an experiment in the 1940's called the "Nazi-Bell" that reportedly exhibited side-effects like the crystallization of cell-membranes in plants and the breakdown of living tissue into a greasy substance after repeated exposure. Does this sound similar in any way to what you saw emanating from the back of the impulse-generator?



Deflection: Deflection of pendulum during testing as a function of discharge voltage.

Podkletnov: Well, I can't speak for what they might have seen – during the 40's I hadn't even been born yet! However, it might be that the side-effects are similar to ours. There are several effects that are similar to this – one is the Hutchison Effect, where he reported molecular distortions & materials juxtapositions, which is similar to the anecdotal claims of "sailors melting into decks" in the Philadelphia Experiment legend.

AAG: Oh, so you're actually talking about a radically different set of associated effects...did you witness anything like atomic transmutations or Low-Energy Nuclear Reaction (LENR) effects occurring, or just the molecular-level anomalies?

Podkletnov: Well, the radiation that emanates from the rear of the impulse-generator might somehow create conditions suitable to LENR effects, but this wasn't an area of focus in our research, so I really don't know. Our primary focus was on studying the gravity-beam itself.

AAG: In terms of the force-beam, you've said that it was hundreds of pounds of force, and I realize that it was very difficult to measure. You've said that it was also enhanced with 5-million volt discharges. Can you tell me a bit more about this?

Podkletnov: Yes, it output force depends on the voltage and also on the effect of how sharp the the impulse is. If the rise-time of the impulse is long in duration, then we have a lower-power impulse, and if it is very sharp – I mean the voltage rises very fast – then the effect is very large and is able to bend metal plates.

AAG: Ok, did you test on anything besides metal or concrete, to try some other substances?

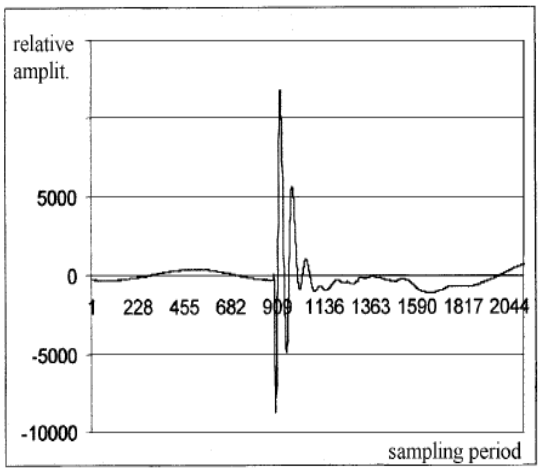
Podkletnov: It's not a drilling-machine, sorry. We're interested mainly in the use of this technology for propulsion in space, and frankly speaking it really is what you'd call "propellantless propulsion".

AAG: Let's focus on that for a second: when you noticed the impulse force on objects in the beam path, was there an equal & opposite force on the superconductor itself?

Podkletnov: No, there wasn't. There was no reaction force at all.

AAG: So if you put the superconductor inside of a spacecraft then, I guess that it wouldn't produce a conventional forward propulsion?

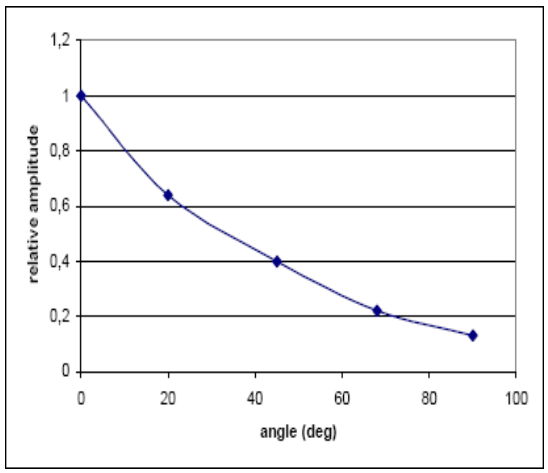
Podkletnov: Yes, it doesn't act according to Newtons third law – that every force has an equal an opposite reaction. But simply the superconducting emitter, whether it is a rotating disk or the discharge-system, is able to create a gravitational wave in what you might call the aether or the space of subatomic particles. Or you call it a gravity-wave. So this wave propagates through space, through all the objects, sometimes it can interact with normal matter, but to my surprise it does not lose its energy at very high distances – it remains collimated as it propagates.



Amplitude: Relative pulse-amplitude from impulse-discharge experimental testing.

AAG: Did you notice any other strange effects in the general area? Anything in addition to the impulse itself, the effect on objects, or the strange radiation coming out behind?

Podkletnov: No, we didn't, but frankly speaking it is not very easy to measure all these additional effects. You know, when you're dealing with millions of volts, it's better to keep a bit of safe distance. We use a faraday cage and special rubber-metal coatings to shield the radiation, because otherwise the high magnetic field strength from the discharge will erase computer hard drives and damage nearby test-equipment.



Deflection: Angle of pendulum deflection correlated with adjusted pulse amplitude.

AAG: When you analyzed the metal sample that was bent with the gravity-beam, did it appear to be only bent forward in the direction of beam propogation? Dr. Bob Baker postulates that gravity-waves may be quadripolar in nature, and I'm wondering if these waves might leave a detectable signature in the materials they deform to help validate his theory...

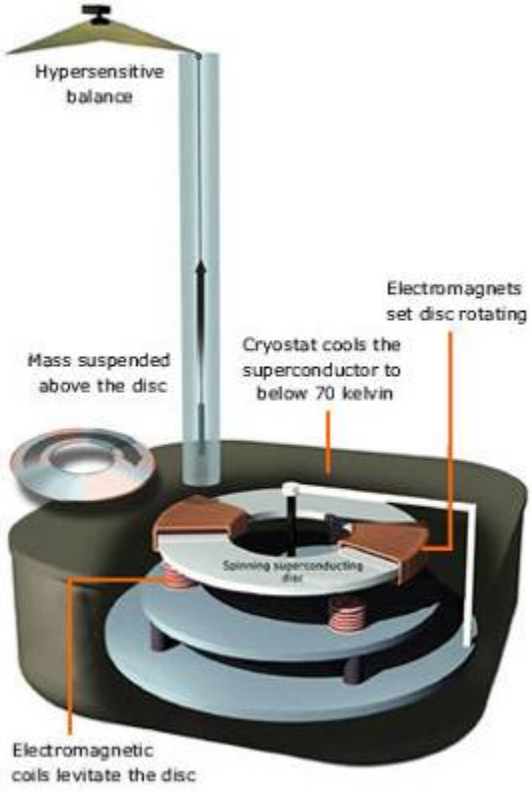
Podkletnov: In our experiments we were able to observe only the forward action.

AAG: Do you think that there might be any torsion physics involved with the impulse-generator?

Podkletnov: I think that torsion or axial fields may be present in our experiments, but it's more suitable to suggest a role for torsion physics in our original rotating disk experiments - the mechanism behind the impulse-generator is a bit different.

AAG: Speaking of which, in terms of the failed NASA replication for the rotating-disk experiment, I'd heard from a NASA insider that they only spun it up to about 200rpm. Does that mean that they didn't fully complete your experiment?

Podkletnov: I cringe every time I hear that NASA failed to replicate my experiment, because no, they didn't fail. They made their own disks, and they were big enough: about 12 inches in diameter. They published some initial test information indicating that they had definitely noticed some unusual effects. Then I got involved in participating to helping them to replicate my experiments, and they practically had everything ready when they ran out of money. So at the last stage they were not able to rotate the superconductor in the magnetic field, and shortly after that the department of defense came in and grabbed all the experiments. All of this research was transferred to Dr. Ning Li – so now NASA has nothing, and we have nothing either.



Rotating Disk: A cutaway of the Type-II disk apparatus from the first experiment.

AAG: So is Dr. Ning Li still in charge of the project then?

Podkletnov: I think so, but the point is that NASA never completed the experiment, and thus nobody can claim that they failed to see results, because they never completed it.

AAG: Have you ever been approached by the Department of Defense for any kind of funding?

Podkletnov: No, they would not do it. I am a citizen of Russia so they wouldn't even try.

AAG: Well, the Chinese, though, have a gravity-lab: have they expressed any interest in your research?

Podkletnov: They expressed real interest and they've invited me to China several times, but they are like kindergarteners: they want me to come just and give them completed technologies. They have a rather good theoretical school but they haven't achieved much in practice, and they seem rather limited in funding, so I am not eager to travel to China and work there at my own expense.

AAG: Have you ever been able to gravity-research lab in China? Bob Baker visited a couple of years ago, and was impressed by their efforts.

Podkletnov: No, but I'm perfectly aware of the projects they have and their progress in development, because I have very good relationships and discussions with my colleagues from different countries, although I haven't seen it with my own eyes.

AAG: One of the responses that we had online was the question, "with nearly a decade of experience, why haven't we been able to see videos or photos of your experiments up until now?"

Podkletnov: Well first of all, when we began those experiments, in Tampere in the early 90's, it just wasn't common practice to make videos or photos of the equipment or of the experiment. I know that it's typical in the United States, but here in Europe it's different...and the same thing goes for Russia, especially with the last experiment in the Moscow Chemical Research Center, because the whole center is a very secure facility and some of the research laboratories are closed to the general public. In our case, nothing was secret, but it was a dangerous environment because we use high-voltages, so it's a closed lab. We have special signs on the walls of the laboratory which do not allow us to make any photos. It's an accepted, established policy at this scientific research center, and I didn't want to break the rules.

AAG: Well, in light of the publicity that you've had recently, have you given thought to doing any photos or video in the near future?

Podkletnov: I've discussed this possibility with the administration and they think it might be possible, but at present we don't have any photos or video to share with you.

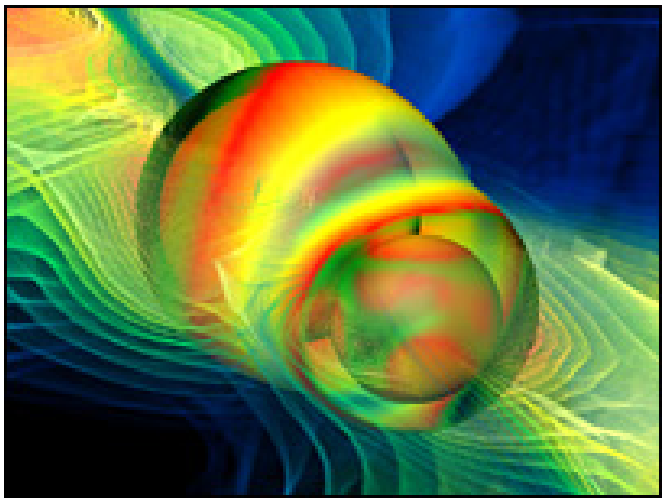
AAG: OK – well, I look forward to hopefully seeing some in the future if it turns out that it's possible. To move along, have you been able to obtain funding from government or private interests? Has there been a fair amount of interest that's come forward and tried to provide funding for your experiments?

Project Delta-G: The now-defunct NASA group tasked with examing superconductive gravity-coupling.

Podkletnov: There has been some interest from the private sector, because by policy the government does all of the research into gravity and experimental gravity. This type of research is not popular, so we don't get much money from the government. Of course, we use the right installations at the technological center. There is some interest in general all over the world – like the United States and Great Britain, but we didn't get any funding from the government. We get rather small funding from the private sector, but our plans are really amazing and we need considerable fundin g. So this topic of gravity is a bit unusual, and we need some exotic materials...we need special installations, we need cryogenic systems, we need the help of top people who are qualified in their own areas, and these all cost a lot.

AAG: Just to wrap things up, because we're almost out of time, again it sounds like you're getting amazing results – you're able to put holes through concrete and bend metals with this at 5 million volts – these are remarkable results. Is there anything you'd like to say in close?

Podkletnov: I don't think that these results are remarkable in general. This subject called experimental gravity research has a very big potential, and if we compare how complicated this problem is to the problem of, let's say, nuclear explosives, I think that gravity research is much more complicated. But even if we speak about nuclear power, there was a period in the United States when everybody was interested, and the military and people wanted to make some research, and the government was interested. Then people came and said, "could you please make a small explosion, and then we will give you money for a big one?"...but it's impossible to make a small nuclear explosion. The same thing refers to gravity – it's an enormous problem, and we can't get much if we don't have an organized approach as it was in the nuclear program for example in the United States. Only combining the knowledge of different fields, and of different physicists, chemists, and materials scientists & theoretical physicists – only through them working together can we make a breakthrough in this field, because it's very, very serious research.



Gravity-Wave: The core of a gravity-wave event as predicted by Dr. Robert Baker's HFGW research.

Dr. Evgeny is a research scientist living in Finland, with an impressive body of experimental research relating to EM/gravitational coupling in superconductive materials. His published abstracts about the impulse generator experiment are online at: Investigation of HV discharges through large ceramic superconducting electrodes, Superconductor Impulse Gravity Generator

Is a Graviton Detectable?

Poincare Prize Lecture
International Congress of Mathematical Physics
Aalborg, Denmark, August 6, 2012

Freeman Dyson, Institute for Advanced Study, Princeton, New Jersey

1. Introduction

It is generally agreed that a gravitational field exists, satifying Einstein's equations of general relativity, and that gravitational waves traveling at the speed of light also exist. The observed orbital shrinkage of the double pulsar [Weisberg and Taylor, 2005] provides direct evidence that the pulsar is emitting gravitational waves at the rate predicted by the theory. The LIGO experiment now in operation is designed to detect kilohertz gravitational waves from astronomical sources. LIGO has not yet detected a signal, but nobody doubts that gravitational waves are in principle detectable.

This talk is concerned with a different question, whether it is in principle possible to detect individual gravitons, or in other words, whether it is possible to detect the quantization of the gravitational field. The words "in principle" are ambiguous. The meaning of "in principle" depends on the rules of the game that we are playing. If we assert that detection of a graviton is in principle impossible, this may have three meanings. Meaning (a): We can prove a theorem asserting that detection of a graviton would contradict the laws of physics. Meaning (b): We have examined a class of possible graviton detectors and demonstrated that they cannot work. Meaning (c): We have examined a class of graviton detectors and demonstrated that they cannot work in the environment provided by the real universe. We do not claim to have answered the question of "in principle" detectability according to meaning (a). In Section 3 we look at detectors with the LIGO design, detecting gravitational waves by measuring their effects on the geometry of space-time, and conclude that they cannot detect gravitons according to meaning (b). In Sections 4 and 5 we look at a different class of detectors, observing the interactions of gravitons with individual atoms, and conclude that they cannot detect gravitons according to meaning (c). In Sections 6 and 7 we look at a third

class of detectors, observing the coherent transitions between graviton and photon states induced by an extended classical magnetic field, and do not reach any definite conclusion.

This paper is a report of work in progress, not a finished product. It raises the question of the observability of gravitons but does not answer it. There is much work still to do.

2. The Bohr-Rosenfeld Argument

Before looking in detail at graviton detectors, I want to discuss a general theoretical question. In 1933 a famous paper by Niels Bohr and Leon Rosenfeld, [Bohr and Rosenfeld, 1933], was published in the proceedings of the Danish Academy of Sciences with the title, "On the Question of the Measurability of the Electromagnetic Field Strengths". An English translation by Bryce de Witt, dated 1960, is in the library at the Institute for Advanced Study in Princeton, bound in an elegant hard cover. This paper was a historic display of Bohr's way of thinking, expounded in long and convoluted German sentences. Rosenfeld was almost driven crazy, writing and rewriting fourteen drafts before Bohr was finally satisfied with it. The paper demonstrates, by a careful and detailed study of imaginary experiments, that the electric and magnetic fields must be quantum fields with the commutation relations dictated by the theory of quantum electrodynamics. The field-strengths are assumed to be measured by observing the motion of massive objects carrying charges and currents with which the fields interact. The massive objects are subject to the rules of ordinary quantum mechanics which set limits to the accuracy of simultaneous measurement of positions and velocities of the objects. Bohr and Rosenfeld show that the quantum-mechanical limitation of measurement of the motion of the masses implies precisely the limitation of measurement of the field-strengths imposed by quantum electrodynamics. In other words, it is mathematically inconsistent to have a classical electromagnetic field interacting with a quantum-mechanical measuring apparatus.

A typical result of the Bohr-Rosenfeld analysis is their equation (58),

$$\Delta E_x(P)\Delta E_x(Q) \sim \hbar|A(P,Q) - A(Q,P)|. \tag{1}$$

Here the left side is the product of the uncertainties of measurement of two averages of the x-component of the electric field, averaged over two space-time regions P and Q. On the right side, $A(P,Q)$ is the double average over regions P and Q of the retarded electric field produced in Q by a unit dipole charge in P. They deduce (1) from the standard Heisenberg uncertainty relation obeyed by the measuring apparatus. The result (1) is precisely the uncertainty relation implied by the commutation rules of quantum electrodynamics. Similar results are found for other components of the electric and magnetic fields.

The question that I am asking is whether the argument of Bohr and Rosenfeld applies also to the gravitational field. If the same argument applies, then the gravitational field must be a quantum field and its quantum nature is in principle observable. However, a close inspection of the Bohr-Rosenfeld argument reveals a crucial feature of their measurement apparatus that makes it inapplicable to gravitational fields. In the last paragraph of Section 3 of the Bohr-Rosenfeld paper, they write: "In order to disturb the electromagnetic field to be measured as little as possible during the presence of the test body system, we shall imagine placed beside each electric or magnetic component particle another exactly oppositely charged neutralizing particle". The neutralizing particles have the following function. Suppose we have a mass carrying a charge or current J whose movement is observed in order to measure the local electric or magnetic field. The movement of the charge or current J produces an additional electromagnetic field that interferes with the field that we are trying to measure. So we must compensate the additional field by adding a second mass, carrying the charge or current $-J$ and occupying the same volume as the first mass. The second mass is constrained by a system of mechanical linkages and springs to follow the movement of the first mass and cancels the fields generated by the first mass. This cancellation is an essential part of the Bohr-Rosenfeld strategy. It is then immediately obvious that the strategy fails for measurement of the gravitational field. The test-objects for measuring the gravitational field are masses rather than charges, and there exist no negative masses that could compensate the fields produced by positive masses.

The conclusion of this argument is that the Bohr-Rosenfeld analysis does not apply to the gravitational field. This does not mean that the gravitational field cannot be quantized.

It means only that the quantization of the gravitational field is not a logical consequence of the quantum behavior of the measuring apparatus. The fact that the electromagnetic field must be quantized does not imply that the gravitational field must be quantized.

3. Can LIGO Detect a Graviton?

In the LIGO experiment, if it is successful, we shall detect a classical gravitational wave, not an individual quantum of gravity. A classical wave may be considered to be a coherent superposition of a large number of gravitons. LIGO is supposed to detect a wave with a strain amplitude f of the order of 10^{-21}. According to [Landau and Lifshitz, 1975], page 370, the energy density of this wave is

$$E = (c^2/32\pi G)\omega^2 f^2, \tag{2}$$

where G is Newton's constant of gravitation and ω is the angular frequency. For a wave with angular frequency 1 Kilohertz and amplitude 10^{-21}, Eq. (2) gives an energy density of roughly 10^{-10} ergs per cubic centimeter. A single graviton of a given angular frequency ω cannot be confined within a region with linear dimension smaller than the reduced wavelength (c/ω). Therefore the energy density of a single graviton of this frequency is at most equal to the energy of the graviton divided by the cube of its reduced wave-length, namely

$$E_s = (\hbar\omega^4/c^3). \tag{3}$$

For an angular frequency of 1 Kilohertz, the single graviton energy density is at most 3.10^{-47} ergs per cubic centimeter. So any gravitational wave detectable by LIGO must contain at least 3.10^{37} gravitons. This wave would be barely detectable by the existing LIGO. For a LIGO apparatus to detect a single graviton, its sensitivity would have to be improved by a factor of the order of 3.10^{37}. Even this vast improvement of sensitivity would probably not be sufficient, because the detection of weak signals is usually limited not only by the sensitivity of the apparatus but also by the presence of background noise. But to see whether detection of single gravitons is possible in principle, we disregard the problem of background radiation and analyze the structure and operation of a super-sensitive LIGO detector.

For a rough estimate of the sensitivity of a LIGO apparatus required to detect a single graviton, we equate (2) with (3). This gives the strain f to be detected by the apparatus,

$$f = (32\pi)^{1/2}(L_p\omega/c), \tag{4}$$

where L_p is the Planck length

$$L_p = (G\hbar/c^3)^{1/2} = 1.4 \times 10^{-33} \text{ cm}. \tag{5}$$

The strain is derived from a measurement of the variation of distance between two masses separated by a distance D. The variation of the measured distance is equal to fD, so long as D does not exceed the reduced wave-length (c/ω) of the graviton. For optimum detectability we take D equal to (c/ω). Then the variation of distance is by (4)

$$\delta = (32\pi)^{1/2}L_p. \tag{6}$$

Up to a factor of order unity, the required precision of measurement of the separation between the two masses is equal to the Planck length, and is independent of the frequency of the graviton.

Is it possible in principle for a LIGO apparatus to measure distances between macroscopic objects to Planck-length accuracy? The following simple arguments give a negative answer to this question. First consider the case in which the objects are floating freely in space. The Heisenberg uncertainty relation between position and momentum of freely floating objects gives the lower bound

$$M\delta^2 \geq \hbar T, \tag{7}$$

for the variation of distance δ, where M is the mass of each object and T is the duration of the measurement. Now T must be greater than the time (D/c) required to communicate between the two masses. If δ is equal to the Planck length, (5) and (7) imply

$$D \leq (GM/c^2). \tag{8}$$

So the separation between the two objects is less than the Schwarzschild radius of each of them, the negative gravitational potential pulling them together is greater than Mc^2, and they are bound to collapse into a black hole before the measurement can be completed.

We next consider the situation that arises when the two masses are clamped in position by a rigid structure. In this case the precision of measurement of the distance between the two objects is limited by quantum fluctuations of the rigid structure. We use a simple dimensional argument to estimate the magnitude of the fluctuations. Let s be the velocity of sound in the structure, let D be the separation between the objects, and let M be the mass of the structure. There will be at least one mode of sound-vibration of the structure which gives a displacement affecting the measurement of D. The mean-square quantum fluctuation amplitude of the displacement in this mode will then be, up to a factor of order unity, at least as large as the zero-point fluctuation,

$$\delta^2 \geq (\hbar D/Ms). \tag{9}$$

The duration of the measurement must be of the order of (D/c), the time it takes the graviton to travel through the apparatus. This duration is shorter than the period (D/s) of the sound-vibration, since s cannot exceed c. Therefore the uncertainty of the measurement is at least equal to the instantaneous vibration-amplitude δ. If the uncertainty is as small as the Planck length (5), then (9) implies

$$(GM/c^2) \geq (c/s)D > D. \tag{10}$$

Again we see that the separation between the two masses is smaller than the Schwarzchild radius of the apparatus, so that the negative gravitational potential of the two masses is greater than Mc^2 and the apparatus will collapse into a black hole. It appears that Nature conspires to forbid any measurement of distance with error smaller than the Planck length. And this prohibition implies that detection of single gravitons with an apparatus resembling LIGO is impossible.

It is clear from Eq. (3) that we have a better chance of detecting a single graviton if we raise the frequency into the optical range and use a different kind of detector. When

the frequency is of the order of 10^{15} Hertz or higher, a single graviton can kick an electron out of an atom, and the electron can be detected by standard methods of atomic or particle physics. We are then dealing with the gravito-electric effect, the gravitational analog of the photo-electric effect which Einstein used in 1905, [Einstein, 1905], to infer the existence of quanta of the electromagnetic field, the quanta which were later called photons. The possibility of detecting individual gravitons in this way depends on two quantities, (a) the cross-section for interaction of a graviton with an atom, and (b) the intensity of possible natural or artificial sources of high-frequency gravitons. Most of this talk will be concerned with estimating these two quantities.

4. Graviton Detectors

The simplest kind of graviton detector is an electron in an atom, which we may approximate by considering the electron to be bound in a fixed non-relativistic potential $V(r)$. We choose coordinate axes so that the z-axis is the direction of motion of a graviton. There are then two orthogonal modes of linear polarization for the graviton, one with the wave-amplitude proportional to xy, and the other with the amplitude proportional to $(x^2 - y^2)$. We choose the x and y-axes so that they make angles of 45 degrees to the plane of polarization of the graviton. Then the matrix element for the electron to absorb the graviton and move from its ground state a to another state b is proportional to the mass-quadrupole component,

$$D_{ab} = m \int \psi_b^* xy \psi_a d\tau, \tag{11}$$

where m is the electron mass. Eq. (11) is the quadrupole approximation, which is valid so long as the wave-length of the graviton is large compared with the size of the atom. The total cross-section for absorption of the graviton by the electron is

$$\sigma(\omega) = (4\pi^2 G\omega^3/c^3) \sum_b |D_{ab}|^2 \delta(E_b - E_a - h\omega), \tag{12}$$

where E_a and E_b are the energies of the initial and final states. It is convenient to consider a logarithmic average of the cross-section over all frequencies ω,

$$S_a = \int \sigma(\omega) d\omega/\omega. \tag{13}$$

Integration of (12) gives the sum-rule

$$S_a = 4\pi^2 L_p^2 Q, \tag{14}$$

where the Planck length L_p is given by (4), and

$$Q = \int |(x\partial/\partial y + y\partial/\partial x)\psi_a|^2 d\tau \tag{15}$$

is a numerical factor of order unity. It is remarkable that the average cross-section (14) is independent of the electron mass and of the nuclear charge. The same formula (14) holds for the absorption of a graviton by a neutron or proton bound in a nuclear potential.

For simplicity we assume that the electron is in an s-state with a wave-function $f(r)$ which is a function of distance r from the nucleus. Then (15) becomes

$$Q = (\int r^4 [f'(r)]^2 dr)/(3 \int r^2 [f(r)]^2 dr). \tag{15}$$

The inequality

$$\int r^4 [f' + (3/2r)f]^2 dr > 0 \tag{16}$$

implies that for any $f(r)$

$$Q > 3/4. \tag{17}$$

On the other hand, if

$$f(r) = r^{-n} \exp(-r/R), \tag{18}$$

then

$$Q = 1 - (n/6). \tag{19}$$

From (17) and (19) it appears that for any tightly-bound s-state Q will be close to unity. The cross-section for absorption of a graviton by any kind of particle will be of the same magnitude

$$4\pi^2 L_p^2 = 4\pi^2 G\hbar/c^3 = 8 \times 10^{-65} \text{ cm}^2, \tag{20}$$

spread over a range of graviton energies extending from the binding-energy of the particle to a few times the binding-energy. For any macroscopic detector composed of ordinary matter, the absorption cross-section will be of the order of 10^{-41} square centimeters per gram.

5. Thermal Graviton Generators

We have a splendid natural generator of thermal gravitons with energies in the kilovolt range, producing far more gravitons than any artificial source is likely to generate. It is called the sun. Stephen Weinberg long ago calculated [Weinberg, 1965] the graviton luminosity of the sun, caused by gravitational bremsstrahlung in collisions of electrons and ions in the sun's core. A later calculation [Gould, 1985] corrected a mistake in Weinberg's paper but does not substantially change the result. For an electron-ion collision with energy E, the differential cross-section $p(\omega)$ for producing a graviton of energy $\hbar\omega$ is divergent at low energies, so that the total cross-section has no meaning. The physically meaningful quantity is the integral of the differential cross-section multiplied by the energy of the graviton,

$$\int p(\omega)\hbar\omega d\omega = (320/9)Z^2\alpha^2 L_p^2 E, \tag{21}$$

where α is the electromagnetic fine-structure constant and Z is the charge of the ion. Including a similar contribution from electron-electron collisions, (21) gives a total graviton luminosity of the sun

$$L_g = 79 \text{ Megawatts}, \tag{22}$$

or about 10^{24} gravitons per second with energy in the kilovolt range. This gives a flux at the earth of

$$F_g = 4 \times 10^{-4} \text{ gravitons per cm}^2 \text{ per second.} \tag{23}$$

If we imagine the whole mass of the earth to be used as a graviton detector, with the cross-section (20) per electron and the flux (23), the counting-rate is 2.4×10^{-17} per second. If the experiment continues for the life-time of the sun, which is 5 billion years, the expected total number of gravitons detected will be 4. The experiment barely succeeds, but in principle it can detect gravitons.

According to [Gould, 1985], there exist in the universe sources of thermal gravitons which are stronger than the sun, namely hot white dwarfs at the beginning of their lives, and hot neutron stars. Gould estimates the graviton luminosities of a typical white dwarf and a typical neutron star to be respectively 10^4 and 10^{10} times solar. Their luminosities are roughly proportional to their central densities. But the life-times during which the stars remain hot are shorter than the life-time of the sun, being of the order of tens of millions of years for the white dwarf and tens of thousands of years for the neutron star. The life-time output of gravitons will therefore be respectively 100 and 10^5 times solar. To stretch the theoretical possibilities of detection to the limit, we may suppose the detector to have mass equal to the sun and to be orbiting around the source of gravitons at a distance of 0.01 astronomical unit with an orbital period of 8 hours. Then the expected number of gravitons detected will be of the order of 10^{13} for the white dwarf and 10^{16} for the neutron star. The detection rate is roughly one per minute for the white dwarf and 3×10^4 per second for the neutron star. The conclusion of this calculation is that graviton detection is in principle possible, if we disregard the problem of discriminating the graviton signal from background noise.

The most important source of background noise is probably the neutrinos emitted by the sun or the white dwarf or the neutron star as the case may be. These neutrinos can mimic graviton absorption events by ejecting electrons from atoms as a result of neutrino-electron scattering. The neutrinos have higher energy than the gravitons, but only a small fraction of

the neutrino energy may be transferred to the electron. From the sun, about 10^{14} neutrinos are emitted for each graviton, and the cross-section for neutrino-electron scattering is about 10^{20} times the cross-section for graviton absorption, [see Fukugita and Yanagida, 2003]. Therefore there will be about 10^{34} neutrino background events for each graviton absorption event.

For white-dwarfs and neutron-stars the ratio of background to signal is even larger, since neutrino production and scattering cross-sections increase with temperature more rapidly than graviton production and absorption cross-sections. Without performing detailed calculations, we can assert that for all thermal sources of gravitons the ratio of neutrino background to graviton signal will be of the order of 10^{34} or greater. In all cases, the total number of detected graviton events is vastly smaller than the square-root of the number of background events. The graviton signal will be swamped by the statistical scatter of the background noise.

Before jumping to conclusions about the detectability of gravitons, we must explore possible ways in which the neutrino background events might be excluded. The first possible way is to surround the detector with a shield thick enough to stop neutrinos but let gravitons pass. If the shield is made of matter of ordinary density, its thickness must be of the order 10^{10} kilometers, and its mass is so large that it will collapse into a black hole. The second possible way is to surround the graviton detector with neutrino detectors in anti-coincidence, to catch the outgoing neutrino after each scattering event. This way fails for the same reason as the shield. The neutrino detectors would need to be at least as massive as the shield. The third possible way is to build a shield or a set of anti-coincidence detectors out of some mythical material with super-high density. The known laws of physics give us no clue as to how this might be done. We conclude that, if we are using known materials and known physical processes, detection of thermal gravitons appears to be impossible.

6. Non-thermal Gravitons

It is possible to imagine various ways in which energetic objects such as pulsars may emit non-thermal gravitons of high energy. One such way is a process first identified by

[Gertsenshtein, 1961], the coherent mixing of photon and graviton states in the presence of an extended classical magnetic field. The graviton emission from various celestial objects resulting from the Gertsenshtein process was calculated by [Papini and Valluri, 1989]. Some interestingly high graviton luminosities were predicted.

The Gertsenshtein process results from the interaction energy

$$(8\pi G/c^4)h_{ij}T_{ij}, \tag{24}$$

between the gravitational field h_{ij} and the energy-momentum tensor T_{ij} of the electromagnetic field. This interaction expresses the fact that electromagnetic fields have weight, just like other forms of energy. Now suppose that h_{ij} is the field of a graviton traveling in the z direction and

$$T_{ij} = (1/4\pi)(B_i + b_i)(B_j + b_j), \tag{25}$$

is the energy-momentum of the photon magnetic field b_i superimposed on a fixed classical magnetic field B_i. Then the interaction (24) contains the term

$$I = (4G/c^4)h_{xy}B_x b_y, \tag{26}$$

bilinear in the graviton and photon fields. The effect of this bilinear term is to mix the photon and graviton fields, so that a particle that is created as a photon may be transformed into a graviton and vice versa. There is an oscillation between graviton and photon states, just like the oscillation between neutrino states that causes neutrinos to change their flavors while traveling between the sun and the earth. If a photon travels a distance D though a uniform transverse magnetic field B, it will emerge as a graviton with probability

$$P = \sin^2(G^{1/2}BD/2c^2) = \sin^2(B/L), \tag{27}$$

with the mixing-length

$$L = (2c^2/G^{1/2}B) \tag{28}$$

independent of wave-length. In all practical situations, D will be small compared with L, so that

$$P = (GB^2D^2/4c^4). \tag{29}$$

The quadratic dependence of P on D makes this process interesting as a possible astrophysical source of gravitons. The numerical value of L according to (28) is roughly

$$L = (10^{25}/B), \tag{30}$$

when L is measured in centimeters and B in Gauss.

We may also consider the Gertsenshtein process as the basis of a graviton detector consisting of a hollow pipe of length D filled with a transverse magnetic field B. The tube must be accurately pointed at a putative source of gravitons in the sky. At the far end of the tube is a shield to block incident photons, and at the near end is a detector of photons resulting from the conversion of gravitons on their way through the tube. If D is one astronomical unit (10^{13} cm), then (29) gives

$$P = 10^{-24}B^2. \tag{31}$$

The field B must be very strong to obtain a reasonable rate of conversion of gravitons to photons. A detector with the same design has been used in a real experiment to detect axions that might be created by thermal processes in the core of the sun [Zioutas et al., 2005]. The axion field is supposed to interact with the electromagnetic field with an interaction energy similar to (26), but with a much larger coupling constant. The experimenters at CERN in Switzerland are using a surplus magnet from the Large Hadron Collider project as an axion-detector, pointing it at the sun and looking for kilovolt photons resulting from conversion of axions into photons. The length of the magnet is 9 meters and the magnetic field is 9×10^4 Gauss. They have not yet detected any axions.

The Gertsenshtein process does not require the classical magnetic field to be uniform. For a non-uniform field, the conversion of photons to gravitons still occurs with probability

given by (27), if we replace the product BD by the integral of the transverse component of B along the trajectory of the photons. Likewise, the conversion will not be disturbed by a background gravitational field, even when the field is strong enough to curve the photon trajectory, because the gravitational field acts in the same way on photons and gravitons. In a curved space-time, the photons and the gravitons follow the same geodesic paths, and the photon and graviton waves remain coherent.

7. Non-linear Electrodynamics

However, there is an important disturbing factor which was neglected in previous discussions of the Gertsenshtein process. The disturbing factor is the non-linearity of the electromagnetic field caused by quantum fluctuations of electron-positron pairs in the vacuum, [Euler and Heisenberg, 1936; Wentzel, 1943]. The fourth-order term in the electromagnetic field energy density is [Wentzel, 1943, page 190],

$$(\alpha/360\pi^2 H_c^2)[(E^2 - H^2)^2 + 7(E.H)^2], \tag{32}$$

where α is the fine-structure constant and

$$H_c = (m^2c^3/e\hbar) = 5.10^{13}\text{Gauss} \tag{33}$$

is the critical magnetic field at which electron-positron pair fluctuations become noticeable.

When the field in (32) is divided into classical and photon components as in (25), there is a term quadratic in both the classical and photon fields,

$$(\alpha/360\pi^2 H_c^2)(4(B.b)^2 + 7(B.e)^2), \tag{34}$$

where b and e are the magnetic and electric fields of the photon. From (34) it follows that the photon velocity v is not equal to c but is reduced by a fraction

$$g = 1 - (v/c) = (k\alpha B^2/360\pi^2 H_c^2). \tag{35}$$

The coefficient k is equal to 4 or 7 for a photon polarized with its magnetic field or its electric field parallel to B. We consider the case $k = 4$, since that case is more favorable to the Gertsenshtein process. Since the graviton field is not affected by the non-linear electromagnetic interaction (32), the graviton velocity is precisely c, and the photon and graviton waves will lose coherence after traveling for a distance

$$L_c = (c/g\omega) = (90\pi^2 c H_c^2/\alpha B^2 \omega) = (10^{43}/B^2\omega). \tag{36}$$

If the propagation distance D is larger than L_c, the Gertsenshtein process fails and the formula (29) for the photon-graviton conversion probability is incorrect. A necessary condition for the Gertsenshtein process to operate is

$$DB^2\omega \leq 10^{43}. \tag{37}$$

Furthermore, even when the Gertsenshtein process is operating, the probability of photon-graviton conversion according to (29) and (37) is

$$P \leq (10^{36}/B^2\omega^2). \tag{38}$$

We are interested in detecting astrophysical sources of gravitons with energies up to 100 kilovolts, which means frequencies up to 10^{20}. With $\omega = 10^{20}$, (37) and (38) become

$$D \leq (10^{23}/B^2), \quad P \leq (10^{-4}/B^2). \tag{39}$$

We consider two situations in which (39) has important consequences. First, with typical values for the magnetic field and linear dimension of a pulsar, $B = 10^{12}$ and $D = 10^6$, (39) shows that the Gertsenshtein process fails by a wide margin. The calculations of the graviton luminosity of pulsars in [Papini and Valluri, 1989] assume that the Gertsenshtein process is producing high-energy gravitons. These calculations, and the high luminosities that they predict, are therefore incorrect. Second, in the hollow pipe graviton detector which we considered earlier, (39) shows that the Gertsenshtein process can operate with a modest

field, $B = 10^5$ Gauss, and a pipe length $D = 10^{13}$ cm, but the probability of detection of each graviton traveling through the pipe is only 10^{-14}. If the field is made stronger, the length of the pipe must be shorter according to (39), and the probability of detecting a graviton becomes even smaller.

8. Conclusions

Many papers have been published, for example [Eppley and Hannah, 1977; Page and Geilker, 1981], claiming to demonstrate that the gravitational field must be quantized. What these papers demonstrate is that a particular theory with a classical gravitational field interacting with quantum-mechanical matter is inconsistent. Page and Geilker assume that the classical gravitational field is generated by the expectation value of the energy-momentum tensor of the matter in whichever quantum state the matter happens to be. They performed an ingenious experiment to verify that this assumption in fact gives the wrong answer for a measurement of the gravitational field in a real situation.

In this paper I am not advocating any particular theory of a classical gravitational field existing in an otherwise quantum-mechanical world. I am raising two separate questions. I am asking whether either one of two theoretical hypotheses may be experimentally testable. One hypothesis is that gravity is a quantum field and gravitons exist. A second hypothesis is that the gravitational field is a statistical concept like entropy or temperature, only defined for gravitational effects of matter in bulk and not for effects of individual elementary particles. If the second hypothesis is true, then the gravitational field is not a local field like the electromagnetic field. The second hypothesis implies that the gravitational field at a point in space-time does not exist, either as a classical or as a quantum field.

Now I assert that both of the two hypotheses may or may not be experimentally testable. Analysis of the properties of graviton-detectors, following the methods of this paper, might be able to throw light on both hypotheses. Three outcomes are logically possible. If a graviton detector is possible and succeeds in detecting gravitons, then the first hypothesis is true and the second is false. If a graviton detector is possible and fails to detect gravitons, then the first hypothesis is false and the second is open. If a graviton detector is in principle

impossible, then both hypotheses remain open. Even if their existence is not experimentally testable, gravitons may still exist.

The conclusion of our analysis is that we are still a long way from settling the question whether gravitons exist. But the question whether gravitons are in principle detectable is also interesting and may be easier to decide.

A Model for a Gravity Wave at the Quantum Level

Karl V. Thompson

May 7, 2012

Abstract

A classical model that meets the requirements of the Stochastic interpretation of Quantum Mechanics as laid down by D. Bohm and J.P. Vigier is proposed for further study. It appears to explain the wave/particle duality of both photons and electrons. It suggests that a steady state solution is applicable to DeBroglie waves. It yields an explanation for both the nature and source mechanism of the gravitational wave, both on the quantum and astronomical scales. A computation for the gravitational wave of the electron at rest in the earth's gravitational field is given. It suggests a direct link between gravity and electrodynamics. Both elastic and inelastic collisions between photons and electrons are discussed as well as the mechanism of the influence of a magnetic field on an electron. This model does not conflict unduly with the existing work by Einstein, Maxwell, or DeBroglie, nor with any experimental evidence the author is aware of.

A. THE MODEL

The generalized model to be investigated has been suggested and discussed many times in the past by DeBroglie, Dirac, Bohm, Vigier, and others. It is a binary model consisting of a wave that acts as an oscillator and propagates a second wave thru an aether. Unfortunately a good understanding of the oscillator has kept the model from reaching maturity. This following development of a model of this sort is sorely needed for examination by the physics community because it opens up new possibilities for investigation and leads directly to a model showing that a single wave may act as the source of both the gravitational and electromagnetic fields simultaneously, as well as furnish a detailed explanation of wave/particle duality for the electromagnetic wave and the electron.

It differs from previous efforts in four ways. First, the oscillator is proposed to be a wave that always travels with a constant wave momentum[1] under the influence of gravity while the generated wave is proposed to be a wave that travels with a varying wave momentum. The oscillator is only affected by gravity at the time of emission[1]. Secondly, there is no need to propose an aether as a separate entity. The generated waves, collectively from all the oscillating systems throughout the universe, form the needed aether. Thirdly, a set of boundary conditions have been worked out that satisfy existing experimental evidence and make new predictions. Fourth, the model applies equally well to the electron as to the electromagnetic wave.

B. OUTLINE OF DEVELOPMENT

First, the author wants to make it clear that this entire article is only a model and it only attempts to justify qualitatively the effects of the gravitational effect derived from this model. Such justifications and proofs, outside of the gravitational effect, will be left to others to verify or discredit.

Assumptions will be made early in the development and all of these assumptions will seemingly become justified by the results of the predictions of the model being in agreement quantitatively with all experimental observations, and with Einstein's General Theory, and in qualitative agreement with Maxwell's Equations. Despite a difference in form, the model will agree quantitatively with DeBroglie's conditions for matter waves. The energy considerations of the model will differ radically with those of the standard model of the electromagnetic wave.

Classified in terms of wave momentum, only two types of waves can exist. They are waves that travel with wave momentum constant, and waves that travel with their wave momentum not constant. If everything is believed to have a wave nature, then following this reasoning everything could have at its base a model no more complicated than a binary wave system if you ignore geometry.

In setting up the initial model we will seek to divest ourselves of the problem of describing observer dominated events and initially develop, in Euclidian space, the physical properties of a modified electromagnetic wave, having a mass, that always travels through changes in gravitational potential with a wave momentum that is constant. We want to see just what such a wave's characteristics will be.

It should be noted that in section J. we will address the objection, held by so many, to assignment of a mass greater than $hf/C^2$to the electromagnetic wave.

Einstein (1911)[2] had already reasoned, that the electromagnetic wave must travel, under the gravitational influence in Euclidian space, with a constant wave momentum and that this would cause light to bend as it traveled around the sun. Subsequently, observations [3] by Campbell and Trumpler in 1923 verified this prediction in a qualitative manner based on this reasoning. Quantitatively, their measurement was twice the arc predicted by the 1911 article, however the General Theory , in 1916, corrected the 1911 prediction and agreed with Campbell and Trumpler. Therefore it seems that the assigning of a constant wave momentum to an electromagnetic wave is neither new nor unreasonable. Light does exhibit a wave particle duality, and we normally associate a mass with a particle. The assignment of a mass to the electromagnetic wave allows investigation of the gen-

eralized case.

We will develop the relativistic equations describing such a wave and consider them against experiment. There will be a discrepancy in energy at emission when considering the measured shift in wavelength between photons produced in different gravitational intensities. We will work out the boundary conditions for our wave to satisfy the experimental results, and in so doing will conclude that there had to be a three way energy transfer at emission, and that part of the energy appeared to be transferred from the gravitational field to the modified electromagnetic wave.

It will next be postulated that the modified electromagnetic wave must be more complicated. We will then conclude that our model is incomplete and will then propose a new model that consists of two components. We will postulate that a photon wave, acting as an oscillator, coupled to an associated matter wave exists. We will proceed to develop the boundary conditions for this model. We will then postulate that this model can exist in two geometries, one for the electron and one for the electromagnetic wave. Using the results previously developed, we next derive a steady state solution for matter waves in the case of the electron. This model strongly suggests that gravitational waves are components of DeBroglie waves[4] in this steady state.

We will numerically compute the properties for an electron in this state and break the matter wave into two components thereby uncovering how conservation of energy can work at its most basic level. We will then compute and find that this model does indeed match DeBroglie's calculations on a quantitative basis. This model conforms exactly to the precepts of the General Theory and confirms some of Einstein's opinions on the base nature of matter and the existence of an aether as a possibility. We will find that there is a remarkable similarity of this DeBroglie wave's geometry to the characteristics of the electric and magnetic fields and this will be discussed.

We should note here that such a model has been suggested before. A good review of efforts along these lines is given in a discussion by L.V.Chebotarev [5], "The Bohm-Vigier Approach in Quantum Mechanics". Indeed, we already know that a binary system exists at the base level from experiment[6] showing that an electron in motion has a wave associated with it.

Ç. DEFINITIONS and TERMINOLOGY

Before beginning the development of the model we need to make definitions to make the reading of the development easier.

1. The first definition is that, since this entire presentation is basically about gravitational effects, the concept of a force opposing, or in the direction of motion, is really a statement of the gravitational intensity decreasing or increasing respectively. Force is taken to be a function of the gravitational intensity Φ, i. e., $F = f(\Phi)$. Force increases when Φ increases. Early in the development the concept of force is replaced with change in gravitational intensity. Actually later in the development we will show that force is a function of both energy and geometry and that Newton"s "Law of Universal Gravitation" does not hold between systems of different DeBroglie wave geometry.

2. The second definition is that when we refer to a photon we are referring to the standard model of the photon without any electromagnetic components and modified by the assigning of a mass to it.

3. Any time we refer to a photon without mass we will call it "The standard model".

4. Anytime we refer to the standard model with its electromagnetic attributes we will use the term "electromagnetic wave".

5. The fifth definition is that when we we refer to a wave of "constant wave momentum" we are referring to the model described above in the second definition.

6. The sixth definition is that when we refer to a wave of "non-constant wave momentum" we are speaking of a DeBroglie wave.

7.When we speak of the induction of energy between the DeBroglie wave of our model and other DeBroglie waves we are referring to constructive/destructive wave interference that alters the energy distribution within our model's DeBroglie wave.

8. The last definition is that all results are obtained using the boundary condition that when Φ approaches zero that $hfo = moC_0^2$. This allows one to eliminate observer dominated results by referencing all discussion to this boundary condition.

D. THE PHOTON IN A GRAVITATIONAL FIELD

We will initially be interested in deriving all of the characteristics of a electromagnetic wave with mass under the influence of gravity, however we will only be interested initially in the energy of this wave. Since, under standard theory no energy is attributed to the electromagnetic characteristics of the wave we will ignore them. We will call the wave itself a photon and its wave energy will be defined by Planck's hypothesis

$$E_\lambda = nhf \tag{1}$$

, and its wave characteristics will obey the wave equation,

$$C_0 = f\lambda \tag{2}$$

. Since we are assigning an arbitrary mass to the wave its mass energy must obey Einstein's equation,

$$E = mC_0{}^2 \tag{3}$$

. We are initially interested in seeing what effect gravity will have on this photon system and we will assume a boundary condition that will be a function of the gravitational intensity, Φ, of the form

$$nhf_0 = m_0C_0{}^2 \tag{4}$$

where f_0 and m_0 are the values of the frequency and the mass when $\Phi = 0$. We will set n=1 for the remainder of this article.

Because we are building a model and we want this model to obey general relativity we will take the liberty of introducing a negative sign in equation (10) to insure that the frequency decreases as the gravitational intensity Φ increases[7][1].We will also introduce a negative sign to Newton's Law of Gravitation to assure that Φ represents the gravitational intensity, not the gravitational potential energy.

Consider first a quanta of energy, E, at some great distance from a large mass, say the Sun. Let it have a mass, m, defined according to Equation (3), $E = mC_0^2$ Let it be free from any influence except the gravitational field of the Sun. It is "at rest". Now let it fall solely under the gravitational influence on its mass to some distance r from the Sun.

Since for a mass,

$$F = C_0^2\frac{dm}{dr} , \tag{5}$$

and

$$F = -\frac{GMm}{r^2} , \tag{6}$$

we can then say

$$C_0^2\frac{dm}{dr} = -\frac{GMm}{r^2} ,$$

and for a quanta of energy of mass m falling into a gravitational field from infinity we would say

$$\int_{m_0}^{m}\frac{dm}{m} = -G\frac{M}{C_0^2}\int_{\infty}^{r}\frac{dr}{r^2} , \tag{7}$$

where m varies from m_0 at infinity to m at some distance r from the center of the source of the gravitational intensity. Defining the gravitational intensity Φ, at r as:

$$\Phi = \frac{GM}{r} \; and \; d\Phi = -\frac{GM}{r^2}\,dr ,$$

and changing variables, we have

$$\int_{m_0}^{m_\Phi}\frac{dm}{m} = \frac{1}{C_0^2}\int_0^{\Phi} d\Phi , \tag{8}$$

and integrating with respect to Φ we get

$$\ln\frac{m_\Phi}{m_0} = \frac{\Phi}{C_0^2} ,$$

or

$$m_\Phi \;=\; m_0 e^{\frac{\Phi}{C_0^2}} \;. \tag{9}$$

Now assume that the quanta of energy is in the form of a wave that obeys equation (2), the wave equation. We will assume that this is a photon. The frequency of the photon is linked to the mass of the photon by the boundary condition of equation (4)which describes a stable condition at $\Phi \;=\; 0$.

We then have,

$$-h\frac{df}{dr} \;=\; -\,G\frac{Mm}{r^2} \;. \tag{10}$$

But since we saw that

$$m_\Phi \;=\; m_0 e^{\frac{\Phi}{C_0^2}} \; or \; m_\Phi \;=\; m_0 e^{\frac{GM}{rC_0^2}} \;,$$

using the substitutions and noting that Φ_0 was taken to be zero,

$$\Phi \;=\; \frac{GM}{r} \; and \; d\Phi \;=\; -\,\frac{GM}{r^2}dr$$

we can obtain

$$-h\int_{f_0}^{f} df \;=\; m_0 C_0^2 \int_{\Phi_0}^{\Phi} \frac{1}{C_0^2}\, e^{\frac{\Phi}{C_0^2}}\, d\Phi \;. \tag{11}$$

This can be shown to yield when , Φ_0 equals zero,

$$f_\Phi \;=\; f_0 e^{\frac{-\Phi}{C_0^2}} \;, \tag{12}$$

for the frequency in terms of the photon's initial frequency f_0, and the potential difference, Φ. Our photon obeys the wave equation $C \;=\; \lambda f$ at emission, and wavelength was assumed to be thereafter a constant for our model. Summarizing, the general equations describing the internal attributes of a photon's wave in a potential Φ are:

$$m_\Phi \;=\; m_0 e^{\frac{\Phi}{C_0^2}} \;. \tag{9}$$

$$f_\Phi \;=\; f_0 e^{\frac{-\Phi}{C_0^2}} \;, \tag{12}$$

The approximate forms are:

$$m_\Phi \;=\; m_0\,[1+\frac{\Phi)}{C_0^2}] \tag{9a}$$

and,

$$f_\Phi \;=\; f_0\,[1-\frac{\Phi)}{C_0^2}] \tag{12a}$$

where C_0 is the speed of the photon's internal wave at emission and is defined by equation (19).

As a matter of convenience, we will define m_0 and f_0 by

$$hf_0 \;=\; m_0 C_0^2 \tag{13}$$

where m_0,f_0 , and C_0^2 are the values obtained when a photon is emitted in a zero gravitational intensity ($\Phi \;=\; 0$), our boundary condition .

These same results were predicted in 1916 in Einstein's "The Foundation of the General Theory of Relativity"[7].

Calculation of the ratio of the periods of like photons on the Sun and the Earth gives,

$$\frac{Period\;(sun)}{Period\;(earth)} \;=\; 1.0000021 \;,$$

which is in very good agreement with the predictions of the General Theory of Relativity according to Lieber[9].

The photon's wave momentum was assumed always constant and , if so, would be given by

$$p_\lambda \;=\; h\frac{f_\Phi}{C_0} \;=\; \frac{h}{\lambda} \;. \tag{14}$$

If this is so then we deduce that the frequency[1] of the wave can not change as the wave travels thru changing gravitational intensities since C_0 and λ are constants. This implies, that for our model, the wave energy does not change as the photon(the oscillator) travels thru varying gravitational intensities. Therefore, it must be concluded that equation (12) applies only at emission. However we note that there are no such limits placed on the mass of our model. It will obey equation(9) as Φ changes.

At this point in this paper no discussion or assumptions are made about what happens in elastic

or inelastic collisions or interactions with an electromagnetic field. This is really outside of the scope of this article and will be covered later in the summation.

It can be shown that the difference, at emission, between the wave energy, calculated using (12) with (1), and the mass energy, calculated using (9) with (3), is twice the difference between the rest mass energy and the wave energy. The mass energy represents the total energy our photon model has according to $E = mC_0{}^2$ .This result will be shown later in this discussion to have a significant physical meaning and this difference is probably the most significant step toward the results of the rest of this article.

A correspondence between the model and General Theory seems to be emerging. The photon's frequency seems to be equivalent to the rate at which a relativistic unit clock precesses, and the increase in the photon's mass in Euclidian space seems to be equivalent to a contraction of a relativistic unit measuring rod[8] lying along the radius between the gravitational source and the photon as described by the General Theory. This can be confirmed by comparing Einstein's g_{11} and g_{44} tensors of the second rank with the case of the photon in a gravitational field.

Note that f_Φ is a spacial variable related only to the gravitational intensity, while m_Φ is also a spacial variable but is related both to the gravitational intensity and to the total energy of the photon model through both (3) and (13). This means that we can express f_Φ and m_Φ in terms of (12) and of (9) taking $\Phi_0 = 0$. We used this property of the mass in setting up the differential of (11).

E. THE EMISSION OF A PHOTON

We are now in a position to discuss the photon attributes in more detail. Equation (12) tells us in what manner our photon model's frequency, at emission, adjusts to it's potential environment. It decreases as Φ increases. Equation (9) shows that the mass, $\frac{totalenergy}{C_0{}^2}$ adjusts in a similar manner at emission ,however, for our model, there were no limits placed on the mass so it is assumed that, not only at emission, the mass also changes, according to equation (9), as it moves thru varying changes in Φ.

We have already concluded that for equation (12) the assumption of constant wave momentum precludes any changes in frequency as the photon moves from one Φ to a different Φ .

There were results first reported by Evershed and Adams[10] that showed that the wavelengths of spectral lines arriving on Earth from Sirius, Procyon, and Arcturus were longer than the wavelengths of spectral lines originating on the Earth. Obviously, something happens at the birth of a photon that is a function of Φ but is not adequately described by our development of equations (9) and (12) to date. Our understanding of the photon at the boundary condition of birth is incomplete.

We will assume that the wavelength is a function of the potential environment, Φ, at birth, and that this wavelength is given by

$$\lambda_{\Phi'} = \frac{C_0}{f_{\Phi'}} \ , \ \Phi' \text{ being the potential of birth.} \quad (15)$$

If an amount of energy E is transferred to the photon at birth, it must be defined by Einstein's mass energy relationship (3),

$$E = mC_0^2 \ ,$$

which gives an expression for the boundary condition of birth of the form

$$\lambda_{\Phi'} = \frac{1}{f_{\Phi'}} (\frac{E}{m})^{\frac{1}{2}} \ , \quad (16)$$

where the ratio,$(\frac{E}{m})$, must be a constant independent of the birth potential if the results of the Evershed and Adams experiments are to be satisfied.

Consider what happens if the ratio $(\frac{E}{m})$ is adjusted to the potential of the birth environment.

If, using the wave and total energies as a function of Φ , then:

$$\lambda_{\Phi'} = \frac{1}{f_{\Phi'}} (\frac{hf_{\Phi'}}{m_{\Phi'}})^{\frac{1}{2}} \ , \ f_{\Phi'} = f_0 e^{-\frac{\Phi'}{C_0^2}} \ ,$$

and

$$m_{\Phi'} \;=\; m_0 e^{\frac{\Phi'}{C_0^2}} \;,$$

then

$$\lambda_{\Phi'} \;=\; \frac{1}{f}_0 (\frac{E_0}{m_0})^{\frac{1}{2}} \quad . \tag{17}$$

We find that the wavelength is a constant for all like processes and environments, i.e., the wavelength of a sodium D photon emitted on the sun would be the same as the wavelength of a sodium D photon emitted on the earth. This would cause our model to violate experimental observations[10].

Now look at what happens when the ratio $(\frac{E}{m})$ is a constant. If we define this ratio as $(\frac{E_0}{m_0})$, where m_0 is the mass of a photon that is in a force free environment such that $E_0 \;=\; m_0 c_0^2 \;=\; hf_0$, then

$$\lambda_{\Phi'} \;=\; \frac{1}{f}_{\Phi'} (\frac{E_0}{m_0})^{\frac{1}{2}} \;,$$

and we have

$$\lambda_{\Phi'} \;=\; \frac{e^{\frac{\Phi'}{C_0^2}}}{f_0} (\frac{E_0}{m_0})^{\frac{1}{2}} \;. \tag{18}$$

Then if Φ_1 is greater than Φ_2, $f_{\Phi 1}$ will be less than $f_{\Phi 2}$, and thus the wavelength of a photon born on the sun will be longer than that of a photon emitted on earth, satisfying experimental evidence[10] and General Relativity. If we substitute, into the wave equation, (2), the wavelength λ', and $f_{\Phi'}$ and solve this simultaneously with (19) under the definition of (13), eliminating E_0 we obtain the result that $C' = C_0$.

All photons are born with an initial wave velocity equal to C_0. C_0 is linked to the energy given to the photon at birth according to the relation

$$E_0 \;=\; m_0 C_0^2 \tag{19}$$

, where m_0 is the mass that photon would have in a force free environment at rest, i.e. when Φ approaches zero.

The circumstances of a photon's emission define the frequency(12) and the mass(9) as functions of Φ. The wavelength, defined by the wave equation is $\lambda \;=\; \frac{C_0}{f'_\Phi}$.

Immediately we see from the boundary conditions at emission, that the photon development requires that the creation of a new photon involves a three way energy transfer. The emitting system gives up an amount of energy E_0, the photon wave itself gets energy

$$E_\lambda \;=\; hf_{\Phi'} \;, \tag{20}$$

and an amount of energy dE must be transferred to some other entity, where

$$dE \;=\; E_0 \;-\; hf_{\Phi'} \;=\; h(f_0 \;-\; f_{\Phi'}) \;. \tag{21}$$

Now being perfectly objective about this missing energy, there is an alternative explanation. It could be argued that the energy is transferred back into the emitting system itself, i. e. , the atom. Otherwise it seems that the gravitational field must be the recipient of this energy. It is the third party in this event.

We should note for future discussion that the emission of our photon is the result of an electromagnetic event, i.e. a change in the status of an electrical system. The discussion of the necessity for a three way energy interchange,(21), gives a first indication that our model is incomplete. We note that we have been discussing a wave that travels always with its wave momentum constant. We note also that if we accept the premise that all energy is in the form of waves, that there is only one option available to us to describe the form of the missing energy. It has had to be transferred to a wave that travels with its wave momentum not constant. These waves are generally called DeBroglie waves. Classified in terms of wave momentum only two types of energy can exist.

This implies that the gravitational field is composed of DeBroglie waves and this is a profound conclusion that cannot be reached under the standard model of the photon in such a direct manner if at all. This implication means that the difference in energy between equation (9) and equation (12) using the birth potential, Φ' , gives the exact energy of the DeBroglie wave at emission.

This three way transfer, at emission, can be shown to satisfy conservation of energy over the photon's life cycle. The Evershed and Adams experiments cannot be satisfied for a photon by any other conclusions. This is the first indication that, for a photon to have a mass, a binary model is required. At this point we will assume, following DeBroglie[11], D. Bohm, and J.P Vigier[12][13][14][15] that the mechanism for producing the DeBroglie wave is that the our photon model (wave of constant wave momentum)acts as an oscillator creating a disturbance in the gravitational aether and generates a DeBroglie wave in the aether creating a wave (of non constant wave momentum) having a wave energy of

$$hf_0 \ - \ hf_{\Phi'}$$

, and that, at emission, a similar equal amount of energy is induced from the gravitational aether into the generated DeBroglie wave, thus accounting for the discrepancy in energy between equations (9) and 12) of the amount, $\Delta E \ = \ m_0 C_0^2 \ [e^{\frac{2\Phi'}{C_0^2}} \ - \ 1]$.

Now, an interpretation of the scope of influence of equations (9) and (12) is possible. It is immediately apparent that we are forced to consider a binary model. We will discuss this in the context of energy considerations as this binary model climbs out of the gravitational well of the sun and travels to earth.

If the photon wave (of constant wave momentum), the oscillator, of the our binary model must travel unchanged from sun to earth it is easily seen that it is the Debroglie wave which must lose energy in the amount of the change in potential energy between the sun and the earth, the same amount as said to be lost from the standard photon model due to a decrease in its frequency.

Furthermore, as the system travels, the energy lost from the debroglie wave can be considered lost by the mechanism of a reduction in the energy induced from the aether. This is easily deduced because the oscillator will continue to generate the same amount of energy into the debroglie wave but the level of energy in the aether will decrease as the system moves out of the well so the interaction (induction) will decrease proportionately to the to the decrease in gravitational intensity.

This reasoning of this section furnishes the basis for the discussions in the remainder of this paper.

F. GENERAL PROPERTIES OF WAVES WHEN P IS NOT CONSTANT

In this section we want to digress from our discussion of the photon to discuss a wave with mass that travels with non-constant momentum and increasing energy when a force is applied in the direction of motion. The wave equation for such a wave would be given by

$$v \ = \ \lambda \ \times \ f \ , \tag{22}$$

instead of (2),

$$c \ = \ \lambda \ \times \ f \ .$$

For such a system, if its wave energy is to increase, the force differential describing its frequency would be given by

$$F \ = \ nh\frac{df}{dx} \ , \tag{23}$$

and the force differential describing its mass would be given by,

$$F \ = \ C_0^2 \frac{dm}{dx} \ ,$$

and Newton's hypothesis would apply.

$$F \ = \ \frac{d(mv)}{dt} \ , \tag{24}$$

i.e., force is equivalent to the derivative of the momentum of a system with respect to time.

We solve for mass as a function of velocity. Taking the force to be in the direction of motion we have

$$C_0^2 \frac{dm}{dx} \ = \ m\frac{dv}{dt} \ + \ v\frac{dm}{dt} \ ,$$

which yields

$$C_0^2 dm \ = \ mvdv \ + \ v^2 dm \ ,$$

or

$$\frac{dm}{m} \ = \ \frac{vdv}{(C_0^2 - v^2)} \ .$$

Letting $u = C_0^2 - v^2$ and $du = -2vdv$, and integrating and substituting for u and du, we have

$$\ln\ m\ |_{m_0}^{m} \ = \ -\frac{1}{2}\ln(C_0^2 - v^2)\ |_{v_1}^{v}\ ,$$

which evaluates to

$$\ln(\frac{m}{m_0}) \ = \ -\frac{1}{2}\ln\ \frac{(C_0^2 - v^2)}{(C_0^2 - v_1^2)}\ ,$$

which then gives

$$m \ = \ m_0[1 \ + \ \frac{1}{C_0^2}(v_1^2 - v^2)]^{-\frac{1}{2}}\ . \qquad (25)$$

Similarly, we can solve equations (23) and (24) simultaneously by eliminating force and we will obtain an expression for frequency as a function of velocity. Taking force to be in the direction of motion we have

$$h\frac{df}{dx} \ = \ m\frac{dv}{dt} \ + \ v\frac{dm}{dt}\ ,$$

or

$$hdf \ = \ mvdv \ + \ v^2dm\ . \qquad (26)$$

using $m = \frac{hf}{C_0^2}$ and $dm = \frac{hdf}{C_0^2}$ we can obtain

$$C_0^2df \ = \ fvdv \ + \ v^2df\ . \qquad (27)$$

Integrating f from f_1 to f, and v from v_1 to v, we get;

$$\frac{f}{f_1} \ = \ [\ (\frac{C_0^2 - v^2}{C_0^2 - v_1^2})\ ]^{-\frac{1}{2}}\ ,$$

or

$$f \ = \ f_1[1 \ + \ \frac{1}{C_0^2}(v_1^2 - v^2)]^{-\frac{1}{2}}\ . \qquad (28)$$

Now (25), when $v_1 = 0$, is the well-known relationship for relativistic mass containing the Lorentz factor. We now have relationships relating the mass and frequency to the motion for waves that travel with momentum not constant.

G. A BINARY SYSTEM

Now we essentially proposed a modification to our model in section E. It was proposed that our photon model was only part of a more complicated system. This extended photon system, we will refer to a "binary system" because it is composed of two interrelated waves of different characteristics. We will propose that exactly the same binary system can have dual geometries. Both geometries are composed of a photon and an associated DeBroglie wave. Both geometries will share exactly the same energy characteristics except for the effect of geometry on the energy distribution in space.

Both of the geometries will consist of a photon(acting as an oscillator) that generates an attached DeBroglie wave. The geometry of the oscillator can exist in either a linear(open geometry) or in a circular(closed geometry) state. The electron will have closed geometry and the photon will have open geometry. Closed geometry will imply that the photon(the oscillator)of our binary model is in a closed circular orbit. Open geometry will imply that the photon (the oscillator)of our binary model travels in a linear manner. This will be discussed in more detail in a later section.

As mentioned earlier in this article, this proposal is neither new nor radical. The Stochastic, Causal, interpretation of quantum mechanics as put forth by D. Bohm and J.P. Vigier and resulting in the Bohm-Vigier model[5][13][15] describes a similar model. This model consisted of two waves. A linear pilot wave, P wave, that described the particle's drift motion and a non linear soliton wave, S wave, that followed the flow of the P wave provided that the phases of the two waves coincided. The S wave that represented the core of the particle acted as an oscillator.

The proposed dual states of geometry herein described were not considered in the earlier work referenced above. Unfortunately, the state of experimental evidence supporting the General Theory was not as complete as it now is.

This proposal is prompted by the missing energy of equation (21) in section E. , the difference in the total energy and the wave energy as dictated by (9) and (12) respectively, and by the realization that if all energy resides in waves, then classified in terms of wave momentum, a binary system could exist.

Because the mass of (9) indicated total energy in

excess of that lost in (21), it seemed reasonable to assume that the gravitational field, the only other party to these equations, must be contributing energy to our photon system at emission and that because our photon model is proposed as a wave that always travels with its wave momentum constant under the gravitational influence, that the energy of the gravitational field must exist in the form of a different sort of wave. It must be composed of waves that travel with the wave momentum not constant, i. e. , DeBroglie waves. We will proceed to show that this is possible in terms of energies and will calculate the exact gravitational energy and wavelength of the DeBroglie wave of an electron at rest in the laboratory on the earth's surface using the energy for the wave predicted by our model. It will be shown that this predicted wavelength, using the energy for the wave predicted by our model, is exactly that which would be predicted for this model by DeBroglie. Also the established expression for the escape velocity will be derived directly from the model. These two calculations will establish that the model is correct.

H. MATTER WAVES and DEBROGLIE WAVES

We have experimentally observed waves associated with particles, first proposed by Louis DeBroglie[4], and first confirmed by Davisson and Germer[6], that travel with momentum not constant. These waves are called either matter or DeBroglie waves and are seemingly part of the electron system, as well as part of the systems of other particles such as the proton and even the neutron, etc. We will , however confine our efforts to the electron.

DeBroglie waves[4] obey the following conditions:

$$W = \frac{C_0^2}{v} , \tag{29}$$

$$E = h\gamma , \tag{30}$$

$$P = \frac{h}{\lambda} , \tag{31}$$

and the wave equation (2), written as

$$W = \lambda\gamma , \tag{32}$$

where W is the speed of the DeBroglie wave, and v is the group velocity of the wave. Its wavelength is λ , and its frequency is γ. The momentum, P, is equal to the product of its total mass times its group velocity. We see that when v approaches zero, its momentum and energy approach zero, but its wavelength and wave speed approach infinity. Consequently, its frequency approaches zero. We also see that the wavelength of the DeBroglie wave is a variable.

Now it can be shown using the equations of section F., "General Properties of Waves When P is Not Constant", and the DeBroglie conditions, equations (29),(30),(31) and (32) that the DeBroglie wave already exists, even at the boundary condition that the group velocity $v = 0$ in the laboratory. The initial energy in the DeBroglie wave when the system is at rest in the Earth's gravitational intensity, Φ depends on the rest mass of the entire system. This indicates that the system has a DeBroglie wave component even when at rest in the laboratory. It is the energy and wavelength of this DeBroglie component that we will be interested in because it's energy will be the energy of a gravitational wave for the electron in the Earth's Φ.

It should be noted that the definition of rest mass used in this presentation may vary from the conventional definition of rest mass. In section C., equation (4), we effectively defined the rest mass to be that of a zero gravitational environment such that $hf_0 = m_0 C_0^2$. The conventional definition of rest mass , for our model of the electron is, I believe, given by (9),

$$m = m_0 e^{\frac{\Phi}{C_0^2}} . \tag{9}$$

where m is the conventional rest mass in the laboratory and Φ is the gravitational intensity of the laboratory. This is a point that should be carefully examined when using published rest masses in calculations. Equation (25), to be complete should read as,

$$m = m_0 e^{\frac{\Phi}{C_0^2}} [1 + \frac{1}{C_0^2}(v_1^2 - v^2)]^{-\frac{1}{2}} . \tag{25a}$$

when considering the total mass of the electron.

The energy in the matter wave, in the steady state, can be expressed as the difference between the total mass energy of the electron calculated using (9), and the energy in the oscillator component of our model for the electron calculated using (12)

$$E_{db} \;=\; E_{total} \;-\; E_{\lambda}$$

and this yields, for the steady state energy of the matter wave,

$$E_{db} \;=\; m_0 C_0^2 \; [e^{\frac{2\Phi}{C_0^2}} \;-\; 1] \; . \qquad (33)$$

in terms of the gravitational rest mass, m_0.

We have two equations, (9) and (25) for the mass of our model for the electron. Equation (9) gives the mass as a function of Φ and equation (25) gives us the mass as a function of the group velocity, v, of the matter wave. Both are referenced to the boundary condition that when $\Phi \;=\; 0$, $E_{db} \;=\; 0$. You might consider that v represents the velocity of the laboratory when $\Phi \;=\; [\Phi_{earth}]$.

$$m_0 e^{\frac{\Phi}{C_0^2}} \;=\; m_0 [1 \;-\; (\frac{v_g^2}{C_0^2})]^{-\frac{1}{2}} \; . \qquad (34)$$

Now this can be shown to reduce to,

$$v_g \;=\; C_0 \; [1 \;-\; e^{\frac{-2\Phi}{C_0^2}}]^{\frac{1}{2}} \; . \qquad (35)$$

and further reducion will lead to,

$$v_g \;=\; (2\;\Phi)^{\frac{1}{2}} \; . \qquad (35a)$$

The reader will notice that v_g of (35a) is exactly that of the quantity conventionally called the "escape" velocity. However (35) is the relativistic form and agrees with the Newtonian expression (35a) at the lower gravitational intensities while at extremely large intensities it increases asymptotically to a value of C. This in effect predicts that the speed of a particle can never reach the speed of light under the influence of gtavity alone. This is , of course, in complete agreememt with experimental physics.

This yields , to a first order approximation, a group velocity of $v_g \;=\; 11.182 \times (10)^5$ cm/sec when $[\Phi_{earth}]$ is, in cgs units, estimated at $62.496 \;\times\; (10)^{10}$.

What we are primarily interested in at this point is a description of this DeBroglie wave, for the model of closed geometry, i.e., a free electron, in the steady state, i. e. at rest in the frame of the laboratory such that the group velocity relative to the laboratory is zero. The reason, as mentioned previously, that this is of such importance is because it should yield, quantitatively, a description of a gravitational wave.

So far in this article we have been primarily interested in the development of the model. It is time to point out a dichonomy that arises between the macro scale and the quantum scale. We will do this by showing that two electrons can have the same energy in the debroglie wave at the quantum scale but differring velocities on the macro scale. This will serve to illustrate more clearly how the model seperates out macro effects based on quantum characteristics.

Case 1 following is a calculation for an electron , either created in the laboratory and brought to escape velocity, (35a), in the laboratory or captured after falling into the laboratory from empty space without encountering any accelerations except those provided by the Earth's gravitational field. We will use Debroglie's equation (31), $P \;=\; \frac{h}{\lambda}$, to calculate it's debroglie wavelength.

Case 2 following is a calculation for an electron simply created in the laboratory , brought stationary between two capacitor plates, and then released to fall a short distance to the measuring apparatus for a measurement of it's wavelength. One half of the total energy of our debroglie wave given by equation (33) will be used in the calculation of P using equation (36) so that the escape velocity is eliminated from the calculation. We will find that the calculated wavelength using (31), is the same wavelength calculated in case 1. The numerical calculations follow next.

Case 1

Using the published mass, $9.1066 \;\times\; (10)^{-28}$ gm for m_{Φ}, we can compute the momentum

$P = m_\Phi \times v_g$ to be $1018.3 \times (10)^{-24}$ gm cm/sec. By DeBroglie's condition (31), we compute λ to be equal to be on the order of $650 \times (10)^{-8}$ cm or 650 angstroms.

Case 2

Now as a cross check on the above computations we will compute λ using the computed energy of the matter wave as given by (33). We will consider that 1/2 this energy is equivalent to the kinetic energy,T, of our model of the electron. It can be shown that (33) reduces to $E_{db} = 2m_0\ \Phi$, and this is approximately $1.14 \times (10)^{-16}$ ergs. Using

$$P = (2\ m_\Phi\ T)^{\frac{1}{2}}\ , \tag{36}$$

we calculate P to be $1018.3 \times (10)^{-24}$. Using (31) we obtain for λ a wavelength of $650 \times (10)^{-8}$ cm or 650 angstroms. These two estimates of the electron's steady state λ are obviously the same.

The author would like to state that an analysis of the basic model of a binary system in section E. in the discussion of the open geometry binary system climbing out of a gravitational well suggests that only 1/2 of E_{db} as given in (33) contributes to the changes in the motion. The oscillator, staying unchanged after emission would therefore continue to generate a constant energy into the wave. This result of 650 angstroms should be slightly too small because for convenience we used the approximation $m_0 = m_\Phi$, the published value for the mass of the electron.

This is exactly the wavelength obtained using the computation $P = m_\Phi \times v_g$ and the v_g from (35). That computation did not require the use the energy of motion, instead using the gravitational group velocity of the electron that a free electron in the laboratory would have if it had been created in the Φ of the laboratory with no kinetic energy other than that equal to the escape velocity. The difference in computation of λ is resolved, and additionally we see that, indeed, only 1/2 of the energy of (33) is related to motion. This knowledge will be useful in extending the model past this presentation to date.

There is a principle of locality that applies here but we are ignoring it presently for the sake of clarity of presentation.

Furthermore, the reader will note that this division of the DeBroglie wave into two components allows an elegantly simple scheme for the conservation of gravitational energy in a fixed Φ . The oscillator is continually generating an essentially spherical wave of energy $m_0 C_0^2\ [e^{\frac{\Phi}{C_0^2}} - 1]$, into the gravitational aether and at the same time this wave is inducing from the aether an equal amount of energy, while in the Φ of emission, essentially along a wavefront perpendicular to a vector corresponding to the radius between gravitational source and the closed geometry system, into the DeBroglie wave component thus creating a relativistic mass and conserving energy.

We raise the question here as to whether we may have succeeded in defining a gravity wave for the electron on the quantum scale. One might object to this conclusion as being misleading because there seems to be an alternative interpretation to these results. The apparently induced energy may not be stored in the DeBroglie wave, but may be merely the energy due to motion, rather than the energy causing motion. This is a very fine example of the difficulty one experiences in following this model. This induced energy is indeed, the energy of motion, the source of the kinetic energy. However motion is only the effect. The cause is the anisotropic energy distribution of the debroglie wave as discussed in section K, Motion. At this point the results of the closed geometry model seem to fit experimental evidence.

The reader will note that although we earlier proposed an exact description, in the form of closed geometry, for the oscillator, that it matters not if the oscillator is a point oscillator or a closed geometry oscillator. All that really matters is that the oscillator and resultant DeBroglie wave obey the boundary equations so far presented.

We can also express the energy of the total De-

Broglie wave, both that generated by the oscillator and also the component induced from the gravitational field, in terms of the rest frequency of the EM wave as,

$$E_{db} \;=\; hf_0\,[e^{\frac{2\Phi}{C_0^2}} \;-\; 1]\;. \qquad (37)$$

Now let us consider our model to be an electron with rest mass m_0. Let it be at rest so that its DeBroglie component holds only the gravitational tie to the electromagnetic wave.

So the wave energy of the DeBroglie wave, P not constant, using (28) and (30), is given by;

$$E_\lambda \;=\; h\gamma_0[1 \;+\; \frac{1}{C_0^2}(v_0^2 - v^2)]^{-\frac{1}{2}}\;, \qquad (38)$$

and if we set this equal to the total energy of the electromagnetic wave component less the wave energy of the EM component of the electron we have, using (33) and (38),

$$m_0C_0^2\;[e^{\frac{2\Phi}{C_0^2}} \;-\; 1]$$

$$=\; h\gamma_0[1 \;+\; \frac{1}{C_0^2}(v_0^2 - v^2)]^{-\frac{1}{2}}\;, \qquad (39)$$

which gives

$$\gamma_0 \;=\; \frac{m_0C_0^2}{h}\;[\;\frac{e^{-\frac{2\Phi}{C_0^{(2)}}} - 1}{[1 \;+\; \frac{1}{C_0^2}(v_0^2 - v^2)]^{-\frac{1}{2}}}\;]\;, \qquad (40)$$

which finally yields, when the electron is in its steady state in the laboratory, at rest and $v \;=\; v_0$,

$$\gamma_0 \;=\; \frac{m_0C_0^2}{h}\;[e^{\frac{-2\Phi}{C_0^2}} \;-\; 1]\;, \qquad (41)$$

This shows us again that for any v_0 of equation (28), the initial energy in the DeBroglie wave is equal to twice the energy lost by the electromagnetic system. It is a very small amount of energy contributed both by the gravitational environment and the oscillator wave. It should be noted that equations (37) and (41) assume that the electron was created in the Φ of the laboratory. If it were were created, born, in any other Φ then the potential energy difference between the two Φs must betaken into account by adding or subtracting as appropriate this potential energy difference from the energies of (37) and (41).

This is understandable. DeBroglie assumed a model referenced to his laboratory. The binary model is a different model. It is always referenced to a gravitational intensity where Φ approaches zero. At the risk of becoming tedious let us restate this in a different manner. The V_0 of DeBroglie's equations are equivalent, when the General Theory is considered, to the classical Escape Velocity, $v_g \;=\; (2\;\Phi)^{\frac{1}{2}}$. The task is to bring these models together so that we do not contradict experimental evidence. It appears that DeBroglie's model may be a special case of our binary model where everything is referenced to the boundary conditions at $\Phi \;=\; 0$. It should be possible to extend DeBroglie's conditions to encompass the stationary state relative to the boundary conditions of this article. There is no error implied about DeBroglie's conditions. We are looking at the problem from a different perspective. This difference in velocity is so small compared to C that it would have no significance on normal observations. However, when we are looking for such small quantities as the momentum and energy of the electron's gravity wave then this becomes a very important quantity. This is the only place in this article where we have to discuss information from an observer dominated position.

For consistency we should express the Debroglie conditions to the boundary conditions at $\Phi \;=\; 0$. To do this we must modify the DeBroglie expressions (30) and (32), and so the modified DeBroglie conditions are:

$$W \;=\; \frac{C_0^2}{v'}\;, \qquad (42)$$

$$E \;=\; h\gamma_0\;[1 \;+\; \frac{1}{C_0^2}(v_0^2 - v^2)]^{-\frac{1}{2}}\;, \qquad (43)$$

$$P \;=\; \frac{h}{\lambda}\;, \qquad (44)$$

$$\text{and } W \;=\; \lambda\gamma_0\;[1 \;+\; \frac{1}{C_0^2}(v_0^2 - v^2)]^{-\frac{1}{2}}\;, \qquad (45)$$

where γ_0 is given by (40) evaluated at some time t such that $v = v_0$.

Under these modified conditions DeBroglie waves have a steady state solution consistent with the closed binary system. Measurement of the wavelength of the matter waves of the electron should, in practice, yield the same results as are found for DeBroglie waves. Normally the initial energy of the waves is too small to be observed at P equal to 0.

To this extent at least, you can consider that an photon(the oscillator) wave with its associated DeBroglie wave could constitute one of the basic systems of our universe.This would be true whether the photon has either open or closed geometry.

When we make a measurement of a given binary system, such as the measurement of the mass or momentum of an electron in an accelerator, or in the cases of an elastic or inelastic collision, we are measuring its total system as dictated by equations (25a) and (28), not just the energy in it's DeBroglie wave.

We see now, that for a binary system, it seems that it is the oscillator wave that is associated with a particle. The DeBroglie wave contains the energy associated with the interactions between electromagnetic systems(i.e., the forces) and with gravity.

As a matter of clarification, let us note that the reference frame, in which V equaled V_0, was chosen carefully and was assumed to be at rest in the gravitational field. We have referred to this situation frequently as the "steady state". It is apparent that for the electron to stay at rest in the laboratory we would have to apply some artificial force and that since the electron contains internally the energy of acceleration, when the restraining force is terminated the electron will continue to fall into the gravitational field.

Any initial energy in the DeBroglie component shown by (41) resides in the gravitational link to that field. It was further assumed that there was no residual relativistic energy residing in the DeBroglie component due to forces applied to the electron that brought it to rest in our frame of reference. This , of course , is a fictional convenience.

When the group velocity in the laboratory is zero, if the electron is released to move freely in the gravitational field it will still have a gravitational group velocity, v_Φ such that,

$$v_\Phi = v' - v \,, \tag{46}$$

This means that the group velocity, v , of (29) must be replaced in (42) by v'. Then v_Φ can be defined by solving (42) and (45) simultaneously for the v' of equation(42), taking $v = v_0$.

The development to date, proposes an actual mechanical basis and a description thereof, of Einstein's aether[16] in the form of the DeBroglie waves associated with oscillators(photons).

I. CLOSED GEOMETRY AND THE PHOTON

Earlier we only considered the photon as a one dimensional entity. We have set forth the proposition, in the previous section, that a photon, a wave of constant wave momentum, can exist in two states. We have called the state of the photon free geometry and that of the electron closed geometry.

Consider what you would have if the photon, a wave of constant wave momentum, existed in a closed geometry state such as in a closed circular orbit. From the viewpoint of an observer on the binary system, the closed binary system would still retain the wave properties it had before the event, but to an outside observer the binary system would no longer have the property of spacial motion unless the observer could use a measuring device several magnitudes smaller than the closed binary system's circumference. In any energy transference experiment the outside observer would still observe for an element dx of the turn, the same results as for a free binary model, and conclude that the closed binary system had a mass. You would effectively have a particle with mass, not a wave with mass.

The really interesting consequence of this closed geometry is the change, to an outside observer, in the attributes of the DeBroglie component. The photon, the oscillator, would now effectively be infinite in length, and thus extremely stable. It could not lose energy. It would effectively be an infinite power

line. Furthermore, it would have a dipole, and to an observer magnitudes greater in size than its orbital radius, would appear to have a Debroglie wave emanating from a point source.

This Debroglie wave would appear as a spherical wave, with the elements of spin, caused by the spin of the oscillator, a wavefront pressure, and an amplitude decreasing with R^2.

The wavefronts of the DeBroglie wave would correspond exactly to the geometries of an electron's magnetic lines of force, and the equal energy pressure vectors on the wavefront would correspond exactly to the lines of force of the electric field, everywhere perpendicular to the magnetic lines of force. Additionally the amplitudes, when at a distance, fall off at a rate corresponding to $1/R^2$. In the case of the gravitational interaction the spin of our closed geometry DeBroglie wave is not canceled out by the gravitational field. It will contribute to the interaction with the gravitational field, a low frequency wave of spin = 0, where all of the other random spins of all the other closed geometry systems have canceled each other out.

It appears possible that this single DeBroglie wave interacting with other systems could account for both the gravitational influence and the electromagnetic influence.

J. MECHANISMS

At this point we should elaborate on several points not sufficiently discussed in the previous sections of this article.

Forces

First let us explain why a photon is said by many to have no mass except possibly one that would be defined at all times by the relationship $m = hf/C^2$.

We have discussed, in the previous section, the spherical nature of the closed geometry binary system's DeBroglie wave and the similar geometries of its DeBroglie wave attributes to those of the electron. Now for the photon, which has open (linear) geometry and its attached DeBroglie wave which will have cylindrical wavefronts with the pressure of the wavefront everywhere perpendicular to the cylindrical geometry of each wavefront one can immediately recognize that this is the geometry normally associated with an electromagnetic wave.

Now it is suggested that Newton's Law of Universal Gravitational Force is not only "proportional to the product of the masses of the particles and inversely proportional to the square of the distance between them" but is also a function of the geometry of the DeBroglie waves attached to the particles. The empirical constant "G" was derived using systems of closed geometry. "G" is not valid for expressing the force between a system of closed geometry and a system of open geometry, as defined herein. This would explain why the electromagnetic wave does not exhibit a force proportional to its mass of $m_\Phi = m_0 e^{\frac{\Phi}{C_0^2}}$ similar to that of a system of closed geometry when under the influence of gravity.

It is suggested that the laws of electrodynamics governing the interactions of the electromagnetic fields for a current flowing through a single turn of wire and the same current flowing along a linear line may be used demonstrate this and to possibly derive a constant, " G' " that will illustrate the gravitational force exerted on one open geometry particle by the other, a particle of closed geometry. It is further suggested that the interaction between a single turn of current carrying wire will be greater and is proportional in some manner to the gravitational forces between two particles, closed geometry, of matter. However It is realized that a proper verification of this model's field characteristics matching experiment, both for the gravitational and electric fields and for variations in geometry can only be done by extensive modeling of energy distributions within the model's own DeBroglie wave for various situations. This is outside the scope of this article.

Pair Production

It is felt that pair production[17], a well established experiment shows without any doubt that at least one mechanism exists for conversion of an open geometry

system to one of closed geometry. This experiment shows that a gamma ray of energy 1.02 Mev or more can, in the vicinity of a nucleus, be converted into an electron/positron pair each of 0.51 Mev energy. Any energy in excess of 1.02 Mev held originally by the gamma ray is converted into kinetic energy shared equally by the electron and the positron.

There is also evidence[18], for inelastic light-by-light scattering involving only real electromagnetic waves, of an electron-positron pair resulting from the collision between a high-energy electromagnetic wave and several laser photons. This however is not felt to influence the discussion of the model presented in this paper.

Elastic and Non Elastic Collisions

Although it is outside the scope of this article it is felt that some discussion of the mechanisms of elastic and non elastic collisions between open geometry photons (oscillators) and closed geometry oscillators (electrons) is warranted. The electron is known to be extremely stable and this is because electromagnetic waves in power lines and antennas do not leak energy except at their ends. The electron, a closed geometry system, has no ends to its' oscillator so it is extremely stable. The open geometry of the photon's oscillator allows it to alter its energy state in elastic and non elastic (Compton effect)[19][20] encounters with particles having oscillators of closed geometry. The wave energy, hf, and wave momentum, $\frac{h}{\lambda}$ of the open geometry oscillator can be changed, probably transferring energy and momentum to the electron's DeBroglie wave. A transference of energy and momentum between their DeBroglie waves may occur. This is a process that others, perhaps, can examine and explain more thoroughly in terms of our model.

This effect is also seen to occur in the process of pair production, but the exact mechanism is not so clear. This case does not fit into the definition of an elastic collision. Furthermore a reverse effect is seen in pair annihilation. This case does not really fit the definition of a non elastic collision. In both of these cases the oscillators change form and the exact mechanisms are not definitely known. It does seem , however, to fall into the category of an "electromagnetic event" because the energy in the oscillator of an electromagnetic wave appears to be affected. If that is so the same reasoning stated concerning the emission of an electromagnetic wave should apply. The author will not speculate further on these events.

When a non elastic collision occurs the open geometry (photon) system appears to transfer all of the energy of both its oscillator and DeBroglie systems, its total energy, into the DeBroglie system of the closed geometry (electron) system resulting in an increase in kinetic energy and increased momentum of the electron.

The laws of conservation of total energy and total momentum, of course, are honored.

Aether

The question of the existence of an Aether has plagued physics for over a hundred years. If there is any substance to this model then the question is answered. The model provides for every quanta of energy of closed geometry to have an attached DeBroglie wave and except for the electromagnetic wave that these DeBroglie waves should exhibit the property of a spin. If this is so the gravitational field consists simply of a sea of these DeBroglie waves with the spins well canceled out. This is easy to see as positive and negative charges are distributed fairly evenly throughout the universe. Also the amplitudes of these waves cannot help but be fairly low frequency at any reasonable distance from a source and would of course, exhibit a decrease in energy at any given point as r increases according to $\frac{1}{R^2}$.

Unity

In the last sentence of the previous section we stated "It appears possible that this single DeBroglie wave interacting with other systems could account for both the gravitational influence and the electromagnetic influence" As also previously stated the geometries of the electromagnetic fields seem to correspond exactly to the geometries of the DeBroglie wave portion of our binary model. If so, then why are they so different in field strengths and the geometries of their energy vectors?

The answer to this has to be that the binary model of the electron has spin.

Our binary model's DeBroglie wave can interact with the gravitational field which has no spin. Our very same model with spin can interact with other similar binary models that do have spin and the results are totally different geometrically and in magnitude. The disturbance caused in the energy distribution of the Debroglie wave in the case of gravity is totally different from the disturbance in the energy distribution of the very same Debroglie wave in the case of interacting with another DeBroglie wave that has spin. Whether the DeBroglie wave of our closed geometry model acts like a charge or like a mass to the outside observer depends on the characteristics of the system that it is interacting with. It can actually interact with both a charge and a gravitational field at the same time!

We will not comment further on the case of a open geometry (electromagnetic wave) system interacting with a closed geometry system with spin (the electron).

We will have to leave it to others to map the energy distributions and prove or disprove this model.

K. MOTION

We ask the question, how in a purely classical sense, could this induced energy cause the motion of our model of the electron through the gravitational aether of Euclidian space? The author suggests that the mechanism is the attempt at reassertion of equilibrium of the DeBroglie wave from a anisotropic energy distribution thereby causing a distorted geometry back to essentially a spherical geometry. As the wave attempts to return to equilibrium its center of gravity will shift. As long as it is subjected to an induced energy change in a given region of space it will continue to shift its center of gravity and would be accelerated. If the inducing force is terminated, say the accelerator is turned off, the DeBroglie wave will reassert equilibrium and cease to be accelerated. It will then continue to move with a constant velocity. This is the same mechanism as was described by D. Bohm [12] [13] for his pilot wave in terms of the P wave which was in an anisotropic energy state attempting to return to an isotropic energy state.

L. NONLOCALITY of REST MASS

This model demonstrates that there is strong evidence for a prediction of nonlocality dependent on the gravitational intensity at the quantum level.

The quantity that we refer to as rest mass appears to be a function of the Φ of creation.

The most obvious example is apparent when considering the emission of electromagnetic waves in different gravitational intensities. The photon component(the wave of constant wave momentum) for a given spectral emmision , say the sodium D line, of the electromagnetic wave varies with Φ . The author sees no experimental evidence that the total emission energy varies so this would imply that the energy in the matter wave component might also be non local. This would have the effect of predicting that the charge of electrons created in different gravitational environments would be different. The difficulty of confirming such an effect would be in obtaining unaltered electrons from known sources of sufficiently different Φ .

CONCLUSIONS AND COMMENTS

At this time we would like to acknowledge that the section on the emission of a binary photon, an electromagnetic wave, was a matter of testing the various possibilities afforded by equations (9) and (12)against experiment until we found the one that satisfied all experimental requirements and preexisting theory of Einstein, DeBroglie and Maxwell. It is hoped that it is understood that the initial object of this article was merely to explore the characteristics of an electromagnetic wave with mass and subsequently we found that there were multiple forks in this path so we followed experiment keeping faith with the General Theory.

It should be noted that C. O. Alley's article, "Proper Time Experiments in Gravitational Fields with Atomic Clocks, Aircraft , and Laser Light Pulses"[1], figures, 43, 45, and 47 along with his closing discussion appear to demonstrate clearly the need for a binary model of the electromagnetic wave. In the article's conclusion, he discusses the fact that regarding the question of a change in wave energy, E

= hf, by an electromagnetic wave propagating thru a changing gravitational potential, his experiments show that this does not happen and that this was further confirmed by experience with test GPS equipment in orbit. This further strengthens the case for our binary model. As an electromagnetic wave climbs out of a gravitational well it must, to conserve energy, suffer a loss of energy. This energy must come from its' DeBroglie wave. This makes a binary model a necessity.

Equation (35), a known gravitational quantity, also lends a strong credibility to the concept of a binary model based on a photon, having a constant wave momentum and a mass, being possible. The results leading to (35)encompass the entire derivation of this paper, including the assumption that the energy imbalance between (9) and (12) is due to the gravitational influence.The expression of this imbalance given by equation (33) led to the prediction of a wavelength of approximately 650 angstroms for an electron's gravity wave when at rest in the Earth's Φ .

It should be possible to devise, at low temperatures, an experiment to look for a fourier component, a strong spectral line near 650 angstroms, in Debroglie waves associated with the free electron by the diffraction method. The discussion of Section H. , Matter Waves suggests that, perhaps at low temperatures in a weak electric field, some statistical experiment similar to the Millikan oil drop experiment[21] might be employed to produce electrons with low enough energies for diffraction results to be meaningful. The object of the experiment is to simply bring an electron to rest, and then to drop it and let it move solely under the influence of gravity through the diffraction grating.

This presentation was basically confined to gravitational forces only for simplicity and brevity of presentation.

This presentation has been confined to the quantum level but the implications of this model could have far reaching significance on the astrophysical scale and has been shown to apply qualitatively to further development of a unified theory. It should aid experimentalists searching for a new avenue for the detection of gravity waves on the macro level.

It should be noted that the references given were kept to a minimum because the author could find no later experimental or theoretical material that would discredit or significantly enhance this model, the principles used being of such a basic nature. There are many speculations on various points of the model but the author does not feel inclined to argue them, since none found seem to form a complete picture. Reiterating, this presentation is of a physical model, not of a mathematical theoretical one.

Ending, we see that our model, in either geometry, is indeed an electromagnetic wave. What this article has accomplished is to break that electromagnetic wave into its individual components and show how each component fits into the world around us. The author has no illusions to the effect that this article is a completed work.

SYMBOLS

Co denotes a universal constant
C denotes the speed of an electromagnetic wave.
E denotes energy
f denotes the frequency of the oscillator.
F denotes a force applied to the quantum of energy (in direction of motion).
G denotes the universal gravitational constant.
h denotes Planck's constant.
K denotes a constant.
m denotes the total mass of the model.
M denotes the mass of a gravitational source.
n is a constant, usually set to 1.
p denotes momentum.
r denotes the distance from the center of a gravitational source.
t denotes time.
v denotes group velocity in general.
W denotes the speed of a DeBroglie wave.
x denotes distance in general.
λ denotes the wavelength of a wave.
Φ denotes the gravitational intensity.
γ denotes the frequency of a DeBroglie wave.

Detection of gravitational waves

L Ju, D G Blair and C Zhao
Department of Physics, The University of Western Australia, Nedlands, WA 6907, Australia

Received 4 January 2000

Abstract

Gravitational wave detectors have been under development since the pioneering work of Weber in the 1960s. The long and painstaking research effort has yielded enormous improvements in detector sensitivity. Astronomical observations of binary pulsar systems have confirmed the existence of gravitational radiation. Direct detection is inevitable once planned detectors reach sensitivity goals.

This review begins by introducing the concept of gravitational waves, and discusses their significance. Section 2 discusses sources of gravitational waves, giving estimates of signal characteristics and signal strengths. Section 3 presents an overview of gravitational wave detection and the critical issues of data processing.

In the fourth section the physics of resonant-mass gravitational wave detectors is discussed in some detail, covering all areas from antenna materials to transducers and the quantum limits to measurement. This section reviews the major operating antennas in the existing worldwide array but also discusses the prospects for achieving substantial increases in sensitivity in the future.

The fifth section presents the concepts and designs for laser interferometer gravitational wave detectors. Large-scale devices will be in operation in the first decade of the twenty-first century and should eventually be certain of detecting a known class of gravitational wave source. At their predicted sensitivity, space interferometers will be able to detect numerous known galactic sources of gravitational waves and also will be able to detect black hole mergers that are thought to have occurred as primordial galaxies merged and grew in the early universe.

1. Introduction to gravitational waves

1.1. Listening to the universe

Our sense of the universe is provided predominantly by electromagnetic waves. During the twentieth century the opening of the electromagnetic spectrum has successively brought dramatic revelations. For instance, optical astronomy gave us the Hubble law expansion of the universe. Radio astronomy gave us the cosmic background radiation, the giant radio jets emerging from black holes in galactic nuclei and neutron stars in the form of radio pulsars. X-ray astronomy gave us interacting neutron stars and black holes. Infrared astronomy gave us evidence for a massive black hole in the nucleus of our own Galaxy.

Gravitational waves offer us a new sense with which to understand our universe. If electromagnetic astronomy gives us eyes with which we can see the universe, then gravitational wave astronomy offers us ears with which to hear it. We are presently deaf to the myriad gravitational wave sounds of the universe. Imagine you are in a forest: you see a steep hillside, massive trees and small shrubs, bright flowers and colourful birds flitting between the trees. But there is much more to a forest: the sound of the wind in the treetops, the occasional crash of a falling branch, the thump thump of a fleeing kangaroo, the pulse of cicadas, the whistles of parrots and honking of bell frogs. The sense of hearing dramatically enriches our experience.

The gravitational wave universe is likely to be rich with 'sounds' across a frequency range from less than one cycle per month (below one microhertz) up to tens of kilohertz. Frequencies in the audio frequency band will be detectable using Earth-based detectors. But lower frequencies will require observatories in space. Gravitational waves are produced whenever there is non-spherical acceleration of mass–energy distributions. The lowest frequencies will consist of extremely red-shifted signals from the very early universe, as well as the slow interactions of very massive black holes, and a weak background from binary star systems. Signal frequencies often scale inversely as the mass of the relevant systems. Black holes below 100 solar masses, and neutron stars will produce gravitational waves in the audio frequency range: nearly monochromatic whistles from millisecond pulsars, short bursts from their formation, and chirrups from the coalescence of binary pairs.

During the twentieth century, at each opening of a new window in the electromagnetic spectrum, the universe surprised us with unexpected phenomena. Our imagination and ability to predict is limited. The sources we predict today are probably just a fraction of what we will hear when our detectors reach sufficient sensitivity.

Gravitational waves are waves of tidal force. They are vibrations of spacetime which propagate through space at the speed of light. They are registered as tiny vibrations of carefully isolated masses. Their detection is primarily an experimental science, consisting of the development of the necessary ultra-sensitive measurement techniques. While the gravitational waves can be considered as classical waves, the measurement systems must be treated quantum mechanically since the expected signals generally approach the limits set by the uncertainty principle.

The binary pulsar PSR 1913+16 has played a key role in the unfolding story of gravitational waves. This system has proved Einstein's theory of general relativity to high precision, including the quadrupole formula which states that the total emitted gravitational wave power from any system is proportional to the square of the third time derivative of the system's quadrupole moment. The pulsar loses energy exactly as predicted by this formula [1]. Hulse and Taylor, who discovered the system more than 20 years ago [2], were rewarded by a Nobel prize in 1993, by which time careful monitoring had shown gravitational wave energy loss from the system in agreement with theory to better than 1%.

1.2. Gravitational waves in stiff-elastic spacetime

In Newtonian physics spacetime is an infinitely rigid conceptual grid. Gravitational waves cannot exist in this theory. They would have infinite velocity and infinite energy density because in Newtonian gravitation the metrical stiffness of space is infinite. Conversely general relativity introduces a finite coupling coefficient between curvature of spacetime, described by the Einstein curvature tensor, and the stress energy tensor which describes the mass–energy which gives rise to the curvature. This coupling is expressed by the Einstein equation

$$\boldsymbol{T} = \frac{c^4}{8\pi G}\boldsymbol{G}. \tag{1.1}$$

Here $\boldsymbol{T}$ is the stress energy tensor and $\boldsymbol{G}$ is the Einstein curvature tensor, c is the speed of light and G is Newton's gravitational constant. The coupling coefficient $c^4/(8\pi G)$ is an enormous number, of order 10^{43}. This expresses the extremely high stiffness of space which is the reason that the Newtonian law of gravitation is an excellent approximation in normal circumstances, and why gravitational waves have a small amplitude, even when their energy density is very high.

The existence of gravitational waves is intuitively obvious as soon as one recognizes that spacetime is an elastic medium. The basic properties of gravity waves can be easily deduced from our knowledge of Newtonian gravity, combined with knowledge that spacetime curvature is a consequence of mass distributions.

First, consider how gravitational waves might be generated. Electromagnetic waves are generated when charges accelerate. Because a negative charge accelerating to the left is equivalent to a positive charge accelerating to the right, it is impossible to create a time-varying electric monopole. The process of varying the charge on one electrode always creates a time-varying dipole moment. Hence it follows that electromagnetic waves are generated by time-varying dipole moments. In contrast to electromagnetism, gravity has only one charge: there is no such thing as negative mass! Hence it is not possible to create an oscillating mass dipole. Action equals reaction. That is, momentum is conserved and the acceleration of one mass to the left creates an equal and opposite reaction to the right. For two equal masses, their spacing can change but the centre of mass is never altered. This means that there is a time-varying quadrupole moment, but there is no variation in monopole or dipole moment.

To be certain of the quadrupole nature of gravitational waves, think of a system which collapses under its own gravity. First think of a spherically symmetrical array of masses that collapse gravitationally towards a point. At a distance there is no difference between the gravitational field of a point mass and that of the same mass distributed in a uniform spherical distribution. (This is a consequence of the inverse square law, and is also true for electric fields.) Hence the process of gravitational collapse of a spherical distribution creates no variation in the external gravitational field, and hence no gravitational waves. Clearly gravitational waves must be created by non-spherical motions of masses. Consider a ring of eight test masses, such as the one illustrated in figure 1.

The simplest non-spherical motion is one in which the edge masses move inwards and the top and bottom masses move apart as shown in figure 1(*a*). Such a quadrupole motion does vary the external field and does create gravitational waves. For a small amount of vertical stretching, and an equal horizontal shrinking, it is obvious that the diagonally placed masses have no radial motion. There is clearly a second polarization rotated 45° from the first in which the diagonal masses move radially, and the top, bottom and edge masses have no radial motion. Unlike electromagnetic waves, gravitational wave polarizations are just 45° apart.

Gravitational wave detection can be easily understood from the symmetry between sources and detectors—time reversal invariance. A gravitational wave will distort a ring of test masses

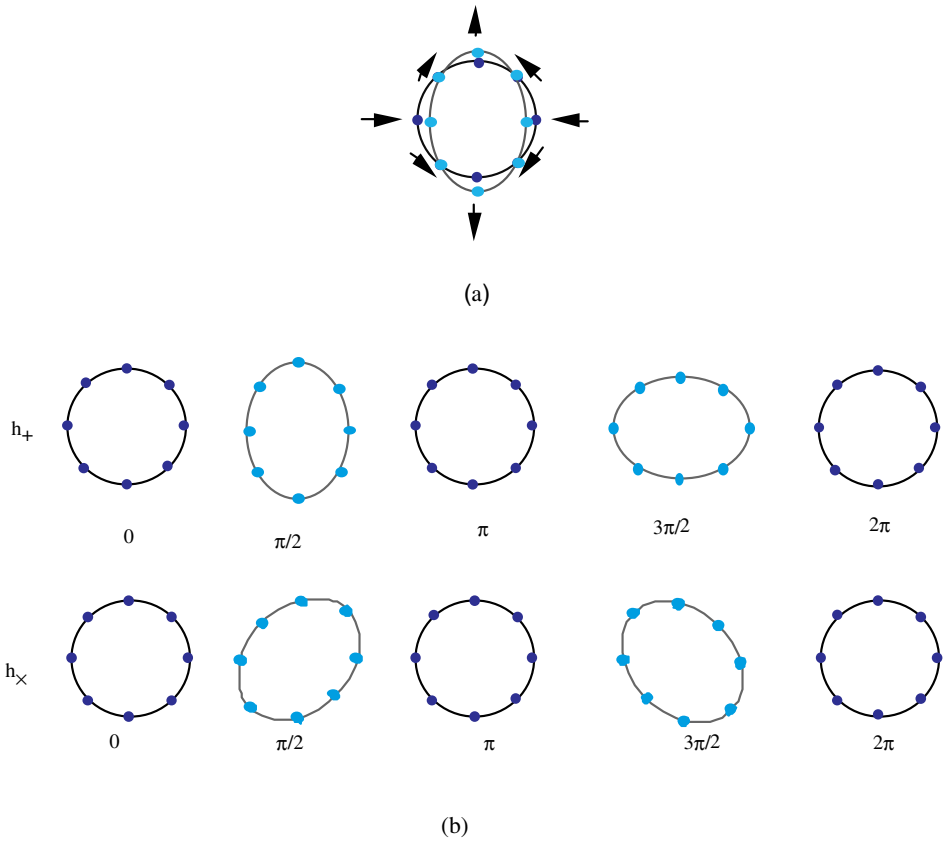

Figure 1. (*a*) The lowest order non-spherical deformation of a ring: the diagonal masses *are not moved*. (*b*) The deformation of a ring of test particles in one cycle of a gravitational wave field.

in exactly the same way that the distortion of a ring of test masses creates gravitational waves. The non-spherical deformation pattern we just observed is exactly like the tidal deformation of the Earth created by the gravity gradient due to the Moon. A gravitational wave is indeed a wave of time-varying gravity gradient. The amplitude of a gravitational wave is measured by the relative change in spacing between masses. That is, the wave amplitude, usually denoted h, is given by $\Delta L/L$, where L is the equilibrium spacing and ΔL is the change of spacing of two test masses. Whereas electromagnetic luminosity depends on the square of the second time derivative of the electric dipole moment, the gravitational wave luminosity is proportional to the square of the *third time* derivative of the mass quadrupole moment. The extra derivative arises because gravitational wave generation is associated with the differential acceleration of masses.

The above deformation patterns also apply to solid or fluid bodies. The rigidity of normal matter is so low compared with that of spacetime that the stiffness of the matter is utterly negligible. Considering the deformations of figure 1(*a*) applying to a solid sphere, such as the Earth, it also follows that the 45° points must involve circumferential motions since the deformation shown acts to transfer matter from the 'equator' to the poles in the same way that the lunar tides act on the Earth.

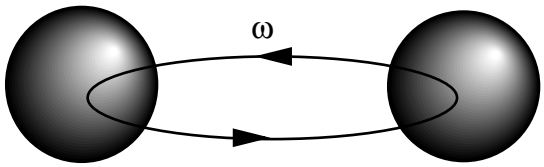

Figure 2. A rotating dumbbell or a binary star system, viewed edge-on, has a maximal variation of quadrupole moment.

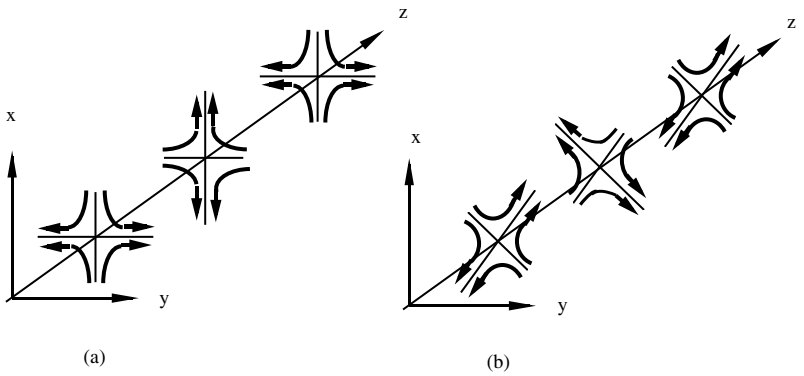

Figure 3. Gravitational wave field force lines. (*a*) '+' polarization; (*b*) '×' polarization.

The gravitational wave has an effective force field determined by the displacement vectors of the test masses. The force field is discussed further below, and is shown in figure 3. The force field indicates that detectors can be designed to couple to gravity waves in several different ways. They may detect straight linear strains, orthogonal strains, or circumferential strains.

The weak coupling of gravitational waves to matter is a consequence of the enormous elastic stiffness of spacetime. If the elastic stiffness of spacetime were infinite (Newtonian physics) the coupling would be zero. In general relativity the generation of gravitational waves is given quantitatively by combining the third time derivative of the quadrupole moment described above, with the appropriate coupling constant. The latter can only depend on the constants G and c (for classical waves) and by dimensional analysis this constant must have the form G/c^5. The luminosity of a source is given by

$$L_G \sim \frac{G}{c^5}\left(\frac{\mathrm{d}^3 D}{\mathrm{d}t^3}\right)^2. \tag{1.2}$$

Except for a numerical factor, this is the Einstein quadrupole formula [3]. There are two useful formulae one can derive from equation (1.2). The first is the formula for a hypothetical terrestrial source or binary star system. The second is for an interacting black hole system. The terrestrial source might be a pair of oscillating masses joined with a spring. Ideally, the spacing of the masses should change from zero to L. This is achieved in the edge on view of a rotating dumbbell or binary star system in a circular orbit as shown in figure 2. Viewed edge-on the masses appear to move in and out periodically twice per rotation cycle. The quadrupole moment for two masses distance x apart is Mx^2. If the motion is sinusoidal at an angular frequency of ω, the square of the third time derivative is $\sim M^2L^4\omega^6$. Thus the gravitational

wave luminosity of such a system is

$$L_c \sim \frac{G}{c^5} M^2 L^4 \omega^6. \tag{1.3}$$

This equation applied to any natural or artificial source in our solar system gives a depressingly small luminosity, due to the extraordinarily small value of G/c^5. However, the situation is different in an astrophysical context.

Suppose that the system is a similar binary system, except that it consists of a pair of gravitationally bound masses, of size such that their escape velocity approaches c and their radius is near to the Schwartzchild radius: that is, a pair of black holes. In this case we can express L in units of the Schwartzchild radius, using $r_s = 2GM/c^2$ and replace $L\omega$ with velocity expressed in light speed units. Then it follows immediately that

$$L_G \sim \frac{c^5}{G} \left(\frac{v}{c}\right)^6 \left(\frac{r_s}{r}\right)^2. \tag{1.4}$$

The remarkable difference between equation (1.3) and equation (1.4) expresses the difference between the physics of normal matter and black holes. Equation (1.3) is scaled by the tiny factor G/c^5, while equation (1.4) is scaled by its enormous reciprocal. Normal matter in our solar system creates negligible curvature of spacetime. A black hole creates an extreme distortion of spacetime. Hence normal matter sources are intrinsically extremely weak, while very large amplitude waves are created in events such as the coalescence of a pair of black holes (for which we would expect $v \sim c$ when $r_s \sim r$). The factor c^5/G is roughly the total electromagnetic luminosity of the universe. This is the upper limit to the gravitational wave luminosity of black hole systems. In reality, equation (1.4) does not take into account the gravitational redshift effects and other spacetime curvature effects which act to reduce the maximum luminosity. However, to order of magnitude, equation (1.4) indicates the extreme luminosity of gravitational waves that can be expected in short bursts when gravitationally collapsed systems with strong gravity, such as black holes (escape velocity $= c$) and neutron stars (escape velocity $\sim 0.1c$), are involved.

As we saw above, a gravitational wave is a wave of gravity gradient which causes relative displacements, or strains between test masses. The detection of gravitational waves requires the detection of small strain amplitudes. We should now consider the typical size of such strain amplitudes. One can very crudely estimate this by scaling the amplitude of the gravitational wave relative to the extreme amplitude at the point of coalescence of two masses to form a black hole. At the point of black hole formation spacetime curvature is very large. For example, the deflection of light for a light beam passing near to the event horizon can approach a complete orbit of a black hole. At the point of generation the dynamic curvature of space that will become the outgoing gravitational wave is unlikely to be able to exceed the static curvature represented by the maximal deflections of light past a black hole. The strain $\Delta L/L$ represented by such deflections can be estimated from the difference in light travel time for the deflected path around the black hole (say half an orbit) and the direct path between the same points in the absence of the black hole. For a half-orbit (in Euclidean geometry) the circular path is $\pi/2$ longer than the direct path, so roughly $\Delta L \sim L$, and the maximum possible strain amplitude is $\sim$unity. But by the inverse square law, the amplitude of the wave reduces as $1/r$. (The energy density which is proportional to the square of the amplitude reduces as $1/r^2$.) So for such a black hole source we can give the strain amplitude at distance r as simply $h \sim r_s/r$. For more realistic sources only a fraction of the total energy will participate in quadrupole motion. Thus it is more reasonable to include an efficiency factor ε which characterizes the fraction of the total system rest mass which can convert to gravitational waves. In this case we

can write

$$h \sim \varepsilon^{1/2} \frac{r_s}{r}. \tag{1.5}$$

Since the Schwartzchild radius of a solar mass is a few kilometres, the maximum strain amplitude that can be expected from any stellar source is numerically equal to the reciprocal of its distance in kilometres. Because r_s is linearly proportional to the mass, gravitational wave amplitudes from very high mass sources, such as colliding 10^9 solar mass black holes in galactic nuclei, will be of correspondingly larger amplitude. Putting in numbers, equation (1.5) gives $h \sim 10^{-16}$ for 10 solar masses and 100% efficiency at the galactic centre, and $h \sim 10^{-13}$ for 3 billion solar masses at 3 Gpc (towards the edge of the visible universe).

Clearly these maximal numbers are very small. It might seem that the supermassive black hole sources might be much more detectable than the stellar mass source. The strain amplitude in this case corresponds to the detection of a motion equal to the size of an atomic nucleus on a one-metre baseline, or one metre between here and Neptune. In fact the detection of such small strains on Earth is probably impossible, because the frequency of the waves from supermassive black hole sources must always be very low. The peak frequency, or its reciprocal, the burst duration, can be estimated from the time the binary black hole system takes to complete its final orbit before coalescence. Its value is about 10 kHz for one solar mass, reducing inversely as the mass. Thus, the peak frequency will be about 1 kHz for the above galactic centre source, and 3×10^{-6} Hz for the distant massive black holes. The latter frequency will be reduced towards 10^{-6} Hz by cosmological redshifts. At such low frequencies environmental effects, and particularly gravity gradients associated with tides and weather variations in the surrounding environment, create perturbations which greatly exceed the desired signal. The only known means around this obstacle is by using drag-free satellite technology to create very stable free-floating masses in space, and laser interferometry between them. In this case detection does look relatively straightforward, though expensive, since it requires several widely spaced spacecraft. For frequencies above 1 Hz, terrestrial detection appears to be possible, limited only by fundamental quantum measurement limits.

For even lower frequencies than 10^{-6} Hz it is possible that radio pulsars can replace man-made spacecraft in detection systems. The pulsar ideally provides a perfect monochromatic timing signal. The radio beams from the pulsar are traversed by incoming gravitational waves. If several pulsars are observed in the same part of the sky, gravitational wave signals would appear as correlated arrival time variations of pulses from pulsars in different directions. In this case it is more convenient to consider the gravitational wave acting not on the pulsar itself, but on spacetime geometry near to the Earth through which the pulsar signal propagates.

Today detectors are in long-term operation which exceed the 10^{-16} sensitivity indicated above by more than two orders of magnitude. Advanced detectors of two types are under development which should achieve another three orders of magnitude in amplitude sensitivity.

For 50 years after Einstein predicted gravitational waves [3] physicists considered them to be of academic interest only. It was not until after the pioneering work of Joseph Weber [4], and his reported discoveries [5, 6] that a growing number of physicists around the world started to develop different types of antennas to search for gravitational waves. Since Weber's first reports, which were never confirmed, the improvement in detectors has been quite remarkable. Relating them to optical telescopes, the improvement achieved so far is equivalent to the step from a 3 cm diameter optical telescope to a 3 m diameter instrument. In the next decade it is hoped that the improvement will be equivalent to a step up in size from 3 m to 3 km. At this sensitivity gravitational wave detection is practically certain, and the field of gravitational astronomy will be able to slowly map and explore the new spectrum, and the objects that it reveals.

In the following sections we will discuss gravitational wave sources in more detail before going on to discuss detectors, first in the form of a general overview, and then with specific emphasis on existing ground-based detectors and their future prospects.

1.3. Gravitational waves in general relativity

Here we give a brief summary of the mathematical basis for gravitational waves. For further details on the theory of gravitational waves, readers are referred to [7–12].

The geometry of spacetime can be expressed by the metric tensor $g_{\alpha\beta}$ which connects the spacetime coordinate $\mathrm{d}x^{\alpha}(\alpha, \beta = 1, 2, 3, 4)$ to the spacetime interval $\mathrm{d}s$ by way of the relation

$$\mathrm{d}s^2 = g_{\alpha\beta}\,\mathrm{d}x^{\alpha}\,\mathrm{d}x^{\beta}. \tag{1.6}$$

In reality, gravitational waves in the vicinity of the Earth will always be very weak. The background curvature can be ignored and the background metric can be approximated as that of the Minkowski flat metric η. An approximation of the gravitational wave field can then be expressed in the form [7]

$$g_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta}, \tag{1.7}$$

where $\eta_{\alpha\beta}$ is the metric of the flat background, and $|h_{\alpha\beta}| \ll 1$ is the perturbation on this background. If there is no stress-energy source term in Einstein's field equation, i.e. $T = 0$ in equation (1.1), we are left with the weak field vacuum approximation to the Einstein equations. To obtain an explicit statement of the metric perturbations h it is necessary to make a gauge choice. The most useful gauge is the transverse traceless gauge in which the coordinates are defined by the geodesics of freely falling test bodies. In this gauge, and in the weak field limit discussed above, the equations of general relativity become a system of linear equations, specifically a system of wave equations [7]

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right) h_{\alpha\beta} = 0. \tag{1.8}$$

Equation (1.8) is a three-dimensional wave equation, telling us that gravitational waves travel at the speed of light c. The gravitational wave curvature tensor $\boldsymbol{h}$ can be considered as the gravitational wave field. The wave field is transverse and traceless, and for waves travelling in the z-direction may be expressed as follows:

$$h_{\alpha\beta} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & h_{xx} & h_{xy} & 0 \\ 0 & h_{yx} & h_{yy} & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}. \tag{1.9}$$

There is no z-component due to the transverse nature of the waves, and to be traceless h satisfies

$$h_{xx} = -h_{yy}. \tag{1.10}$$

Because the Riemann tensor is symmetric, h also satisfies

$$h_{xy} = h_{yx}. \tag{1.11}$$

The symmetry of h means that there are just two possible independent polarization states which are usually denoted h_{+} and $h_{\times}$. In the case of sinusoidal gravitational waves we can express these polarizations as

$$h_{+} = h_{xx} = \mathrm{Re}\,[A_{+}\mathrm{e}^{-\mathrm{i}\omega(t-z/c)}], \tag{1.12}$$

$$h_{\times} = h_{xy} = \mathrm{Re}\,[A_{\times}\mathrm{e}^{-\mathrm{i}\omega(t-z/c)}]. \tag{1.13}$$

Here A_{+} and $A_{\times}$ are the strain amplitudes of each polarization.

We have already seen that a gravitational wave field moves masses in the same way that an electromagnetic wave sets charged particles in motion. Each wave field exerts tidal forces on objects through which it passes. The corresponding lines of force have a quadrupole pattern as shown in figure 3. Figure 3(*a*) shows the force lines of the '+' polarization and (*b*) shows the '×' polarization which is rotated 45° with respect to the '+' state. These time-varying tidal forces can deform an elastic body or change the distance between mass points in free space. A ring of particles placed perpendicular to the wave propagation direction will be distorted as we already saw in figure 1.

Einstein's famous quadrupole formula describes the gravitational wave amplitude from a source. Einstein derived his formula in a slow-motion weak field approximation, but Thorne [8] emphasizes that the result is accurate as long as the reduced wavelength exceeds source size. This condition applies to all but the most compact sources such as forming or coalescing black holes. The latter are potentially the strongest and most detectable sources. It is unfortunate that these are just the ones where the nonlinearity of general relativity, and in particular the gravitational redshift of the outgoing gravitational waves due to the gravitational energy of the spacetime curvature itself, makes the gravitational radiation amplitude extremely difficult to estimate.

The quadrupole formula states that the gravitational wave amplitude h at a distance R from a source is proportional to the second time derivative of the transverse traceless projection of the quadrupole moment evaluated at the retarded time $t - r/c$. That is

$$h_{jk} = \frac{2}{r}\frac{G}{c^4}\frac{\partial^2}{\partial t^2}[D_{jk}(t - R/c)]^{TT}, \qquad (j, k = 1, 2, 3) \tag{1.14}$$

where $[D_{jk}(t - R/c)]^{TT}$ is the transverse traceless projection of the quadrupole moment evaluated at retarded time $(t - R/c)$. The transverse traceless requirement relates to the transverse nature of gravitational waves, and the lack of wave generation from spherically symmetrical motions. For weak fields, for which gravitational self-energy is small (see Damour [13]) $\boldsymbol{D}$ is given by the second moment of the source mass density ρ:

$$D_{jk} = \int \rho(t)[x^j x^k - \tfrac{1}{3}x^2\delta^{jk}]\,\mathrm{d}^3x. \tag{1.15}$$

In this equation the term with the Kronecker delta ensures that D is trace-free.

The total gravitational wave power is proportional to the square of the third time derivative of the mass quadrupole moment [14]. In general, the total energy radiation rate L_G is given by the sum of the squares of all the projections of the quadrupole moment

$$L_G = \frac{1}{5}\frac{G}{c^5}\sum_{jk}\left|\frac{\mathrm{d}^3 D_{jk}}{\mathrm{d}t^3}\right|^2. \tag{1.16}$$

The very small universal constant

$$\frac{G}{5c^5} = 5.49 \times 10^{-54}\ \mathrm{s\,J^{-1}} \tag{1.17}$$

sets the characteristic gravitational radiation power output.

The presence of the factor (G/c^5) in equation (1.16) indicates that unless the $\dddot{D}_{jk}$ involves energy of astronomical proportions, the gravitational wave power will be extremely small. It is easy to show that it is impossible to generate detectable gravitational waves on the laboratory scale, even at extreme limits of known technology. We can only hope to observe gravitational waves emitted by astrophysical sources.

It is useful, however, to consider a laboratory source simply as an application of equations (1.15) and (1.16). Suppose the source consists of a pair of masses distance L apart,

and joined by a spring to allow sinusoidal oscillation of their spacing at angular frequency ω. From equation (1.15), $D = ML^2$, and if $L = L_0 + a \sin \omega t$, it follows that

$$D = ML_0^2 + 2ML_0 a \sin \omega t + Ma^2 \sin^2 \omega t. \tag{1.18}$$

From equation (1.18), taking the third time derivative, it follows that this source will produce gravitational waves at the frequencies of ω and 2ω. If the amplitude a is small compared with L_0, the 2ω term is small and the gravitational wave luminosity is given by

$$L_G = \frac{G}{5c^5} 4M^2 L_0^2 a^2 \omega^6. \tag{1.19}$$

For any practical harmonic oscillator on Earth L_G is infinitesimal. However, such mass quadrupole oscillators have been created as sources of near-field dynamic gravity gradients (not waves) for the purpose of calibrating gravitational wave detectors. Such systems has been successfully used for low-frequency detectors tuned to the Crab pulsar [15] and also by the Rome group to calibrate their resonant-bar detector and measure the inverse square law of gravitation [16].

2. Sources of gravitational waves

2.1. Introduction

Astrophysics provides us with a variety of candidate systems which should be observable in the spectrum of gravitational waves. However, it is important to remember that our powers of prediction of new phenomena are poor, so any list of sources is almost certain to be incomplete.

Amongst stellar mass systems we expect detectable gravitational radiation from the formation of black holes and neutron stars, and the coalescence of binary neutron stars and final collapse of such binaries to form a black hole. We would expect not only discrete sources, but also continuous stochastic backgrounds created from large numbers of discrete sources. In our Galaxy the very large populations of binary stars create a stochastic background in the 10^{-2} to 10 Hz range. In the universe as a whole all of the above neutron star and black hole formation events are likely to merge to form a continuous background in the audio frequency part of the spectrum. This particular background provides an exciting opportunity to observe the earliest epochs of Galaxy formation, and the birth and growth of the supermassive black holes that appear to reside in the nuclei of many galaxies and quasars. We may also be able to observe gravitational waves from the big bang, amplified during the inflationary era, and possible signatures of cosmological phase transitions and topological defects such as cosmic strings. These very earliest sources in the universe would constitute a probe of physics at energy scales far beyond those accessible in particle accelerators and hence represent the best opportunity we have to obtain experimental data from the era of inflation.

Back in our own Galaxy we would also expect to find many quasi-monochromatic sources of gravitational waves such as individual binary star systems, including binary neutron stars as they evolve towards coalescence, and various rotating neutron star systems such as millisecond and x-ray pulsars.

Figure 16 shows the gravitational wave spectrum across nine decades. The spectrum conveniently divides into a terrestrial detection band, above 1 Hz (generally within the audio frequency band), mainly associated with stellar mass compact objects, and a space detection band, from 10^{-6} to 10^{-1} Hz, where sources include both binary star systems in our Galaxy, and cosmological sources associated with massive black hole interactions.

2.2. Classification of sources

All the above sources can be naturally divided into three distinct classes, according to the methods of data processing and signal extraction. The first class consists of catastrophic *burst sources* such as the final coalescence of compact binary star systems, or the formation of neutron stars and black holes in supernova events. The binary coalescence events can consist of binary neutron stars, binary black holes, or neutron-star–black-hole binaries. The burst signal consists of a very short single event, consisting of one or very few cycles, and hence is characterized by a broad bandwidth, roughly determined by the reciprocal of the event duration.

The second class consists of *narrow-band sources*. These include the rotation of single nonaxisymmetric stars, particularly pulsars and accreting neutron stars, as well as binary star systems far from coalescence. All such systems are quasi-periodic because gravitational wave energy loss must cause period evolution, and in general they are also periodically Doppler shifted by binary motion and Earth's orbital motion. Such sources are generally weaker than the burst sources, but in principle they are always amenable to long-term integration to extract signals from the noise. This requires accurate knowledge of the frequency modulations to maintain a coherent integration. Assuming a white noise background and perfect knowledge of the frequency evolution, the signal-to-noise ratio increases as $N^{1/2}$ where N is the number of cycles. For narrow-band sources it may be possible to integrate for 10^8 s, compared with less than 10 ms for a burst source. Thus, at 100 Hz, N can be 10^{10} allowing a 10^5-fold improvement in signal-to-noise ratio.

The third class of sources are the *stochastic backgrounds* produced from the integrated effects of many weak periodic sources in our Galaxy, or from a large population of burst sources at very large distances, as well as the above-mentioned cosmological processes in the early universe. Stochastic backgrounds are difficult to detect in a single detector because they are practically indistinguishable from instrument noise. If the source was not isotropically distributed (such as a population of binary stars towards the centre of our Galaxy), it might be detectable from the variation of observed instrument noise as the detector orientation varied on the rotating Earth. However, a much better way of detecting stochastic backgrounds is by cross-correlating two nearby detectors. In this case the correlated stochastic signal will integrate up in relation to the uncorrelated instrument noise (assuming both detectors to be truly independent). In this case the signal-to-noise ratio increases as $N^{1/4}$, where N is the effective number of cycles, determined by the observation frequency. This technique allows a 300-fold improvement in signal-to-noise ratio in 10^8 s of integration, (compared again with a 10 ms burst source).

Binary neutron star systems can produce gravitational waves in all the three classes. First, a large population of binary neutron stars in our Galaxy, with orbital periods in the range from days to minutes, can produce a stochastic background of individually unresolvable sources in our Galaxy in the frequency band $\sim 10^{-2}$–10^{-5} Hz. Nearby individual systems which are far from binary coalescence could produce detectable nearly monochromatic waves at any frequency up to 0.1 Hz. In addition to the binary orbit, the individual rotation of the stars themselves (if they are nonaxisymmetric), will also give rise to quasi-periodic gravitational waves. For example, the spin-down of a millisecond pulsar can be entirely due to gravitational wave emission if just $10^{-7} M_\odot$ is located in a nonaxisymmetric configuration on the star [17]. As the binary evolves and radiates away gravitational potential energy, it will gradually spiral inwards. As a result, the frequency of the gravitational wave signal will *increase* with time. At the same time, any periodic waves from the rotation of the individual stars will cause loss of rotational kinetic energy, so that this frequency will *decrease* with time. Eventually the stars will coalesce, resulting in a short intense burst of gravitational waves.

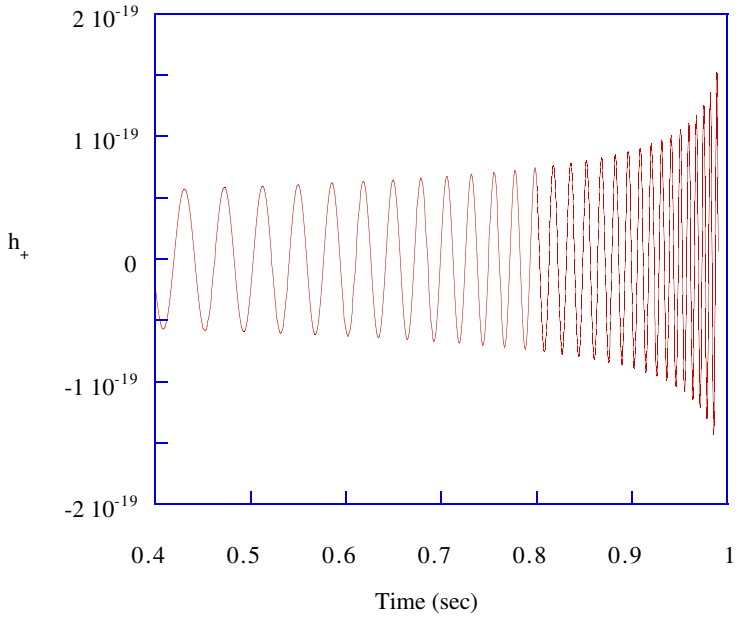

Figure 4. Predicted gravitational waveform from the inspiral of $10M_{\odot}$ black hole binaries [18]. To show the individual cycles near coalescence, the orbital frequency in this graph has been artificially reduced.

Figure 4 is a predicted gravitational waveform produced by the inspiral of a binary made of two black holes [18]. During the final minutes of a coalescing binary the waveform is highly distinctive.

The time evolution of the frequency of two $1.4M_{\odot}$ neutron stars in a binary system is shown in figure 5. Over a period of about 1000 s the frequency rises from about 10 Hz to 1 kHz as the neutron stars spiral together. This part of the merger begins when the stars are within about 1000 km of each other. The orbital velocity is $\sim 0.1c$. Signal detection can make use of exactly the same principles used to extract narrow-band signals due to the fact that the time evolution of the signal frequency and phase is predictable. Matched filtering, based on the existence of a family of accurately predictable waveforms, can allow integration over all of the observed signal cycles. A terrestrial detector may be able to observe more than 1000 gravitational wave cycles from a neutron star binary. The total number of cycles observable increases strongly as the lower cut of frequency is reduced. This provides a strong incentive for creating detectors at the lowest possible frequency. For 1000 observable cycles, the signal-to-noise ratio is improved by the square root of this number, or about 30.

Exactly the same concepts may be applied to supermassive black hole binaries. The signal frequency decreases inversely with the black hole mass. Thus a pair of 10^8 solar mass black holes would produce a chirp of gravitational waves rising from one cycle per year to a cycle per day over a period of 10^{11} s! This is much too long to observe the entire event, so in reality one could only expect to observe rather few cycles. However, since there appear to be a large population of quasars and galaxies containing massive black holes, as well as a large population of interacting galaxies, such events may not be uncommon, and may give rise to numerous strongly detectable sources at very low frequencies.

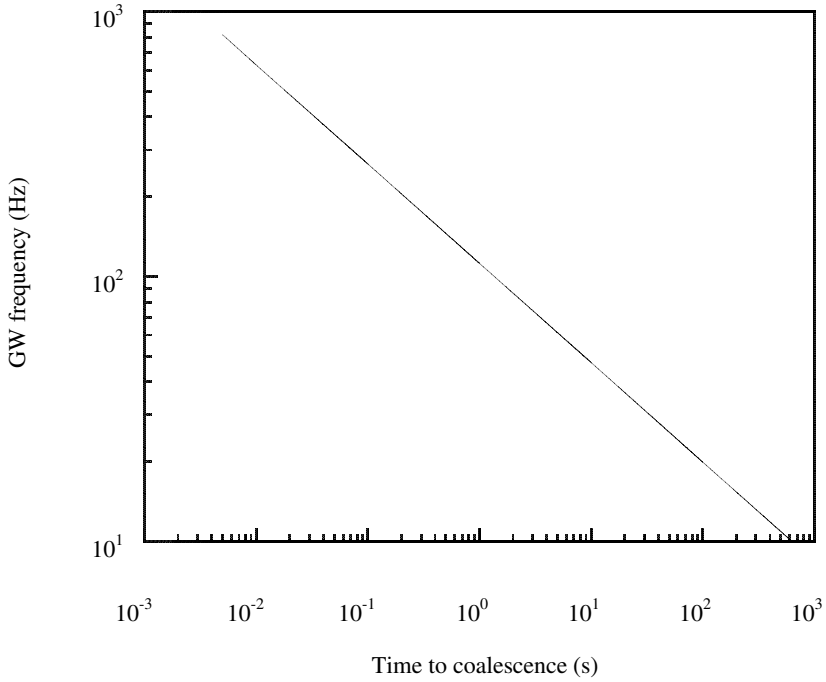

Figure 5. The frequency evolution for coalescence of a binary system consisting of a pair of $1.4M_\odot$ neutron stars.

2.3. Supernovae

Supernovae have long been considered a primary source of gravitational wave bursts. Unfortunately, astrophysics gives us few clues to their efficiency in producing gravitational waves during core collapse. Indeed, the true nature of the various supernova classes is still uncertain. In particular, it is uncertain whether a type I(a) supernova occurs through detonation or collapse in a solitary or binary white dwarf system. Some supernovae, such as the Crab supernova of the year 1054AD, do create neutron stars, but others such as supernova 1987A have failed to yield an identifiable neutron star. It is also unknown whether supernovae can directly create black holes.

The possibility of strong gravitational radiation emission only occurs if the event consists of gravitational collapse to a neutron star or black hole. Even in this case the efficiency of gravitational radiation emission is contentious. (The efficiency ε is defined as the fraction of the rest mass of the system concerned converted to gravitational waves.) Estimates of gravitational wave emission have been based on two quite independent approaches. The first follows the gravitational collapse of a system in two or three dimensions, considering as much of the physics as possible—magnetohydrodynamics, neutrino physics, and general relativity—in an attempt to deduce the time dependence of the quadrupole moment and hence the conversion efficiency to gravitational waves.

The second approach assumes that the collapse has occurred and follows the time evolution of a newly formed hot and rapidly rotating neutron star. Any phenomenon that creates non-axial symmetry will convert rotational kinetic energy into gravitational waves. In addition, convective motions, vibrational modes of oscillation of the star, and nonaxisymmetric emission of neutrinos can convert into gravitational wave emission. To date, many core collapse

calculations have predicted rather low efficiency—say 10^{-6} to 10^{-10} [19, 20], while the post-collapse evolution calculations have predicted far higher efficiencies, of order 10^{-3} to 10^{-4}. We will discuss some of these results below. However, it must be emphasized that all the models used so far are deficient due to uncertainty regarding the equation of state and the viscosity and the difficulty in constructing a full 3D numerical general relativistic hydrodynamical code which must also include magnetic and neutrino phenomena [21]. Due to the enormous difficulties involved it seems most unlikely that theory alone will be able to answer the primary observational questions on the efficiency and the waveforms generated in supernovae. However, almost all models show an unsurprising common feature: the efficiency of gravitational wave production depends on the angular momentum of the progenitor star.

Lai and Shapiro [22] have considered the time evolution of a new-born rapidly rotating neutron star. They have shown that the new-born star is driven by gravitational radiation into a non-asymmetric configuration due to a bar-mode instability. A unique gravitational wave signature ensues: the wave frequency sweeps rapidly downward from a few hundred hertz towards zero, while the wave amplitude increases rapidly from zero at the onset of the instability to a maximum at a few hundred hertz, and then reduces steadily as the frequency falls. Additional gravitational wave signals can also arise in rapidly rotating neutron stars. The rotating stars are modelled as nonaxisymmetric ellipsoids. A secularly unstable Maclaurin spheroid [23] will evolve away from the axisymmetric configuration due to gravitational radiation, and proceed ultimately toward a Dedekind ellipsoid [23].

According to Lai and Shapiro the characteristic amplitude of a gravitational wave during the evolution from a Maclaurin spheroid to a Dedekind ellipsoid is given (within 20% accuracy) by

$$h_c \sim 1.8 \times 10^{22} \left(\frac{10\ \mathrm{Mpc}}{R}\right) \left(\frac{M}{10M_\odot}\right)^{3/4} \left(\frac{r_0}{10\ \mathrm{km}}\right) f^{1/2} \tag{2.1}$$

where M and r_0 are the mass and radius of the star, respectively. Here h_c refers to the effective amplitude which takes into account the number of cycles that the signal is within the detector bandwidth (see below).

At high frequency, gravitational radiation can be expected from the evolution of a Jacobi-like ellipsoid [23] toward a Maclaurin spheroid. This Maclaurin spheroid can evolve further to a Dedekind ellipsoid. The characteristic amplitude during the Jacobi-like evolution can be fitted to the form

$$h \sim 2.7 \times 10^{-20} \left(\frac{10\ \mathrm{Mpc}}{R}\right) \left(\frac{M}{1.4M_\odot}\right)^{3/4} \left(\frac{r_0}{10\ \mathrm{km}}\right) f^{-1/5}. \tag{2.2}$$

Houser *et al* [24] have modelled the gravitational radiation from a bar-mode instability in rapidly rotating neutron stars. Their calculation using Newtonian gravity and without consideration of further collapse to a black hole, nor other hydrodynamic instabilities, gives a gravitational radiation conversion efficiency of $\varepsilon \sim 0.1\%$.

The above examples seem to indicate that supernovae which produce rapidly rotating neutron stars may be reasonably efficient sources of gravitational radiation. The nature of the production process is likely to be through shape instabilities such as those discussed, but it is unlikely that predictions of waveform are accurate. Large amounts of angular momentum may be radiated away in gravitational waves but if the duration and frequency evolution are unknown this presents an additional complication when it comes to trying to dig a signal out of the detector noise. The fraction of supernovae for which high gravitational wave emission occurs is unknown. In the following discussion where we need to use a numerical value, we shall adopt an efficiency of 0.1%. However, the uncertainty of this number must be recalled.

To start with, it is useful to note that a supernova of 0.1% efficiency produces a characteristic strain amplitude of $\sim 10^{-18}$ at 10 kpc (within our Galaxy), and 10^{-21} at 10 Mpc (halfway to the Virgo Cluster of galaxies). The chance of detecting gravitational wave bursts obviously depends strongly on the rate of the burst events. Due to the isolation of the Milky Way Galaxy, and to the large distances required to substantially increase the size of the target population, the amplitude distribution of bursts is extremely non-uniform. Strong events from our Galaxy are almost certainly rare, and to increase the event rate substantially one needs to be able to detect events in the Virgo Cluster. Thus, to have a chance of detecting several events per year, the sensitivity must be able to detect characteristic amplitudes of less than 10^{-21}.

2.4. Rough guide to signal amplitudes

It is useful to have some formulae with which to make rough estimates of signal amplitudes. For a continuous gravitational wave of frequency f_g, the strain amplitude h is related to the power density w through the relation [25, 26]

$$w \approx \frac{\pi c^3}{4G} f_g^2 \langle h^2 \rangle = 3.18 \times 10^{35} f_g^2 \langle h^2 \rangle \ \mathrm{Wm}^2. \tag{2.3}$$

where $h^2 = h_+^2 + h_\times^2$. Because of the large numerical constant in equation (2.3) the amplitude h is extremely small even for a fairly large power density. For a gravitational wave with strain amplitude of $h \sim 10^{-21}$ (typical of possible signals from the Virgo Cluster) at a frequency of 1 kHz, the flux would be 0.3 W m^{-2}, which is about 10^{20} times bigger than typical radio astrophysical energy fluxes. The strain amplitude can be written as

$$h = 4\pi R^2 w \sim \left(\frac{G}{\pi^2 c^3}\right)^{1/2} \frac{L^{1/2}}{f_g R} \sim 1.7 \times 10^{22} \left(\frac{1\ \mathrm{kHz}}{f_g}\right) \left(\frac{10\ \mathrm{Mpc}}{R}\right) \left(\frac{L}{10^{46}\ \mathrm{W}}\right)^{1/2}. \tag{2.4}$$

As we saw above, the modelling of gravitational wave forms in gravitational collapse is extremely uncertain. However, for a gravitational wave burst event, the characteristic time scale of the event τ_g, and the total gravitational energy released E_g, provide a reasonable basis for estimating source parameters. The energy radiation rate L is related to τ_g and E_g by

$$L \sim E_g/\tau_g. \tag{2.5}$$

Burst sources naturally have a broadband spectral distribution. The characteristic frequency of a burst of duration τ_g is roughly

$$f_g = \frac{1}{2\pi\tau_g}. \tag{2.6}$$

This frequency roughly defines the peak frequency in the spectrum. For a roughly Gaussian burst, the width of the spectrum Δf is of the same order of f_g. The strain amplitude can then be written as [8]

$$h \sim \left(\frac{G}{\pi^2 c^3}\right)^{1/2} \frac{(E_g/\tau_g)^{1/2}}{f_g R} \sim 5.8 \times 10^{-20} \left(\frac{E_g}{M_\odot c^2}\right)^{1/2} \left(\frac{1\ \mathrm{kHz}}{f_g}\right)^{1/2} \left(\frac{10\ \mathrm{Mpc}}{R}\right). \tag{2.7}$$

If a gravitational collapse forms a black hole, we can be more specific in estimating the event duration. Defining a characteristic time τ to be the time for the gravitational wave to travel across the region of strong gravitation d_s, which is assumed to be about twice the gravitational radius $2GM/c^2$, and assuming τ_g is approximately the same as the characteristic time τ, we have

$$\tau \sim \frac{1}{2\pi f_g} \sim \frac{d_s}{c} \sim \frac{4GM}{c^3}. \tag{2.8}$$

For a system of several solar masses, this corresponds to a frequency of a few kHz. Putting equation (2.8) into equation (2.7) and using $E_g = Mc^2$, the strain amplitude of a burst event then becomes [8]

$$h \sim \frac{1}{2\pi}\frac{c}{f_g R}\varepsilon^{1/2} \sim 5 \times 10^{-21}\left(\frac{1\ \text{kHz}}{f_g}\right)\left(\frac{10\ \text{Mpc}}{R}\right)\left(\frac{\varepsilon}{10^{-3}}\right)^{1/2}. \tag{2.9}$$

2.5. Neutron star coalescence sources

The modelling of gravitational wave emission from neutron star coalescence has been studied extensively. For most of their evolution, the neutron stars can be considered as point masses, and much of their evolution is well described by the quadrupole formula equations (1.15) and (1.16). The waveform as shown in figure 4 is quite distinctive and amenable to the method of matched filtering for signal detection. A numerical template is used, defined by the set of possible waveforms. When this is cross-correlated with the data and correctly matched in phase, it will produce a large positive correlation. The signal-to-noise ratio is substantially enhanced by this means. The apparent signal enhancement achievable is expressed in terms of the characteristic amplitude h_c. The characteristic amplitude represents the effective amplitude detected after optimal filtering of the waveform. Roughly, h_c includes an enhancement of the signal by the square root of the number of cycles within the spectral band of interest and is roughly a factor of 30 for a neutron star coalescence detected by a laser interferometer detector, although this increases strongly if the waveform is detectable at much lower frequencies where the frequency evolution is slow. For example, the number of observable cycles increases almost 50 times if the detector is able to observe down to 10 Hz instead of 100 Hz. This means that we can only roughly estimate the size of the detectable signal, as it depends on the detailed frequency response of the detector.

Thorne [18] gives the characteristic strain amplitude of the waves from inspiralling binaries as

$$h \sim 0.237\frac{\mu^{1/2}M^{1/3}}{r_0 f_c^{1/6}} = 4.1 \times 10^{-22}\left(\frac{\mu}{M_\odot}\right)^{1/2}\left(\frac{M}{M_\odot}\right)^{1/3}\left(\frac{100\ \text{Mpc}}{R}\right)\left(\frac{100\ \text{Hz}}{f_c}\right)^{1/6}. \tag{2.10}$$

Here M and μ are the total and reduced masses: $M = M_1 + M_2$, $\mu = M_1 M_2/M$, and f_c is roughly the frequency of maximum detector sensitivity.

Lai and Shapiro [22, 27] have modelled neutron star coalescence taking into account the dissipative hydrodynamics of the systems. They showed that a hydrodynamical instability arises through tidal interactions, which significantly accelerates the coalescence at small separations. This leads to a reduction in the coalescence time, and an increase in h compared with a non-viscous system, as shown in figure 6.

The rate of coalescence events is such that the chance of an event in our Galaxy is negligible. Based on the statistics of observed single and binary neutron star systems and on the supernovae rate in external galaxies [28, 29], it is estimated that the merger rate of binary neutron stars in our Galaxy is between 10^{-6} yr^{-1} and 10^{-4} yr^{-1}. For galaxies at $R \leqslant 200$ Mpc a lower limit of this rate is roughly 1–3 yr^{-1}. However, Tutukov *et al* [30] and Yamaoka *et al* [31] have shown that the above merger rate, calculated by means of statistics of observed binaries, is probably wrong because of the short lifetimes of most new-born neutron star binaries. From models based on stellar evolution, they estimate a neutron star binary merger rate up to 100 yr^{-1} in galaxies out to 200 Mpc (assuming a Hubble period of $T_{\text{Hubble}} = 1.5 \times 10^{10}$ yr, which corresponds to a Hubble constant of $H_0 \sim 66$ km s^{-1} Mpc^{-1}).

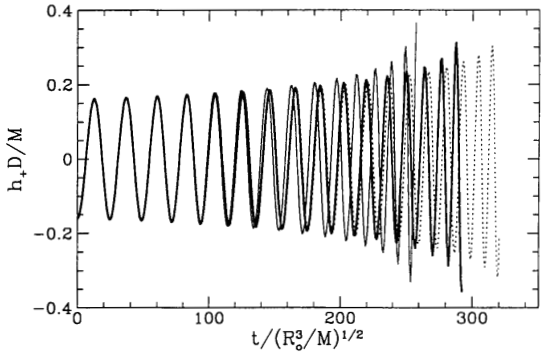

Figure 6. Waveform from neutron star binary coalescence [22]. The thick solid curve corresponds to zero viscosity. The thin solid curve assumes a mass-averaged shear kinetic viscosity $v = 0.5(M/r_0)^{1/2}$, where M and r_0 are the mass and the radius of the star respectively. The dotted curve is the case for two point masses (i.e. as figure 4).

The neutron star coalescence signals amplitude and waveform can be predicted with reasonable confidence, so that such sources are certain to be detected when sufficient sensitivity is achieved. The burst sources are also very promising for advanced gravitational wave detectors [32–34], but suffer from uncertainty in the value of ε. From equation (2.9), the gravitational wave strain amplitude for burst events at 200 Mpc is comparable to that from binary coalescence if $\varepsilon \sim 0.01$. In this case, the event rate will be much greater.

From the estimation of the stellar population with distance, the merger rate would be $\sim$0.1 yr^{-1} for a distance of $R \sim 20$ Mpc, the typical distance to the Virgo Cluster. The burst rate by contrast could be 30 yr^{-1} [35].

2.6. Low-frequency sources

As discussed above, very intense low-frequency gravitational wave sources can be expected from gravitational waves associated with the merger of massive black holes. Rees [36, 37] has argued that massive black holes are inevitable in the cores of young galaxies. There is very strong evidence that such black holes exist in many objects, with masses ranging from 10^6 to 10^9 solar masses. Galactic mergers are likely to give rise to such black hole mergers so one estimate of the rate of powerful gravity wave events can be obtained by estimating the rate of galactic mergers. For large galaxies with central black holes, Haehnelt [38] has estimated this rate at about one per century. This does not include the far more frequent mergers of smaller galaxies for which central black holes have not been confirmed. Vecchio [39] has shown that for the black hole merger rate to reach one per year practically all galaxies out to $z = 1$ would have to contribute black holes to feed the merger process. The latter is not such a strong constraint, however, since the horizon for detecting black hole mergers could be far beyond $z = 1$. For example, if one considers mergers to $z = 3$, only a few per cent of galaxies are required to have a central black hole to achieve one event per year.

Potentially detectable low-frequency gravitational waves can also be created by low-mass objects orbiting massive black holes. The low-mass objects could be smaller black holes or neutron stars, white dwarfs or even main sequence stars. Such sources could exist in the nucleus of our own Galaxy, and could in principle be detectable well beyond the Virgo Cluster (which multiplies up the number of potential sources by several thousand).

The basic physics behind gravity wave emission from sources of this type relates to the question of whether the gravity gradient from the central black hole is sufficient to tidally disrupt the incoming object. Clearly, main sequence stars will be most easily disrupted. Only if the central black hole is capable of swallowing whole the incoming object, will the gravitational radiation be strong. Otherwise the tidally disrupted star will form an accretion disc and slowly

accrete the material with negligible gravitational wave emission. To avoid tidal disruption, the Schwartzchild radius of the black hole must be large compared with the radius of the infalling object. Roughly, the central black hole must be 10^7–10^8 solar masses for main sequence stars, 10^4 solar masses for white dwarfs, and 10 solar masses for neutron stars.

Sigurdsson [40] has estimated the rate of capture of stellar mass black holes by massive black holes in galactic nuclei. The gravitational potential of the central black hole creates a cusp-like stellar density profile. It is difficult to estimate the space density of objects in the central cusp. It depends on star formation in the central high-density region of galaxies. However, the population in the cusp will never achieve dynamic equilibrium because stars approaching too close to the central black hole will be lost into the hole. Sigurdsson estimates the rate of black hole capture by a central object as 10^{-8} per year, meaning that a realistic detectable rate (one per year) requires observations to a range of the order of 3 Gpc. If the high densities in galactic nuclei favour higher mass star formation the event rate could increase by an order of magnitude.

2.7. Gravitational waves from binary systems

Short-period binary systems can create interesting amplitudes of gravitational waves in the 10^{-1}–10^{-5} Hz range. Such binaries exist in several classes. One of the most definite classes consist of the W Ursa Majoris binaries (WUMas), which are contact binary stars, with orbital periods of hours. They are generally low-mass systems. About one star in 150 with mass $>0.6M_\odot$ is a contact binary [41]. Lower mass binaries are difficult to detect: there could be an equal population of such systems with even shorter orbital periods.

A second important class of short-period binary stars are the cataclysmic variables, consisting of an interacting main sequence and white dwarf binary. Cataclysmic variables have orbital periods in the range 1000 s to one day: the shortest-period systems are probably white-dwarf–white-dwarf systems.

Neutron star binaries occur in various forms, from the NS–NS binaries such as the Hulse–Taylor pulsar PSR 1913 + 16, to rather more common systems in which neutron stars have white dwarf or main sequence star companions. The latter often occur as interacting binaries—low-mass or high-mass x-ray binaries, in which x-ray emission occurs due to mass transfer on to the neutron star.

Verbunt [42] has summarized the density and strain amplitude expected from the short-period binary star systems. Table 1 below is based on his review. The table shows the rough number density and mass parameters, and the distances of typical sources. Most produce gravitational waves $\sim 10^{-3}$–10^{-4} Hz, at an amplitude $\sim 10^{-20}$–10^{-22}. There is clearly an abundance of sources in the categories of nearby sources ($<$100 pc), such that the total population creates a stochastic background of gravitational wave noise.

Several x-ray binary systems have been shown to contain neutron stars spinning in the range 250–350 Hz. It is suggested that their spin rate is determined by the balance between the mass accretion which provides a source of energy and angular momentum, and gravitational wave emission which is the dominant energy sink. Emission could occur by a variety of symmetry breaking instabilities. A specific suggestion is the so called r-mode instability, in which rotational fluid flow patterns are induced in the neutron star [43].

Stellar evolution studies suggest that globular clusters are a breeding ground for close-spaced binary black holes [44]. It has been recently suggested that these binaries get ejected from globular clusters by three-body interactions, creating a halo population of binaries which will coalesce in less than a Hubble time. Such binaries might coalesce without electromagnetic signature, and could have a sufficiently large population that they could be detected at a

Table 1. Binary sources of low frequency gravitational waves. The table shows the rough galactic density of each source, the distance within which sources are expected, the typical mass of each binary component, and the typical frequency and strain amplitude from the nearest sources.

Type	Density/number	d (pc)	$M/M_\odot$	$m/M_\odot$	$\log f$ (s^{-1})	$\log h$
WUMa (0.3–0.6$M_\odot$)	2×10^{-4} pc^{-3}	15	0.6	0.3	−4.0	−20.4
WUMa (0.1–0.3$M_\odot$)	2×10^{-4} pc^{-3}	15	0.3	0.1	−3.7	−20.7
Cataclysmic variables	10^{-5} pc^{-3}	45	0.3	0.6	−3.7	−20.7
Double degenerates (AM CVn)		100	0.04	0.6	−2.7	−21.2
Low-mass x-ray binaries ($P_b < 2 \times 10^{-4}$ s)	30	1 000	0.4	1.4	−3.8	−21.7
Low-mass binary pulsars (PSR 2051-08)		1 300	0.03	1.4	−3.8	−21.7
High-mass x-ray binaries (Cyg X-3)	1	10 000	4.0	1.4	−3.9	−21.9
NS–NS binary pulsars (1913 + 16)	$<10^{-5}$	500	1.4	1.4	−3.7	−20.8
Binaries in globular clusters (4U1820-30)		8 100	0.06	1.4	−2.5	−22.3

reasonable rate at $h \sim 10^{-21}$.

Gamma ray bursts which emit energy comparable to a solar mass at cosmological distances could be due to the formation of black holes, or to neutron star binary coalescence, or to the coalescence of neutron-star–black-hole binaries. Except in the case of spherically symmetrical black hole formation, these mechanisms should all include strong gravitational wave bursts. Searches have failed to find correlations between bursts and existing detectors, but this is not unexpected as sensitivity is still not high enough.

Neutron star black hole coalescences, whether or not they are associated with gamma bursts, can allow neutron star structure and microphysics to be probed because the break point in the coalescence waveform is set by the tidal disruption of the neutron star. This depends strongly on the neutron star radius and equation of state.

2.8. Stochastic background from the era of early star formation

We now consider the effects of supernovae and neutron star births at cosmological distances. In this case, we are extrapolating from a radius of 10 Mpc to a radius of several Gpc. For example, we consider supernovae from galaxies at redshift $z = 2$. Such galaxies are much older than massive stellar lifetimes, and the rate of supernovae in such systems is generally thought to be 10–100 times greater than supernovae in contemporary galaxies [45]. This is supported by observations by Cowie *et al* [46] which indicate a fourfold enhancement in faint blue galaxies at $z \geqslant 1$. At greater distances, millimetre wavelength studies of the Hubble deep field region show the presence very-high-luminosity objects consistent with dust-enshrouded galaxies at $z \sim 2$–4. Observations indicate that star formation is occurring at rates ∼50 times that in the present epoch [47]. The significance of these increased star formation rates, and hence increased supernova rates, is that it leads to the possibility that the gravitational waves from supernovae create a nearly continuous stochastic background.

First consider a simple case. Suppose that all supernovae have a gravitational wave burst duration τ, and a mean rate of occurrence within some horizon distance (say 3 Gpc), of R bursts per second. Then the mean duty cycle D of supernova bursts is given by $D = R\tau$. If $\tau \sim 10^{-3}$ s, then D reaches unity when R reaches 3×10^{10} y^{-1}, or 10^3 s^{-1}. When D reaches unity the supernova bursts create an effectively continuous stochastic background. To make an accurate determination of the supernova stochastic background, one needs to take into account both evolutionary effects and cosmological effects. If every population I (second-generation) star was the result of a single prior supernova, then there would need to have been $\sim 10^{21}$ supernovae to create the observed population of second-generation stars. This corresponds

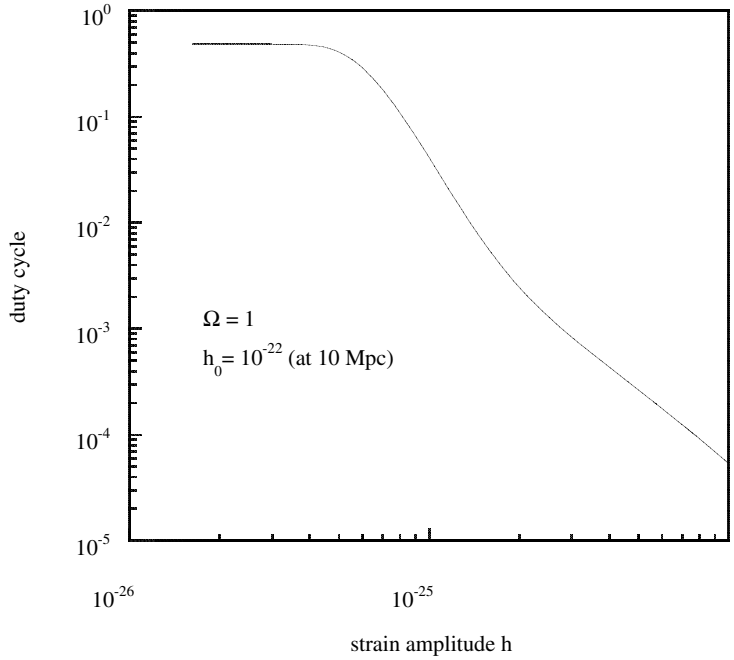

Figure 7. Duty cycle versus strain amplitude for supernova-generated gravitational radiation (with an initial Gaussian burst of star formation at $z = 2$) [49].

to an average rate Excedrin 1000 supernovae s^{-1}. Redshifts both stretch the pulses and the mean time between bursts. The luminosity distance in non-Euclidean geometry changes the observed amplitude of each burst.

A preliminary analysis in flat spacetime with assumed star formation rates showed that the event rate could be as high as 10^4 s^{-1} [48]. Burman *et al* [49] refined the predictions of [48] using various predictions for star formation rates to determine the duty cycle of short bursts of gravitational waves from supernovae within the observable universe for various cosmological models. Ferrari *et al* have separately considered supernovae [50] and gravitational waves from young neuron stars [51]. They obtained event rates $\sim$20 s^{-1}.

Figure 7 gives a typical result [49]. This result uses a Gaussian burst of star formation about $z = 2$. It shows the burst amplitude versus duty cycle for supernovae assumed to have an amplitude $h_0 = 10^{-22}$ at 10 Mpc. The background can only be considered a true stochastic background as D tends to unity: for this model this occurs at $h \sim 10^{-25}$. Most of this signal is due to events occurring during the initial burst of star formation. The amplitude of this stochastic background will be characteristic of the more distant sources at $z = 2$.

Like all stochastic backgrounds, the supernova background can in principle be detected by cross-correlation of signals between nearby detectors (less than half a wavelength separation: for $\tau \sim 10^{-3}$ s, they should be less than 100 km apart) [52]. As discussed above, the signal-to-noise ratio is increased as the $\frac{1}{4}$ power of the effective measurement time defined by the cross-correlation integration time. For 10^7 s, integration at 1 kHz, this represents a 300-fold improvement. Thus, the combined effects of all supernovae is to create a signal which can be detected at a signal-to-noise ratio comparable to that of an individual supernova at 20–30 Mpc. Thus, a detector capable of detection extragalactic supernovae can, with cross-correlation, detect a stochastic background produced at 30 times greater distance.

There are other aspects of the supernova stochastic background which are worth mentioning. Its spectrum represents the average spectrum over all supernovae, but it will be reddened according to the contribution of high-redshift supernovae. The duty cycle is clearly amplitude dependent. Nearer sources will create less-frequent, larger-amplitude bursts. At low duty cycle the background will be like popcorn noise, while for $D > 1$, it will approximate Gaussian noise. There is an important difference in this regard. The presence of a popcorn noise component [53] means that unlike true white noise, the individual short bursts create broadband intensity correlations which might allow more powerful digging into the noise. For example, the broadband correlations might allow the background to be detected as spectral intensity correlations within a single detector. This might be combined with cross-correlation between two detectors to dig still deeper into the noise. Further work in this area is badly needed.

The energy density of the supernovae background Ω_{SN}, expressed as a fraction of closure density, is given by

$$\Omega_{SN} = \Omega f_s f_{SN} \bar{\varepsilon} \tag{2.11}$$

where Ω is the usual fraction of closure density for the universe as a whole, f_S is the fraction of this matter which forms into stars in a Hubble time, f_{SN} is the mass fraction which takes part in supernova events in a Hubble time, and $\bar{\varepsilon}$ the mean gravity wave conversion efficiency for supernovae. It is possible that Ω_{SN} could be in the range 10^{-6}–10^{-8}. However, if $\bar{\varepsilon}$ is low and the duty cycle is low, Ω_{SN} could be $\ll 10^{-10}$.

If the majority of the gravitational waves are generated in relatively long duration spin-downs of neutron stars the spectrum will be dominated by a continuous stochastic component, but if it is emitted in short supernova bursts, the popcorn component will dominates. If the energy density of the early star formation stochastic background is $\sim 10^{-8}$, then it should be eventually detectable by pairs of advanced detectors [54].

To show the signals on the same scale, which relates to detectability, stochastic sources are assumed to have been integrated up for times $\sim 10^8$ s, binary coalescences have been integrated over the coalescence frequency range, while the burst sources signal strengths are the only ones representing the instantaneous signal amplitude.

Finally, to summarize our discussion of sources, we present a graph (figure 8) containing estimates of various events. The comparison is approximate, as it compares various sources detected by various techniques. Supernovae signals would appear as bursts requiring no special signal processing. However, estimates must allow for a wide range of efficiencies and source distances. Black hole formation is similarly uncertain.

2.9. Cosmological gravitational waves from the big bang

Various sources of gravitational waves from the early universe have been hypothesized. These may be thought of as the gravitational wave analogue of the microwave cosmic background radiation. The cosmic microwave background originated at the epoch of last scattering, at a redshift $z \sim 10^3$ when neutral gas first formed in the universe. Thus, the microwave background probes the universe when it was $\sim 10^5$ years old. A similar background of neutrinos should also exist, a relic from their epoch of last scattering, about 0.1 s after the big bang, at a redshift $z \sim 10^{10}$. Due to the weak coupling of gravitational waves with matter, their epoch of release would have been much earlier still, at around the Planck time $\sim 10^{-43}$ s, or $z \sim 10^{30}$.

Thus primordial gravitational waves offer the tantalizing possibility of probing the universe very near to the moment of creation. Unfortunately, we do not have accurate predictions about their amplitude. It has been suggested that the background could have been parametrically

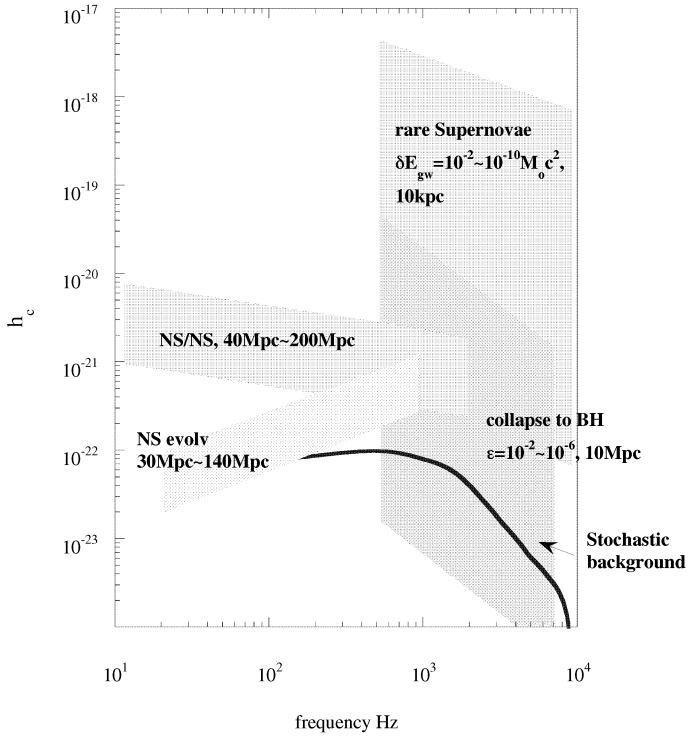

Figure 8. Spectrum of gravitational wave sources [18, 22]. In this figure, the abbreviations are: BH, collapse to black hole; NS/NS, neutron star coalescence; NS evol, secular evolution of a nonaxisymmetric neutron star.

amplified during a period of inflation, or that phase transitions in the early universe (for which there is no experimental evidence) could have created an enhanced background. If there was no process to enhance the background amplitude, then we need consider simply a thermal background that was in equilibrium at the extremely high energies of the Planck era. The background will then have been redshifted like any other radiation. Today this radiation would be in the microwave regime and have an amplitude $h \sim 10^{-35}$, which is beyond the possibility of detection.

If the universe contained an initial inhomogeneity of amplitude h_g [55], then today it would have an amplitude at frequency f given roughly by

$$h \sim 10^{-20} h_g / f. \tag{2.12}$$

We have little idea of the initial amplitude, except for limits set by the cosmic microwave background which implies that inhomogeneities traced by matter had an amplitude $\sim 10^{-5}$. This would imply that the cosmological background amplitude could be 10^{-28} at 1 kHz, (which is beyond terrestrial experiments) and 10^{-21} at 10^{-4} Hz, (which is experimentally accessible by space laser interferometers).

A constraint on the cosmological background is set by considering the energy density, and relating it to cosmological models. Thus cosmological backgrounds are often parametrized in terms of the closure density fraction Ω_g. If the spectrum contains equal energy in each decade, it has a slope of -1 on a log h–log f plot. For example, for the universe to be closed by gravitational waves, $\Omega_g = 1$, the amplitude h_g would be 10^{-13} at 10^{-5} Hz, falling to 10^{-21} at 1 kHz. For $\Omega_g = 10^{-6}$, h_g falls by three orders of magnitude to 10^{-16} at 10^{-5} Hz and 10^{-24} at 1 kHz.

It would appear most unlikely that the universe be closed by gravitational waves, and it would be surprising if gravitational waves contributed significantly to the missing mass. The binary pulsar, in addition to confirming the emission of gravitational waves, also allows limits

to be set on the stochastic background of gravitational waves, and on the time variation of the gravitational constant. Taylor and co-workers [56] have used pulsar timing of the binary pulsar PSR 1913 + 16 to set limits on cosmological backgrounds. The method only works at very low frequencies where both pulsars and atomic frequency standards have sufficient frequency precision that measurement of the arrival time variations of pulsar signals gives useful sensitivity to gravitational waves. Taylor's timing measurements over several years set a limit to $\Omega_g \sim 4 \times 10^{-2}$ in the frequency range 10^{-9} to 10^{-12} Hz [56].

3. Detection of gravitational waves

3.1. An overview of detector technology

The development of gravitational wave detectors was pioneered by Joseph Weber in the early 1960s [4]. He used a massive aluminium bar as the antenna. Following his work, researchers all over the world have been working hard to build different types of gravitational wave detectors. The detection of gravitational waves is based on the following idea (as discussed in section 1.2). A gravitational wave can be considered as a time-dependent strain in space having two linear polarization states (h_+ and $h_\times$). When the wave passes test masses in space it will cause displacements of the test masses, as shown in figure 1. A measurement of the relative displacements of the test masses is a measure of the wave. The gravitational wave does work on electromagnetic field, such as a capacitance or a laser light field. Because the displacements are very small, the momentum of the gravitational wave is in general limited by the uncertainty principle. The *quantum limit* presents a significant but not insurmountable barrier for future detectors.

A gravitational wave detector can be constructed from a pair of masses which can move 'freely' with respect to each other. They can be suspended as pendulums, so that in the horizontal direction they can be treated as nearly free masses above the pendulum resonant frequency. A pair of masses connected by a spring (figure 9(*a*)) can also be used to form a *resonant* gravitational wave detector. Such a mechanical resonator will be driven by a gravitational wave as long as it has spectral components at the resonant frequency of the mass–spring system. If the detector is a high-Q resonator, it will continue to oscillate long after the gravitational wave has passed. That is, the resonator *remembers* the effect of the gravitational wave. A measure of the oscillation of the resonator will give information about the passing gravitational wave.

The resonator need not necessarily be two masses connected by a spring. A lump of metal such as a cylindrical bar is well suited to the purpose (figure 9(*b*)). The difference between the bar detector and two point masses with a spring in between is that the bar detector has a set of higher-order resonant modes. However, for the lowest resonant frequency, the bar can be modelled just like two masses connected by a spring, with an effective mass equal to half the mass of the idealized detector. A multi-spring mass resonator (figure 9(*c*)) can be constructed to detect not only the amplitude of the gravitational waves but also the direction of the waves. This leads to the idea of a spherical antenna [34, 57–59], as shown in figure 9(*d*).

All resonant-mass detectors use cryogenic techniques to reduce the thermal noise and to enable the use of high-sensitivity superconducting transducers. A high Q-factor ensures that the thermal noise (which even after locking has a very large amplitude compared with the signal) is manifested as a highly sinusoidal, and hence predictable, waveform. A gravitational wave induces a small change in the amplitude and phase of this waveform. Typically, the memory effect is used to resolve the signal component averaged over perhaps a few hundred cycles of the antenna. The time over which the signal can be resolved depends most strongly on

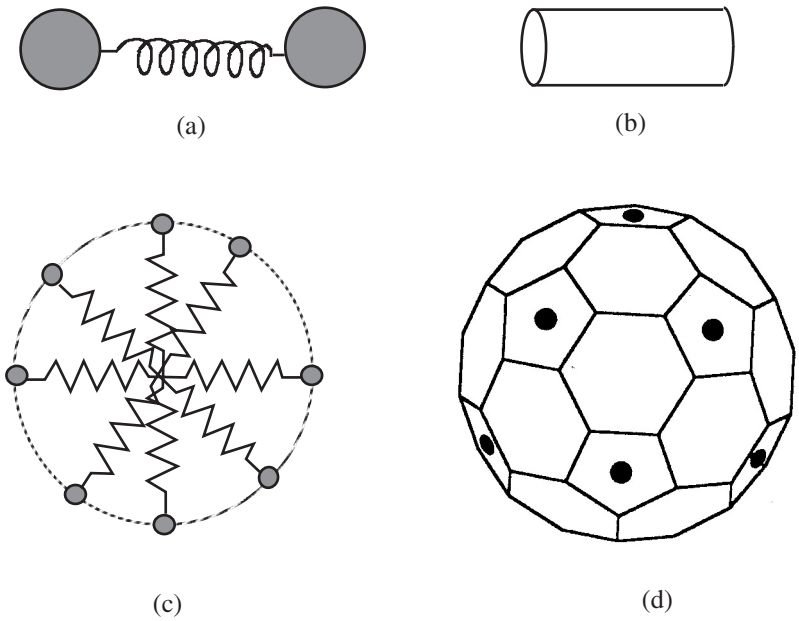

Figure 9. Model of resonant-mass gravitational wave detectors. (*a*) Two masses joined by a spring. (*b*) Bar detector. (*c*) Multi-spring mass detector. (*d*) Spherical detector, in this case formulated as a truncated icosahedron, with six transducers located as indicated.

the sensitivity and electromechanical coupling of the transducer which is used on the antenna. If the transducer is sufficiently strongly coupled, the signal could be resolved in perhaps a single cycle, and then the measured bandwidth would be comparable to the antenna frequency. Practical bar antennas to date have only demonstrated bandwidth of about 10 Hz. However, improved transducers should soon allow the bandwidth to reach $\sim$100 Hz and eventually near-quantum-limited sensitivity [60–63].

As indicated in figure 1, a passing gravitational wave will make a ring of particles stretch and shrink alternately in orthogonal directions. An interferometer configuration which can detect the relative position change between two orthogonal masses is a natural detector configuration [64–66], as shown in figure 10. When a gravitational wave passes, the lengths of the two arms of the interferometer change in antiphase. This results in a change in the interference intensity at the output. This change in light intensity is a measure of the gravitational wave. Since the test masses simply follow the passing wave pattern, these devices can be expected to accurately trace the waveform. The advantage of this type of system is the nonresonant feature and the fact that the scale of an instrument is set, not by the velocity of sound (which limits a resonant bar to a few metres in length if the detector is to detect radiation at $\sim$1 kHz), but by the velocity of light. Thus, a laser interferometer can detect gravitational waves over a wide band of frequencies and can in principle be scaled up to 150 km arm length, (for the same 1 kHz upper frequency) for which the absolute displacement $\Delta L = hL$ is much larger. Because 150 km arm length is impossible on the surface of the Earth (due to the curvature of the Earth), practical instruments must be scaled down to several kilometres.

In reality, the problem of noise always limits the bandwidth of laser interferometers. In their widest bandwidth configuration laser interferometers are limited by seismic and thermal noise at low frequency and photon shot noise at high frequency, as we discuss in detail in

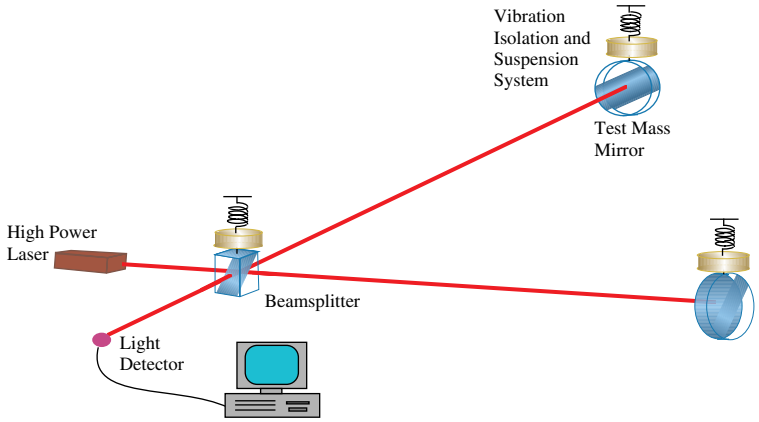

Figure 10. Schematic diagram of a Michelson interferometer for use as a gravitational wave detector.

section 5. This leaves a high-sensitivity bandwidth in the 100–500 Hz range. Optical tuning can in principle be used to restrict the bandwidth considerably, allowing optimum sensitivity to be achieved in narrower bands of several tens of Hz anywhere in the 10 Hz to several kHz range.

There is not a similar size constraint if a laser interferometer detector is placed in space. Laser interferometers can be conceived, of scale size millions of kilometres, in Earth or solar orbit. In this case practical considerations make such devices best suited to search for low-frequency sources in the range of 10^{-1} to 10^{-5} Hz. Free-floating spacecraft carrying test masses shielded from the solar wind, and low-power lasers should be able to achieve very high sensitivity, limited eventually by the confusion limit of gravitational wave 'noise' from the large number of binary star sources in the Galaxy (see section 3.2 for further discussion).

At even lower frequencies, signals from pulsars have been used as gravitational wave detectors. Pulsars, and especially millisecond pulsars, represent precise-frequency sources, close to the limit of the best man-made clocks. While we are accustomed to thinking of gravitational waves changing the relative spacing of test masses, this picture can be confusing when thinking of a pulsar as one of the test masses perhaps 1000 light years away. It is easier to consider the pulsar beam passing through the curved spacetime due to the passage of very-low-frequency gravitational waves in the vicinity of the Earth. (Both pictures are equivalent however.) The result is that the gravitational wave causes changes in the arrival time of the pulsar signal. Because the pulsar signal is weak, and because atomic clocks give best precision over long periods of time, the optimum precision of this method of detection occurs for frequencies $\sim 10^{-7}$ to 10^{-8} Hz [56].

Interferometric detection has the advantage that it gives intrinsic immunity to laser frequency noise. Indeed, a laser interferometer can in principle use white light. However, any single-beam detector is sensitive to frequency fluctuations in the source. The sensitivity limit is set directly by the frequency stability of the radiation source: $h \sim \Delta f/f$. Since frequencies can only be compared against a standard, the limit of a single-beam detector such as a pulsar signal is either the stability of the pulsar, or the stability of the frequency reference: today $\Delta f/f \sim 10^{-16}$.

The pulsar timing technique can to some extent avoid this single-beam clock stability problem by using several pulsars in different directions. A gravitational wave creates correlated fluctuations depending on the pulsar direction so that in principle it should be possible to dig at least an order of magnitude below the clock stability limit. Unfortunately, solar wind refractive

effects and interstellar scintillation are very strong in the MHz–GHz frequency range of strong pulsar signals. This provides an additional noise source that could mimic a gravitational wave.

There is no need in principle to rely on pulsars to provide the timing source for single or multibeam detection of gravitational waves. Interplanetary spacecraft generally transpond a ground-station-generated precision clock frequency back to the ground station. Comparison of the return signal frequency and the transmitted frequency predominantly records the spacecraft velocity, seen as a Doppler shift. Gravitational waves will appear as a perturbation in the Doppler tracking signal. Because the signal strength is stronger than for pulsars, and the path lengths are shorter, Doppler tracking is sensitive in the 10^{-4} to 10^{-5} Hz band. Solar wind refraction is again a very serious limit, but in this case it could be overcome if tracking took place at various frequencies, and if the frequencies used were increased into the millimetre wavelength range. Doppler tracking experiments [67, 68] have taken place successfully as low-cost add-ons to space missions, but the technique is unlikely to compete with space laser interferometers. Future interplanetary spacecraft equipped with nanosecond pulsed lasers avoid all local refractive errors from solar plasma, but solar wind buffeting causes additional noise which must be overcome by drag-free spacecraft technology.

3.2. Space laser interferometer gravitational wave detectors

A joint NASA–ESA space mission has been proposed, to place into solar orbit a set of three laser transponding spacecraft which would form a space laser interferometer for gravitational wave detection. The idea is to create a nested set of interferometers in a triangular configuration, and to use active transponding rather than passive interferometry as used in terrestrial detectors. The space environment allows the path length to be increased to 5 million kilometres. Consider first one vertex of the triangle. A pair of stabilized CW laser beams are transmitted through telescopes in 60° Y-shaped arms of the spacecraft, to two identical target spacecraft 5 million kilometres away. Each receives a very weak signal, but one sufficient to allow an on-board laser to be coherently phase locked to the incoming beam with a slight offset frequency. This laser is then directed back to the originating spacecraft. Thus the distant spacecraft acts like an active mirror, returning the incoming signal to its origin.

LISA (laser interferometer space antenna) as proposed uses three spacecraft in a special solar orbit. All six laser beams create three independent Michelson interferometers. The incoming beam at each arm has its phase compared (by beating) with some of the outgoing signal. That effectively measures the changes in the length of one arm. The same measurement is done in the second arm by the second laser beam. The phase differences are compared, to create a monitor of the arm length differences which could indicate the passage of a gravitational wave.

The above concept can give excellent sensitivity, as shown in the sensitivity curve for LISA in figure 11. This is only achieved if many noise sources are greatly reduced. The first is the buffeting by the solar wind. To overcome this noise the spacecraft are centred around a free-floating test mass, which is shielded from the wind. The spacecraft are controlled by miniature ion drives—field emission electric propulsion thrusters—to maintain the spacecraft location centred on the test mass. The forces required are $\sim 10^{-6}$ N.

A second potential source of noise is the gravity gradient due to the thermal expansion and contraction of the spacecraft structure. This can be overcome with careful design and thermal shielding.

To be able to use low-power thrusters the spacecraft must be placed in an orbit in which their relative positions have very high intrinsic stability. An orbit that achieves this requirement [69] is a heliocentric orbit of about 1 AU, 20° behind the Earth. The orbits of the spacecraft have a small eccentricity of $e = d/(D\sqrt{3})$, and a small inclination $i = d/D$, where d is the

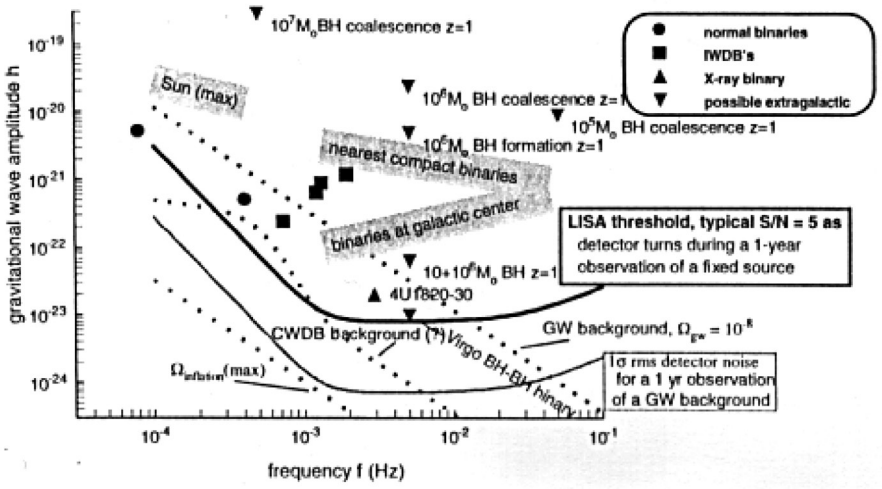

Figure 11. The sensitivity curve of LISA, along with its prime gravitational wave sources [322]. This is the sensitivity achieved after one year of integration.

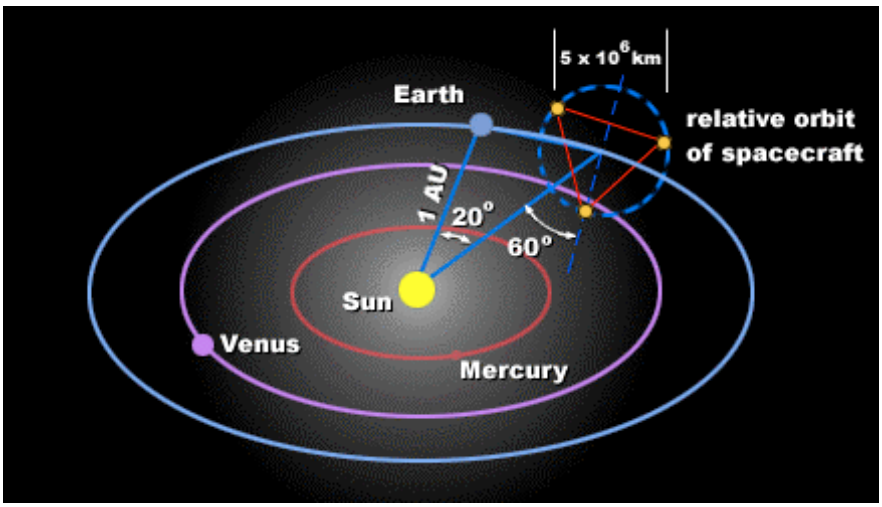

Figure 12. The positions of the proposed LISA spacecraft in heliocentric orbit [323].

triangle arm length and $D = 1$ AU is the semimajor axis of the orbit. Remarkably, three pairs of spacecraft in these orbits, with careful specification of their nodes, appears to maintain a nearly 'rigid' configuration which rotates slowly while maintaining the triangle in a plane which is inclined at 60° to the ecliptic. The positions of the spacecraft are shown in figure 12.

An important question is the orbital stability. If the relative spacing of the satellites changes too rapidly the fringe rate becomes high and the noise contribution from the local oscillator (which is used to apply frequency offsets and measures the fringe rate) becomes relatively larger. Thus it is essential that the fringe rate be low. Ideally the difference in arm length changes between two arms should be reduced to mm s^{-1}, less than the nominal metres per second arm length changes predicted for the proposed orbits. Stabilization schemes for the

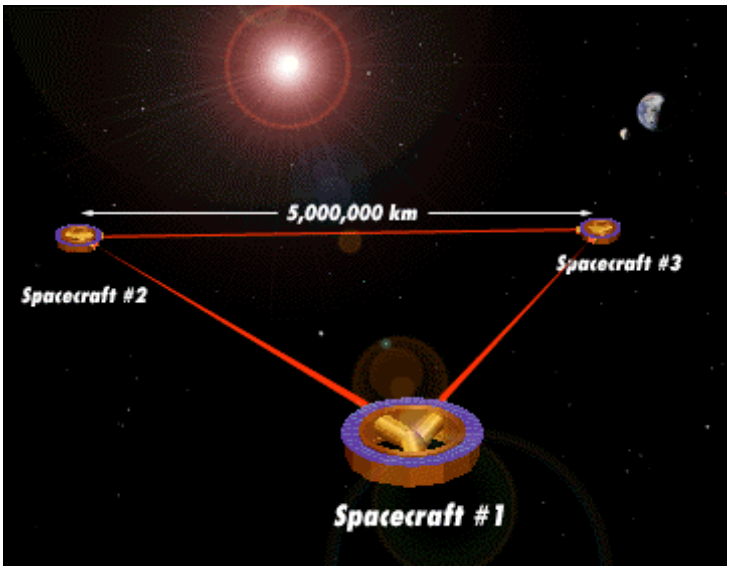

Figure 13. Artist's impression of space interferometer (LISA).

local oscillator through modulating the light in one arm or through the use of improved local oscillators should allow these problems to be overcome. Spacecraft manoeuvres are required occasionally to compensate for accumulated orbital drift.

Figure 13 shows an artist's impression of this remarkably ambitious conception. A large team of scientists is pursuing this project, which should fly in the second decade of the twenty-first century. More details are available from the LISA web page (http://lisa.ipl.nasa.gov/).

3.3. The world array of resonant-mass detectors

The improvement of resonant-bar detectors since they were first reported by Weber has been enormous. Their amplitude sensitivity has been increased several hundred times, corresponding to an improvement in flux sensitivity of about five orders of magnitude. Current detectors are sensitive to narrow frequency bands near 700 Hz and 900 Hz, but improvements will increase the bandwidth of each to >50 Hz. Figure 14 shows one of the present resonant-bar detectors.

An array of five resonant-mass gravitational wave detectors, coordinated under the International Gravitational Events Collaboration is in operation [70, 71, 110, 114, 156]. The detectors are located at Baton Rouge (Louisiana), CERN (Geneva), Legnaro (near Padova), Frascati (near Rome) and Perth (Australia). The data are available at a web address (http://axln01.lnl.infn.it/igec/). Since 1993 between two and four antennas have been in coincident operation searching for bursts at a strain sensitivity better than 10^{-18} (see figure 16). This is sufficient to detect strong galactic gravitational wave bursts, but insufficient for detection beyond our Galaxy. Over the past two decades the limits to the strength and rate of gravitational wave burst events impinging on the Earth has been reduced substantially, but these limits are still below astrophysical predictions. Thus, so far, it can be stated that the rate of gravitational wave bursts is not two orders of magnitude greater than expected from conservative astrophysical predictions, or else that their strength is not at the high end of predicted signal strengths ($\varepsilon > 10^{-2}$, see figure 29 for quantitative results).

Figure 14. Photograph of the antenna NAUTILUS at Frascati, showing the bar and its cryogenic shields.

The resonant bars have been used for rather deep pulsar searches in certain directions ($h \sim 10^{-23}$) [71] (see figure 30) and, by using cross-correlation, have been used to set impressive limits on the stochastic background of gravitational waves ($h \sim 10^{-22}$) [84].

Some of the resonant-bar detectors are being improved with better transducers and amplifiers, allowing their bandwidth to be increased towards 100 Hz. This improves the burst sensitivity and time resolution which in the immediate future should allow an order-of-magnitude improvement in burst sensitivity. Efforts are underway to create quantum-limited transducer systems (e.g. [72]) which should eventually allow a further order-of-magnitude improvement in amplitude sensitivity.

To match the ultimate sensitivity of long-baseline laser interferometer detectors (see below), it is necessary to increase detector mass from a few tonnes to a few hundred tonnes. Such massive spherical detectors have been proposed and development work is underway on small prototypes in Frascati, Leiden, and Sao Paulo [73–75]. As already noted they have the advantage of omnidirectional sensitivity. They use the proven cryogenic techniques of the existing resonant-mass detectors, but to scale up to hundred tonnes represents an exciting major engineering challenge (see section 4.10 for more details).

3.4. Laser interferometer detectors

Three long-baseline laser interferometer gravitational wave detectors have been or are being constructed. The US LIGO Laboratory consists of two 4 km arm length detectors, at Hanford, Washington State, and Livingstone, Louisiana (http://www.ligo.caltech.edu). The Italian/French VIRGO project is completing a 3 km arm length instrument at Casina, near Pisa (http://www.virgo.infn.it). Smaller detectors are under construction at Hannover (the German/British GEO project, 600 m arm length, http://www.geo600.uni-hannover.de), Tokyo (TAMA 300 m arm length, http://tamago.mtk.ano.ac.jp) and Perth (80 m arm length, http://www.gravity.pd.uwa.edu.au). Figure 15 shows some photographs of the LIGO detector in Hanford: (*a*) an aerial view, (*b*) the vacuum pipe tunnel and (*c*) the main cornerstation. The long-baseline laser interferometer detectors are initially expected to achieve sensitivity as shown in figure 16.

Laser interferometers are complex instruments limited by a range of noise sources: internal thermal noise in the mirror test masses, seismic noise, radiation pressure noise, laser frequency noise, control system noise, residual gas refraction noise etc. All noise sources must be reduced as far as possible to allow the detectors to achieve high sensitivity. The first decade of the twenty-first century will see steady improvement of the detectors. Late in that decade it is likely that major improvements to the detectors will be possible using improved lasers, improved test masses and improved vibration isolation. Figure 16 shows the expected improvements.

Ultimately, both laser interferometers and resonant masses can be improved by using various quantum measurement techniques. Laser interferometers can in principle also be improved by use of cryogenic methods, and by increasing their arm length.

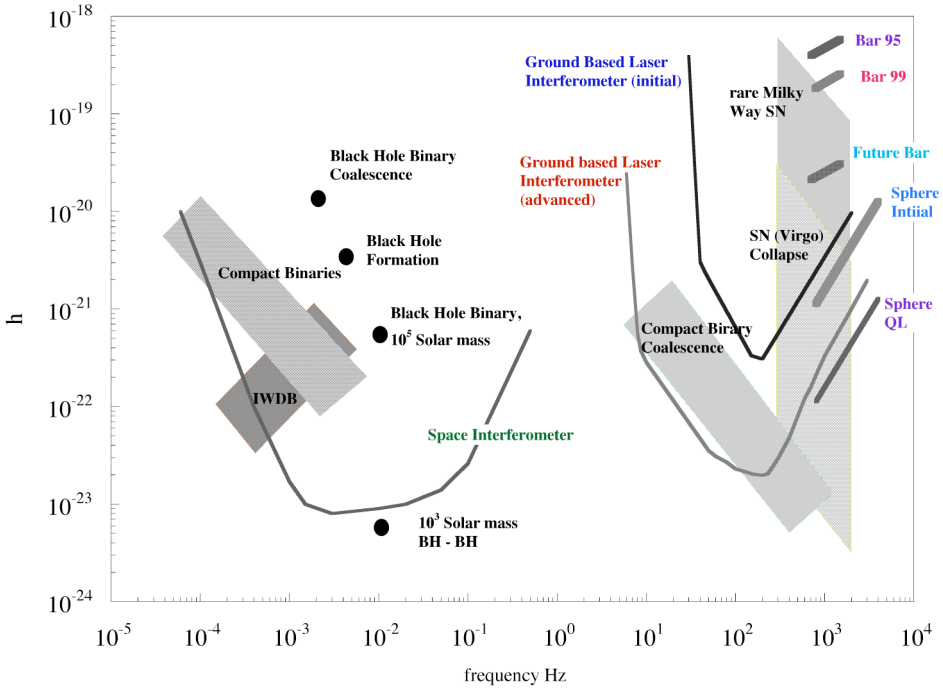

Figure 16. Rough comparison of various detector technologies and some sources. Note that the sensitivity depends on the type of signal searched for: the resonant-mass sensitivities quoted refer to burst sources (e.g. the narrow-band sensitivity of bars has already been demonstrated at 10^{-23}). At low frequencies interacting white dwarf binaries (IWDB) and neutron star binaries are known sources. At high frequency the only known source is neutron star binary coalescence: all the others have unknown signal strength.

All gravitational wave detectors provide data dominated by noise. All face difficult data processing challenges. In the following we shall briefly review some of the main issues in the context of the various classes of gravitational wave sources, before going on to examine resonant-mass and laser interferometer detectors in more detail.

3.5. Issues of data processing and signal detection

There are many important and still unresolved issues of data processing which it is necessary to solve to enable detection of signals to the levels anticipated from a simple analysis. These issues affect burst detection, stochastic background detection and narrow-band detection. Since the general analysis principles are independent of the type of detector used, we will discuss some of them in generality.

The raw data from a detector must first be filtered. In section 2.2 we discussed the use of *matched* filters or optimal filters to extract particular signals. An *optimal filter* is one which maximizes the signal-to-noise power ratio for a particular signal waveform. The term matched filter arose because in the special case where the noise is white, the optimal filter is one with an impulse response which *matches* the shape of the input signal. In these ideal circumstances the matched filter is simply a template of the waveform one desires to detect.

Think of the data from a detector over a particular period of time, due to some input signal. In a perfect noise-free detector it would create an output signal $s(t)$ which is uniquely

determined by incoming signal and the detector impulse response. After sampling, a real detector output consists of a two-dimensional array of output values o_i and time values t_i: $\{o_i, t_i\}$. But $o_i = s_i + n_i$ is a sum of the input signal s_i and the noise n_i. The template is a noise-free array representing $s(t)$, but it has an arbitrary phase, so can be represented $\{s_j, t_j\}$ where the difference between i and j represents a time difference. When the template is aligned with the signal $i = j$ and the sum of the products $o_i s_i (= s_i^2 + s_i n_i)$ over all values of i will be maximal. At times when s_i is zero there is no noise contribution. The template which accurately matches the ideal signal response of the detector is therefore the optimal filter function.

In practice one could apply a large calibration signal and measure the output signal to create such an optimal template.

Often it is more convenient to consider the problem in frequency space. In frequency space the phases of the noise frequency components are random and uncorrelated. If you multiply the Fourier transform of the output data $O(f)$ with the complex conjugate of the Fourier transform of the signal waveform $s^*(f)$, the signal component will be positive definite while the noise phases remain random. Summing over frequency space, the signal will add up but the noise frequency components will tend to cancel. Thus, in frequency space the matched filter transfer function is simply the complex conjugate of the Fourier transform of the input signal $s^*(f)$.

In almost all real situations the noise is not white. However, coloured noise can be whitened by passing it through a filter with a transfer function equal to $S_n^{-1/2}$ where S_n is the noise power spectral density of the noise. Thus, the optimal filter transfer function is simply $s^*(f)/S_n^{1/2}$. In the time domain the same correction for coloured noise is made using the noise autocorrelation function whose Fourier transform is S_n.

All optimal filters require a sum over frequency or time. If the signal is transient, then the sum will be zero after the signal has passed and the detector has stopped responding. For a resonant bar this will be several ring-down times of the bar (after which all memory of the signal is lost). In the same time *before* the signal arrives the bar loses memory of its instantaneous mechanical state. Thus it is only necessary to integrate over a modest time interval before and after the signal arrives. The Louisiana State University (LSU) group have implemented a time domain optimal filter by applying a large 'signal' pulse using a calibrator, and measuring the detector response, as well as the detector noise in the absence of a signal. Other bar groups have used frequency domain filters and obtained similar results [76].

There are many ways to implement optimal filters and the best choice often involves minimization of computation requirements for the particular search. For some systems optimal filters can be implemented in quasi-real time whereas for others the need for prior data requires the search to be conducted off-line.

A particular issue is that of noise stationarity. In practice, stationarity of the noise is not a good approximation. This means that the noise spectrum at the output varies with time, due, for example, to environmental effects such as variable microseismic noise from changes in the ocean wave conditions [77]. To overcome slow changes in the detector noise distribution it is possible to always use recent noise data for the creation of the optimum filter. Several groups use noise from the previous few hours to continually adapt the filter [78].

Another problem relates to the fact that in gravitational wave detectors it is impossible to turn off the signal, and possible signal-like noise events (such as cosmic ray events). Thus, in principle it is impossible to measure the noise spectrum in the absence of signal. In practice today this is not a critical issue (signals are rare and very small), but for future detectors it may be important to ensure that the filter does not suppress signal by confusing it with noise. Heng has shown [79] that periodic transient bursts are indeed suppressed by an optimum filter if the

bursts are present during the measurement of the noise distribution.

For CW signals, a Fourier transform of the entire data set represents an optimal filter. By this method the signal appears as a narrow spectral line. If the Earth's orbital and rotational Doppler corrections are included this method can be used to search for unknown CW signals (such as those due to isolated spinning neutron stars) in a particular direction (because the Doppler correction is direction dependent, see figure 30).

Traditionally the lock-in amplifier or phase-sensitive detector (PSD) has been used to create a matched filter operating in the time domain for CW or near-CW signals. For modern systems this type of filter can be implemented by software (hence not in real time) which allows it to be used for multiple searches through the same piece of data. It also allows CW searches with arbitrarily long integration times. (The traditional analogue lock-in amplifier is limited by the charge storage time of a capacitor.)

The lock-in amplifier form of the matched filter multiplies the data by +1 during the positive going signal cycle, and -1 during negative parts of the cycle. All results are summed. The sum represents the phase coherent integral of the absolute value of the signal over the observation time: hence the alternative name for this method: coherent integration. The noise components average towards zero, and a small signal component previously buried in the noise will emerge.

Assuming that the phase of the incoming signal is unknown, it is necessary to repeat the matched filter at 90° phase shift to determine the magnitude of the orthogonal components of the signal. (For example, if the signal was a pure sine function, the matched filter would give a zero output if the +1 and -1 multipliers were defined by a cosine function.) Clearly, if there were slowly varying phase errors due to errors in the timing of data acquisition, errors in direction for Doppler corrections, or errors in the prediction of the waveform, the accumulated result from a matched filter could average to zero.

For a CW source of fixed but unknown frequency it is usually simpler to replace matched filtering with the fast Fourier transform. However, if the frequency is modulated in a known pattern (such as occurs when you search for a signal from a known binary pulsar) [80] the coherent integration is computationally simpler.

Attempts at gravitational wave burst detection have normally followed techniques first introduced by Weber. By this method the data is first filtered, as discussed above, and then thresholded to obtain a list of candidate events. Some events will be due to spurious effects (see below). These can be vetoed if the appropriate monitor channels are used. Then the event lists for widely spaced pairs of detectors are correlated to search for coincidences. If the time axes for the event lists are randomly displaced one expects all correlation due to possible gravitational wave bursts to be absent. Thus it is possible to compare true-time coincidences with time-shifted coincidences to determine whether there is an excess of 'zero time delay coincidences'. This method is powerful since it allows the probability of accidental coincidence to be experimentally determined by simply running the random time shift analysis a sufficient number of times to obtain an accurate estimation of the probability of the observed peak. However, it is only relevant when the number of accidental coincidences is large.

Consider, for example, a six-month coincidence run which might yield 5000 'candidate events' in each detector, most of which are assumed to be noise or interference. The coincidence analysis might yield 30 true-time coincidences. For such analysis with existing resonant bars the coincidence window is usually more than 0.1 s, so that propagation delays across the Earth ($\sim$40 ms) can be neglected. Then 1000 random time delays are applied to the data of one detector and of these 10 might show 30 or more coincidences. If this was the case, then the zero time delay peak would have a probability that it was accidental of 10/1000 or 1%. This probability could be resolved with more accuracy if more random time delays were used. In

this type of experiment the time delays which are chosen must either be small compared with total duration of the experiment, or they should be modulo the experiment duration so that coincidences are not lost at the ends of the record.

A serious pitfall can occur in this type of analysis if the threshold for candidate event selection, or any other vetoing scheme, is variable during the coincidence experiment. To have such a variable accessible to the persons analysing the data can allow conscious or unconscious selection which can completely invalidate the statistical significance analysis. It can be very difficult to estimate the true significance after such selection has taken place. Since the days of Weber, researchers have been in general very careful to pre-set all thresholds to try to avoid such pitfalls.

For the existing array of five resonant-mass detectors it has been suggested that the entire body of data from all detectors should be used rather than candidate events. As discussed in the next section, the accidental coincidence rate is extremely low for five detectors. The thresholding method means that all phase information is lost. However, it need not be lost if the data from separate detectors are recombined along the lines used by VLBI radioastronomy. If this was done the detectors could represent a single telescope with angular resolution for incoming bursts set by the ratio of the time resolution (in principle $\sim$100 μs) and the near-Earth-diameter baseline (40 ms). However, the noise increases exponentially as one digs to lower and lower energy so the overall amplitude sensitivity of the array would be limited to $\sim$3 times.

Most data from terrestrial gravitational wave detectors can be idealized as the sum of a pair of thermal distributions. The first is the intrinsic Boltzmann distribution of the detector noise that one would measure using a spectrum analyser. This is usually due to some well understood noise sources such as thermal noise, electronics noise or shot noise. The second distribution is described as excess noise. Excess noise arises from rare and poorly understood sources. In the detector NIOBE at the University of Western Australia (UWA) some of the excess noise was correlated with electromagnetic pulses and seismic noise [81]. However, the majority was not identified, but might be due to strain relief events. Surprisingly, the excess noise distribution is rather similar for widely differing types of resonant-mass gravity wave detector. Figure 17 shows the idealized form of these distributions. Both may be expressed as

$$N = N_0 \mathrm{e}^{-E_e/kT}. \tag{3.1}$$

For a typical resonant-bar detector the intrinsic distribution parameters would be: $N_0 \sim 10^5$ per day, and $E_e \sim$ few millikelvin (Kelvin is simply a convenient energy scale). The excess distribution typically would have $N_0 \sim 10$ per day, and $E_e \sim$ few 100 mK: that is, the excess noise distribution has an event rate 10^4 times lower than the thermal distribution, and an effective energy 100 times larger. The presence of these two distributions allow improved data analysis, as discussed in section 4.8.

Periodic signals can be detected by coherent integration or Fourier transform methods. Because, as always, signals are near to the limit of detection sensitivity, long integration is needed. However, in long integrations signals will be smeared out by the Earth Doppler motion unless the source direction is known. Equally, if the source is a member of a binary system such as a binary millisecond pulsar it is necessary to know the ephemeris of the system itself as well as the precise source direction to prevent Doppler smearing of the signal. If coherent integration can be achieved, then the signal-to-noise ratio improves as $\tau^{1/2}$, which can allow very deep searches over a 1–3 year period.

The nearest millisecond pulsar PSR 0437-4715 is a typical such potential source. In this case the pulsar source is a binary system, which is extremely well defined by pulsar timing [82]. The observed radio pulse timing gives very accurate information which can be used to gate the

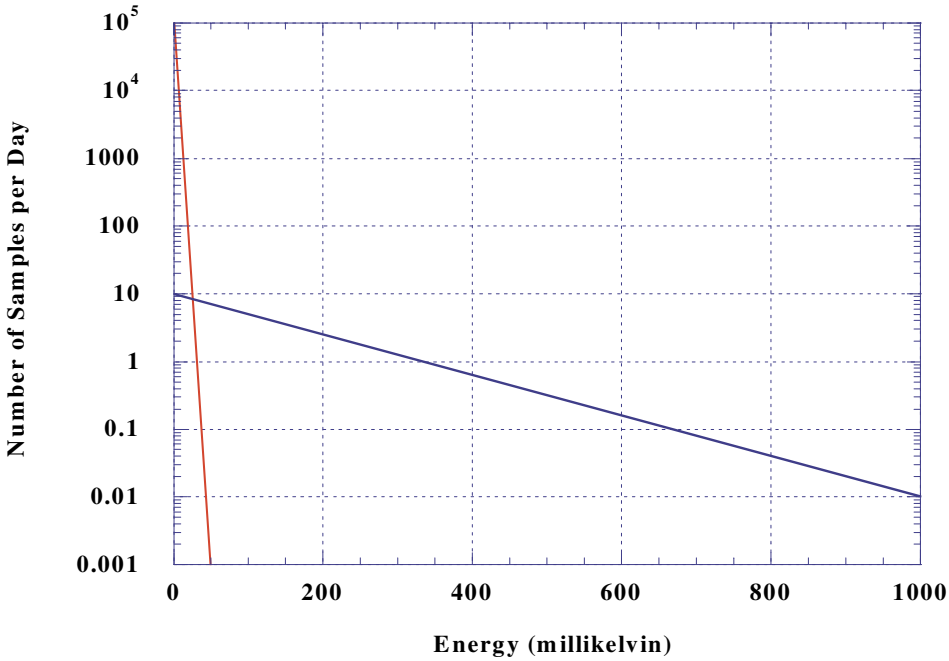

Figure 17. Detector noise is often characterized by a pair of Boltzmann distributions. The steep curve is the typical antenna thermal noise distribution for burst detection in a resonant bar. The flatter curve is the excess noise distribution due to rare disturbances.

phase-coherent integration of the detector output [80]. Such methods were pioneered by the Tokyo group [83] led by Hirakawa searching for gravitational radiation from the Crab pulsar.

It is likely that many such narrow-band sources will not be detected in advance by radio astronomy. Pulsar beaming ensures that the majority of pulsars are not visible in radio, and normal pulsars older than 10^8 years appear to cease to emit radio beams. There could easily be 1000 rotating neutron stars within the range of the nearest observed pulsars ($\sim$100 pc) meaning that a few old neutron stars could exist within 10 pc of the solar system.

Unfortunately, our ability to search for such sources is very poor because of the difficulty of searching all directions in the sky. The most obvious search strategy involves applying a separate ephemeris correction for each of typically 10^{10} source directions, and re-integrating the data 10^{10} times. This already is a daunting computational exercise, but it becomes 10^{10} times harder if the search space has to involve all possible binary orbits of the pulsar. Many investigators are searching for efficient algorithms to solve this problem, based on alternative filtering techniques or hierarchical searches [84].

As discuss in sections 2.2 and 2.8, stochastic signals can be detected by cross-correlation of nearby gravitational wave detectors. For optimum sensitivity the detectors must be located within about one reduced wavelength ($\lambda/2$) of each other. If the spacing requirement is satisfied, the signal-to-noise ratio increases as the $\frac{1}{4}$-power of the number of cycles observed [85]:

$$\frac{S}{N} = \left(\frac{S_{gw}^2}{S_1 S_2} B\tau\right)^{1/4}. \tag{3.2}$$

Here S_{gw} is the gravitational wave background power spectral density, S_1 and S_2 are the spectral

noise density of two detectors, B and τ are the bandwidth and duration of the observation respectively. Thus, a stochastic signal of characteristic frequency $\sim$100 Hz can be cross-correlated to gain a factor of $10^{2.5}$ in signal-to-noise ratio (compared with the observation of a single cycle) after 10^8 s integration. Schutz [85] has shown that this method can be particularly effectively applied to signals in detectors of quite different types: specifically resonant-mass detectors and laser interferometers, which conveniently are planned to be located in sufficiently close proximity to each other to satisfy the above spacing requirement.

The simplest cross-correlation experiment merely gives an output consisting of a single number (and a measure of its statistical significance). This can be quite misleading since there are many ways that cross-correlation can give a false positive result. The major difficulty in cross-correlation signal processing is to ensure that no correlated technical noise components exist in the signals. Remembering that the signal detected is generally going to be at least 100 times lower than the spectral noise floor accessible using normal fast Fourier transform diagnostic instrumentation, correlated features can exist which could never be detected in short-term monitoring. The correlated features could be weak spectral lines such as those created by electrical power harmonics, (which are phase coherent over the electrical grid) or occasional transients such as those due to lightning flashes. To prove that a positive cross-correlation signal was associated with gravitational waves it would be necessary to show that the correlation was preserved across the accessible frequency band, and that it was not due to intermittent transients due to electrical interference. The individual output spectra of the detectors would need to be resolved for weak spectral features to the same depth as the correlation detection threshold. Much effort at developing algorithms and solving some of these practical problems is underway [53, 86].

Giazotto [87] has shown that the stochastic background signal from the combined old radio pulsars in our Galaxy should be detectable in a single detector, due to the fact that they are non-isotropically distributed relative to the solar system. The central concentration of pulsars means that there should be a strong sideband modulation of the stochastic background intensity as the detector sweeps the sky during Earth rotation. This signal should appear in the technically very demanding 1–10 Hz frequency band.

The next two sections present resonant-mass detectors (section 4), and then laser interferometer detectors (section 5), with emphasis on techniques and the solution to various technological challenges.

4. Resonant-mass detectors

4.1. Introduction

Resonant-mass detectors are designed to measure acoustic signals induced in a large mass due to its coupling to a gravitational wave. Resonant detectors were first developed by Weber during the 1960s [4]. They consisted of large vibration-isolated aluminium cylinders instrumented with piezoelectric crystals glued on the surface near to the centre. A low-noise amplifier and lock-in amplifier allowed detection of the energy of the fundamental longitudinal resonance of the bar. A gravitational wave applies a time-varying quadrupole deformation and does mechanical work on the bar. The absorption cross section of the bar to gravitational waves depends on its mass and sound velocity. The cross section is highest at the fundamental resonant frequency. The latter is linked to its length and sound velocity, since its length must be half an acoustic wavelength at the fundamental longitudinal resonance. Weber chose aluminium because of its high sound velocity and availability in large pieces, and because it has quite low acoustic losses. Following Weber, many new resonant-mass detectors using similar techniques, but with

variations and improvements, were developed in the early 1970s. Following null results these were abandoned, but advanced resonant-mass detectors using cryogenics and superconductivity continued to be developed. Fairbank *et al* [88] and Hamilton *et al* [89] first proposed such cryogenic detectors, and proposed cooling to millikelvin temperatures to minimize thermal noise. Today two detectors in Italy are in operation at temperatures below 100 mK.

In all resonant-mass detectors the large amplitude of thermal vibration considerably exceeds the gravitational wave amplitude expected from astrophysical sources. Without methods to suppress this noise the principle of detection by resonant masses would be impossible. Weber's key contribution was the realization that in a high-Q antenna—one with a low acoustic loss—the effective noise energy is reduced by a factor $\sim\tau_i/\tau_a$, where τ_i is the effective measurement integration time, and τ_a is the antenna ring-down time. The advantage of using a low acoustic loss antenna follows directly from the fluctuation–dissipation theorem [90]: the greater the dissipation the greater the fluctuations or noise level imposed by the thermal reservoir. A high-Q antenna approaches an ideal harmonic oscillator, whose motion is exactly predictable at a time in the future from the observed amplitude, frequency and phase at an earlier time. High levels of predictability means that very small deviations from sinusoidal behaviour can be resolved given a sufficiently sensitive transducer for monitoring its motion.

4.2. Intrinsic noise in resonant-mass antennas

To understand the operation of a resonant-mass gravitational wave detector it is convenient to start with an old-fashioned approach first introduced by Gibbons and Hawking [91]. This approach is intuitively obvious but is not consistent with the optimal filter theory discussed in section 3. The instantaneous state of the antenna can be described by the pair of symmetrical harmonic oscillator coordinates X_1 and X_2 given by

$$\begin{aligned} X_1 &= A\cos\phi \\ X_2 &= A\sin\phi, \end{aligned} \tag{4.1}$$

where A is the antenna amplitude and ϕ is the phase. Experimentally, X_1 and X_2 can be easily measured using two lock-in amplifiers or PSDs in a configuration shown schematically in figure 18. They may be analogue or digital or software devices. The state of the antenna can be represented by a point P_1 in the (X_1, X_2) plane. The amplitude $A = |P| = (X_1^2 + X_2^2)^{1/2}$ and phase $\phi = \tan^{-1} X_2/X_1$. This is illustrated in figure 19. A gravitational wave causes the antenna to move from P_1 to P_2. The direction of this motion depends on the relative phase of the gravitational wave and the resonant mass. To extract a signal the measuring system should monitor $\Delta|P_1 - P_2| = (\Delta X_1^2 - \Delta X_2^2)^{1/2}$. The quantity Δ^2 is described as the energy innovation and its magnitude, properly calibrated and expressed in the units of Kelvin (1.38×10^{-23} J) describes the effective temperature of the antenna.

In a noiseless antenna the motions of the vector P would only be due to gravitational waves, but in practice P is driven by thermal fluctuations in the bar. Thermal fluctuations cause the state vector P to execute a random walk in the X_1X_2 plane. A high-Q mode is weakly coupled to the thermal reservoir which is made up of all the higher modes of the system. The antenna loses energy slowly into the reservoir, and equally it is only weakly excited by the reservoir. The relaxation time $\tau_a = 2Q/\omega_a$ thus characterizes both the rate of decay after a high-energy excitation and the rate of amplitude change when the mode is in thermal equilibrium with the reservoir.

Clearly, if τ_a is large and the rate of fluctuation is low, the antenna becomes more deterministic on time scales that are short compared with τ_a. The mean energy is still kT,

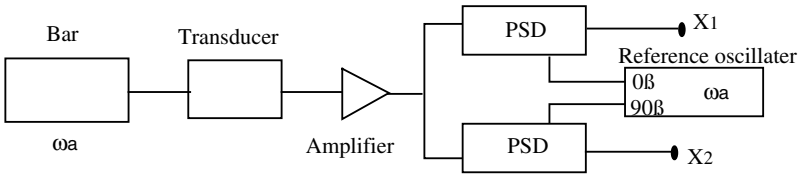

Figure 18. Antenna readout systems for obtaining harmonic oscillator coordinates X_1 and X_2. The down-conversion with the PSD was conventionally done with analogue electronics but today can be achieved in software using fast digital sampling [78].

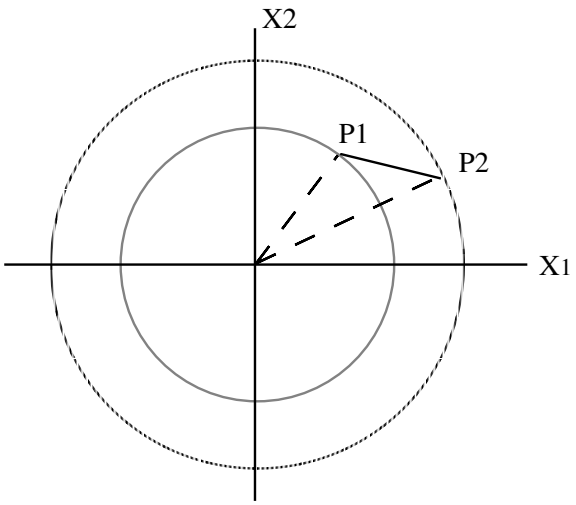

Figure 19. X_1–X_2 representation of the state of the antenna.

but the expected change in energy in a sampling time τ_i is $kT(\tau_i/\tau_a)$. The temperature $T(\tau_i/\tau_a)$ is the effective temperature or noise temperature of the resonator, and quite clearly can be made less than the actual temperature. Indeed, even when transducer readout noise is included, a noise temperature of less than 2×10^{-4} of the thermodynamic temperature has been demonstrated in the detector NIOBE. To use temperature to describe the antenna noise implies that the distribution of Δ^2 has a Boltzmann distribution. This is an excellent approximation (see figures 17 and 28). The slope of the distribution as well as its mean value gives the antenna noise temperature.

The above analysis describes a predictive filter for the detection of short bursts. In this case our prediction is that the amplitude and phase of the detector will remain unchanged over the integration time. Today all operating detectors use optimum filters for the detection of short bursts. The optimum filter improves on the simple predictor discussed above because it implicitly takes into account the dynamics of the system for times of the order of the antenna ring-down time over which the motion is correlated. They are implemented as discussed in section 3 and enable the antenna noise temperature to be improved by a small factor. The most popular optimum filter or matched filter is the Weiner–Kolmogoroff filter which is designed to detect short delta function bursts [92]. Today, such filters are routinely used since they were shown by Pizzella *et al* [93] to give substantially improved performance.

Every antenna must use a sensitive transducer to read out the motion. The transducer, like all electronic devices, has a residual broadband noise floor. This noise floor is equivalent to the Johnson or Nyquist noise of a resistor, given by $V_n^2 = 4kTRB$, where R is the effective resistance of the transducer and B is the measurement bandwidth. However, the bandwidth is roughly the reciprocal of the measurement integration time τ_i. Thus it follows that the noise power is $4kT/\tau_i$. Comparing this with the Brownian motion noise, we see that one noise source varies as τ_i while the other varies as $1/\tau_i$. Thus there is clearly an optimum bandwidth set by the value of τ_i that minimizes the total noise.

Gibbons and Hawking [91] introduced a parameter β to characterize the coupling between the bar and the transducer. They defined β as the proportion of the elastic energy of the detector that can be extracted electrically through the transducer in one cycle. A bar–transducer system with low β (weak coupling) requires more time for the signal energy to appear in the transducer. The longer the energy transfer takes, the more time there is for fluctuations in the antenna to dominate the noise. This point can be clarified by two alternative viewpoints. One is a thermodynamical model. The antenna is considered as a thermal bath at temperature $T_{\text{eff}} = T_a\tau_i/\tau_a$, coupled to a transducer with noise temperature T_t which itself is coupled to an amplifier of noise temperature T_n.

A gravitational wave causes slight 'heating' of the fundamental mode and energy flows through the coupling β. As long as $\beta > 0$ the transducer will eventually come into equilibrium with the bar, but for a rapid response β has to be large. The thermodynamic approach emphasizes that the coupling is not unidirectional: thermal fluctuations in the amplifier or the transducer act back on the antenna producing *back-reaction noise*. Indeed, it is clear that the transducer is a source of thermal fluctuations comparable to those originating within the bar. Voltage noise in the transducer will convert into force noise acting on the bar. Like the forces which act on the bar from the thermal reservoir, the back reaction will produce an additional noise contribution which will diminish as τ_i reduces to zero, as does the Brownian noise.

The second viewpoint is that the antenna–transducer system is effectively a transmission line designed to couple energy into the transducer. One can think in terms of phonons in the bar which may be absorbed by the transducer, with the emission of a photon into the amplifier, or they may be reflected back into the bar. Then β determines the *impedance match* between the output impedance of the bar, Z_{out}, and the transducer's mechanical input impedance Z_{ll}. The ratio Z_{ll}/Z_{out} is simply the coupling coefficient β. See below for more discussion of this point.

Once we begin to think in terms of quanta we are led to ask: what happens if the induced strain in the antenna is equivalent to less than one quantum $h\omega_a$? The profound significance of the quantum mechanical limit to macroscopic measurements was realized independently by several groups, particularly by Braginsky [94] and Giffard [95]. Giffard used the much earlier result of Heffner [96] who showed that, by the uncertainty principle, a linear amplifier has a fundamental limit to its sensitivity, given approximately by $\hbar\omega_a$. Similarly, Giffard showed that a transducer used with a linear amplifier (an amplifier which preserves phase and changes the amplitude by a multiplicative factor) has a maximum sensitivity corresponding to a gravitational wave which produces an equivalent of two quanta in the bar. The term *equivalent* is used because the actual energy absorbed by the antenna depends on its instantaneous amplitude. For linear systems the signal-to-noise ratio is independent of the amplitude, and corresponds exactly to the signal produced in an ideal stationary antenna at absolute zero. Giffard's result meant that the maximum achievable sensitivity of an antenna would be limited to about the single phonon level corresponding to a strain sensitivity $\sim 10^{-21}$. This is described as the standard quantum limit.

Meanwhile, at least as early as 1974, Braginsky and Vorontsov proposed that in principle it might be possible to devise *quantum non-demolition devices* which could read out the state of a system without disturbing it. Braginsky *et al* [97], Caves *et al* [98], Unruh [99] and others went on to identify methods whereby gravitational waves of amplitude less than that required to induce one quantum can in principle be detected using *quantum non-demolition* or back-action-evading techniques. The possibility of mechanical measurements down to and below the quantum limit in sapphire bars has been investigated in detail by Tobar *et al* [100]. The most promising technique is through the use of amplitude-modulated parametric transducers. This represents a small elaboration of parametric transducers of the type we will discuss in section 4.4. The pump signal is amplitude modulated at the signal frequency to create an intrinsically phase-sensitive measuring system. However, classical noise sources need to be beaten down close to the quantum limit before such techniques can successfully pass the quantum limit on real antennas.

4.3. The signal-to-noise ratio for burst detection

Resonant-mass detectors may be used to detect all of the signal classes discussed in section 4.2. However, most effort has concentrated on the detection of bursts. In general, when a gravitational wave in the right frequency range arrives, it excites all normal modes of the bar that have a high quadrupole moment. A transducer attached to the bar will pick up the signal, which must be discerned in the presence of transducer noise and a large Brownian motion background, as discussed in the previous section.

The efficiency of the detector is determined by the fraction of the wave energy absorbed and converted into acoustic energy inside the bar. Clearly, it is important that the bar absorb as much as possible of the energy of the passing gravitational wave. This can be quantified in terms of the antenna cross section as discussed below. Denoting the incident spectral energy density of gravitational waves as $w(f)$, the energy deposited in the bar is given by

$$\varepsilon_g = \sigma w(f). \tag{4.2}$$

The term σ in the above equation is the so-called cross section of a bar, which is the ratio of the absorbed energy to the incoming energy, and thus a measure of the sensitivity of the bar. The cross section is actually a function of frequency $\sigma(f)$ because the detector will absorb energy more readily around the resonant frequency f_o of the antenna. The total energy deposited in the bar is then

$$E = \int \sigma(f) w(f)\, \mathrm{d}f. \tag{4.3}$$

Since for a high-Q system, $\sigma(f)$ is sharply peaked around the resonant frequency f_0, only a narrow portion of the gravitational wave signal around the resonant frequency of the bar can be picked up by the detector. In this case we may write

$$\sigma(f) w(f)\, \mathrm{d}f = w(f_0) \int \sigma(f)\, \mathrm{d}f. \tag{4.4}$$

The cross section, first elaborated by Weber, can be expressed in several forms [7]. The cross section of the bar, integrated over the frequency band, can be expressed as [101]

$$\int \sigma(f)\, \mathrm{d}f = \frac{8GM}{\pi c} \left(\frac{v_s}{c}\right)^2 \ \mathrm{m^2\ Hz}, \tag{4.5}$$

where v_s is the sound velocity in the bar, and M is the mass of the bar. Clearly, to obtain high sensitivity it is desirable to build detectors as massive as possible and from a material having a sound velocity as high as possible. Usually, the size of the bar is chosen such that

the fundamental mode is at about 1 kHz—about the expected frequency for the collapse of a massive stellar core to a black hole. Aluminium has been used for most resonant bars. Niobium is used for the bar detector at the University of Western Australia. Other materials could give substantial advantages, as discussed in section 4.5 below.

A gravitational wave carries an energy flux S(J m^{-2} s^{-1}) given by

$$S = \frac{c^3}{16\pi G}\langle h_+^2 + h_x^2\rangle, \tag{4.6}$$

where h_+ and $h_\times$ denote the dimensionless strain amplitudes of the two possible polarizations of the wave. Since the shape of expected gravitational wave pulses from gravitational collapse events is not accurately known, we cannot accurately determine the expected excitation of an antenna even knowing the total pulse energy. We need to know both the spectral distribution of the pulse energy, and the relationship between h and its time derivative. The details of the expected pulses depend not only on the dynamics of the gravitational collapse, but also on the mass of the collapsing object, both of which are uncertain.

If we assume only knowledge of the pulse duration τ_g (expected to be $\sim 10^{-3}$ s), and that it is predominantly a single cycle, it is sufficient to assume that $\mathrm{d}h/\mathrm{d}t \sim 2h/\tau_g$. Then equation (4.6) can be rewritten

$$S = \frac{c^3}{16\pi G}\frac{4h^2}{\tau_g^2}. \tag{4.7}$$

The total pulse energy E is then given by $S \cdot \tau_g$:

$$E = \frac{c^3}{16\pi G}\frac{4h^2}{t_g^2}. \tag{4.8}$$

If we assume that the spectral distribution of the pulse energy $F(\omega)$ is uniform over a bandwidth $\Delta\omega \sim 1/\tau_g$, it follows that

$$F(\omega) \sim E/\Delta\omega, = E\tau_g \sim c^3 h/4\pi G \text{ J m}^{-2} \text{ Hz}^{-1}. \tag{4.9}$$

Numerically $F(\omega) \sim 20 \times 10^{34}\ h^2$.

The assumption used in obtaining the result must be emphasized: the result is simply an order-of-magnitude estimate of the expected signal spectral densities. Moreover, variations in the pulse durations could make any chosen antenna frequency only suitable for a small proportion of actual events.

The energy deposited in an initially stationary antenna of mass M by a signal pulse $F(\omega)$ follows directly from equation (4.5) combined with geometrical terms:

$$U_s \sim F(\omega)\sin^2\theta\cos^2 2\phi\frac{8}{\pi}\frac{G}{c}\left(\frac{v_s}{c}\right)^2 M \tag{4.10}$$

where θ and ϕ are coordinates describing the orientation of the bar relative to the incoming wave (as given in figure 20).

For a short burst of gravitational waves the bandwidth of the pulse is roughly the inverse of the pulse duration which is roughly equal to the peak frequency. Under these circumstances the strain amplitude $\delta 1/1$ induced in the bar is roughly equal to the incoming wave amplitude h; there is no resonant excitation.

The incoming gravitational wave will only be detectable if the signal U_s is greater than the noise in the antenna U_n. From an engineering point of view it is useful to characterize the noise U_n; we generalize the transducer to a two-port device described by a 2×2 impedance matrix Z_{ij}. The transducer accepts force and velocity inputs F and v, giving current and voltage outputs I and V:

$$\begin{pmatrix} F \\ V \end{pmatrix} = \begin{pmatrix} Z_{11} & Z_{12} \\ Z_{21} & Z_{22} \end{pmatrix}\begin{pmatrix} v \\ l \end{pmatrix}. \tag{4.11}$$

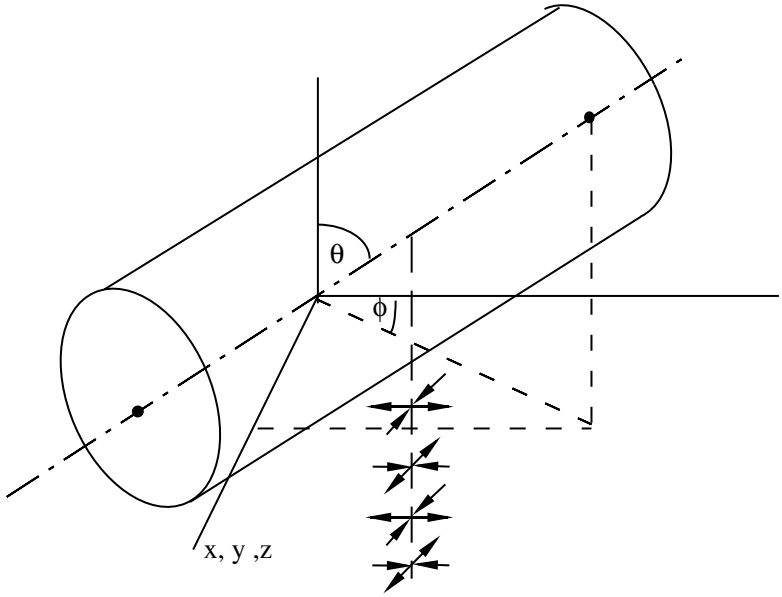

Figure 20. Coordinate system for resonant antenna.

The transducer has input impedance Z_{ll}, measured in kg s^{-1}, and output impedance Z_{22}, measured in ohms. The forward transductance Z_{21}, measured in V m^{-1} s, determines the transducer sensitivity whereas the reverse transductance Z_{12}, measured in kg A^{-1}, determines the back-acting force on the antenna due to currents in the output circuit: see [100, 102–104] for more details. Quantum mechanics tells us that it is impossible to make $Z_{12} = 0$: it is impossible to create a perfect one-way valve.

All the noise sources in the transducer and amplifier can be expressed as equivalent spectral densities of current and voltage noise at the input of the amplifier, denoted $S_i(\omega)$ and $S_e(\omega)$, respectively, as illustrated in figure 21. The current noise S_i is the source of back-action noise in the antenna, whereas S_e describes the series noise contribution. In terms of these quantities the total system noise is given by

$$U_n = 2kT_a\frac{\tau_i}{\tau_a} + \frac{|Z_{12}|^2}{2M}S_i(\omega)\tau_i + \frac{2M}{|Z_{21}|^2}\frac{S_e(\omega)}{\tau_i}. \tag{4.12}$$

The first term in equation (4.12) is the Brownian motion or thermal noise in the antenna discussed above. The second term describes the energy fluctuations arising from the current noise acting back through the reverse transductance, and giving the back-action noise, also proportional to integration time. The third term is the series electronics noise, which for given S_e is reduced as Z_{21} increases. As we saw above this term is proportional to the bandwidth τ_I^{-1}. Only the first term in equation (4.12) can ever be reduced below the quantum limit.

The problem of detecting gravitational waves with resonant-bar antennas to a large extent consists of minimizing equation (4.12). The technical means of achieving this requires some or all of the following:

(a) Reduce the antenna temperature T_a.
(b) Use a transducer with high Z_{21} and low Z_{12}.
(c) Use amplifiers with S_e and S_i as low as possible.

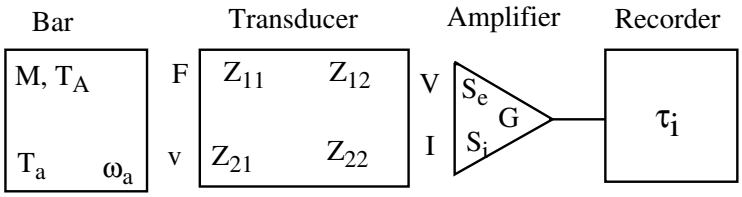

Figure 21. The various quantities used to characterize a gravitational wave antenna system.

(d) Reduce the acoustic loss in the antenna as well as the acoustic and electrical losses in the transducer to obtain high-Q or large relaxation time.
(e) Obtain a reasonable impedance match between antenna and transducer to enable τ_i to be small.

The last requirement can only be achieved by good impedance matching between the mechanical input impedance of the transducer and the mechanical output impedance of the antenna, which we shall discuss further below.

It is convenient to scale the noise in the system relative to the *standard quantum limit* of one equivalent quantum induced in the bar. To do this we rewrite the noise equation (4.12) in terms of *noise number A* (a quantity first used by Weber to characterize noise in masers):

$$A = U_n/\hbar\omega_a = A_T + A_B + A_S. \tag{4.13}$$

Here A_T, A_B and A_S are the equivalent numbers of noise quanta due to thermal noise, back-reaction noise and series noise in the measurement system. The experimentalists need to achieve a total system noise number A approaching unity. For a 1 kHz resonant bar this corresponds to a noise temperature of $\sim$0.1 μK. To achieve this it is necessary not only to have a low-noise transducer, but also to use a low-acoustic-loss antenna material, and to suspend and isolate the antenna so as not to increase the acoustic loss, nor to couple in excess noise from the environment. Because the noise number contributions are additive there is no particular advantage in reducing one of them far below the others.

It is useful to express the thermal and transducer noise contributions directly in terms of the gravitational wave strain equivalent noise. The *Brownian motion noise* h_B is given by [105]

$$h_B \sim \left(\frac{k_B T \tau_i}{M\omega_a l^2 Q}\right)^{1/2}. \tag{4.14}$$

For a bar detector, $\omega_a l = \pi v_s$, so the Brownian noise is given by

$$h_B \sim \left(\frac{k_B T \tau_i \omega_a}{\pi^2 M v_s^2 Q}\right)^{1/2}. \tag{4.15}$$

Expressing the above equation numerically, we have

$$h_B = 10^{-21}\left[\left(\frac{f_0}{1\ \text{kHz}}\right)\left(\frac{10^{10}\ \text{J}}{M v_s^2}\right)\left(\frac{10^9}{Q}\right)\left(\frac{T}{0.1\ \text{K}}\right)\left(\frac{\tau_i}{10^{-2}\ \text{s}}\right)\right]^{1/2}. \tag{4.16}$$

This means that a resonant-mass detector with the hypothetical parameters implied in the above equation will have a Brownian motion noise strain of about 10^{-21}. However, some of the parameters given above are difficult to achieve in practice. For example, the energy term is satisfied by about 10 tonnes of sapphire or 100 tonnes of bronze or niobium. In the case of the UWA niobium bar with mass of 1.5×10^3 kg, resonant frequency of 700 Hz, sound velocity of 3.4×10^3 m s^{-1}, temperature of 4 K, Q-factor of 3×10^7 and measurement integration time 1 s, the Brownian noise strain amplitude is 2.2×10^{-19}. It can be seen that the bar must

have a very high acoustic quality factor or much shorter integration time to reduce the effect of the thermal noise. With today's multimode impedance matching techniques, τ_i can indeed be reduced to 10^{-2} s.

The sensor noise lower limit (series noise and back-reaction noise $A_B + A_S$) is set by the standard quantum limit [105]

$$h_{\mathrm{SQL}} \sim \left(\frac{2\hbar\omega_a}{\pi^2 M v_s^2}\right)^{1/2} \sim 1.1 \times 10^{-21} \left(\frac{f_m}{1\ \mathrm{kHz}}\right)^{1/2} \left(\frac{10^3\ \mathrm{kg}}{M}\right)^{1/2} \left(\frac{10^4\ \mathrm{m\ s^{-1}}}{v_s^2}\right). \tag{4.17}$$

This sets a strain amplitude limit $\sim 10^{-22}$ for a 100 tonne resonant-mass detector such as the proposed spherical detectors.

4.4. Transducers

Transducers for resonant-mass gravitational wave antennas fall into two categories: *passive* transducers and parametric transducers. Passive transducers have no external power source, and their power gain is less than unity. They must always be used with a high-gain, low-noise amplifier at the frequency of the antenna. Parametric transducers, on the other hand, have an external power source (a pump oscillator at frequency ω_p) which is modulated by the antenna motion. They have intrinsic power gain associated with the transfer from the antenna frequency ω_a to the higher frequency ω_p. A laser interferometer is a parametric transducer operating at an optical pump frequency. Parametric transducers for resonant-mass readouts may be optical, microwave or radiofrequency devices.

Most parametric transducers use a high-frequency resonator combined with a low-noise high-frequency amplifier. Passive transducers use an inductive or capacitive readout, coupled to a SQUID amplifier. Figure 22 illustrates their basic structure. The passive transducer illustrated uses a superconducting inductor whose inductance (if constructed in a planar fashion) is proportional to the gap spacing between the coil and the superconducting ground plane on the antenna. Relative motion modulates persistent current trapped in the inductor (since the magnetic flux LI must be conserved). The changing current is detected by a SQUID magnetometer. The parametric transducer illustrated uses a capacitor in a resonant circuit. The capacitance is modulated by the gap spacing between the capacitor and the antenna. The change in capacitance due to motion modulates the resonant frequency of the circuit, creating modulation sidebands on the output signal. Both types of transducer may use capacitive or inductive sensing.

Fundamentally, there is little difference between passive and active transducers. Active transducers use a transduction process that is combined with power amplification but additional amplification of the high-frequency signal is usually necessary. Passive transducers have a complete separation between the transduction process and the amplification process. However, the amplifier itself (such as a SQUID) makes intrinsic use of a parametric up-conversion process. Thus the difference between passive and active transducers is simply in the choice of whether the parametric up-conversion occurs during or after transduction. In the case of an optical pump frequency, amplification is unnecessary: the entire power gain is realized through the up-conversion of the signal frequency to the optical frequency.

One important difference between passive and parametric transducers is in the transducer impedance mismatch ratio or coupling factor β. For the parametric transducer

$$\beta_{\mathrm{para}} \frac{1}{2} \frac{C V_p^2 Q_e}{m\omega_a^2 x^2}. \tag{4.18}$$

In the limit $Q_e > \omega_p/\omega_a$, the electrical Q-factor of the transducer resonator Q_e is replaced by the frequency ratio ω_p/ω_a.

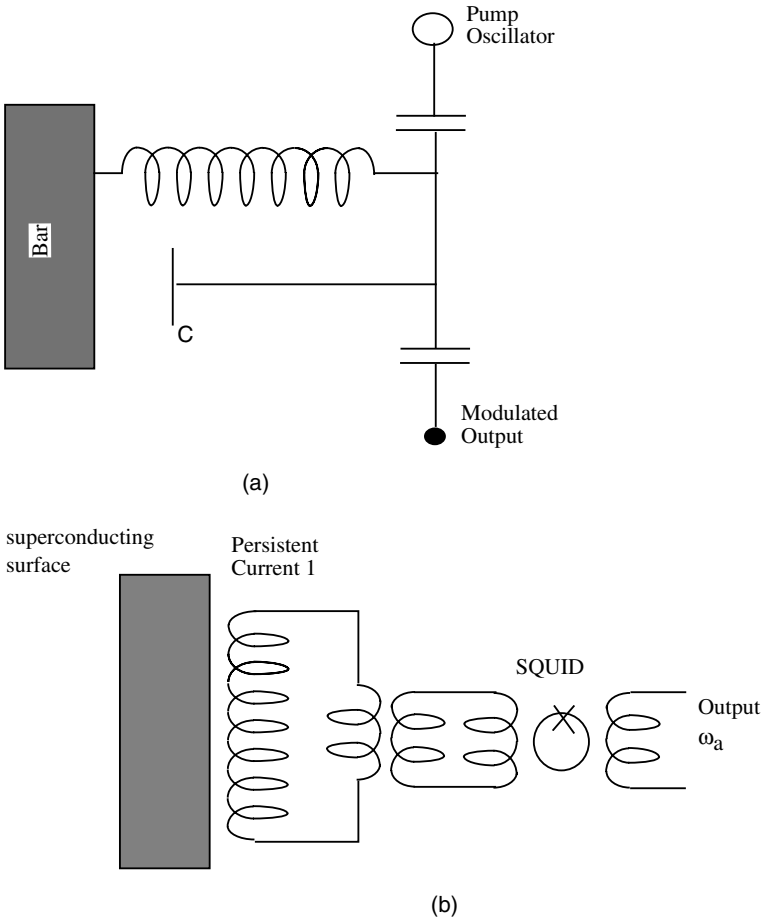

Figure 22. Inductance or capacitance is modulated by a gap spacing. (*a*) Active or parametric transducer use a low-loss resonant circuit pumped by an external oscillator. (*b*) Passive transducers use an inductive or capacitive readout, coupled to a SQUID amplifier. All the circuits are made from superconducting and very-low-loss components.

For the passive inductive transducer

$$\beta_{\text{pass}} = \frac{1}{2}\frac{LI^2}{m\omega_a^2 x^2}. \tag{4.19}$$

Note that the passive transducer coupling factor is not enhanced by a Q-factor term. For a capacitive passive transducer the inductive stored energy $\frac{1}{2}LI^2$ is replaced by the capacitive stored energy $\frac{1}{2}CV^2$. The parametric transducer effectively samples the incoming signal Q_e times per cycle up to a maximum value of ω_p/ω_a, and therefore increases its coupling by the same factor.

Parametric coupling is *reactive* as a result of the position-dependent mechanical forces which act across the electrical resonator. The mechanical forces vary strongly over the transducer *position bandwidth*, defined as the halfwidth of the electrical resonator, measured in terms of displacement. Typically the position bandwidth is ∼pm (10^{-12} m). The stored electrical energy exerts forces across the capacitance which vary strongly over the position

bandwidth. Hence the effective spring constant can be very large, and due to its reactive nature can create problems in maintaining stability.

The passive transducer does not have the same coupling advantage. However, the advantage is to some extent illusory because by moving the coupling structure to a high frequency one reduces its size, so that the absolute value of the L or C is significantly reduced.

The practical problems of the two types of transducer are quite different. Passive transducers are limited by a poorly understood problem of AC losses in their superconducting circuits, and the performance of available SQUID amplifiers. Parametric transducers, on the other hand, are limited by phase noise in the pump oscillator, tuning difficulties, noise degradation in amplifiers at high microwave power, and sometimes by the effects of low-frequency seismic noise. All transducers, both active and passive, are limited in noise performance by the noise of the amplifier with which they are used. In terms of noise number equation (4.13), at 1 kHz a noise number of 1 corresponds to a noise temperature of about 100 nK, whereas at 10GHz the same performance corresponds to $T_n \sim 1$K. In principle, both types of transducer can reach close to the quantum limit. In practice, none have reached this level to date, although SQUID amplifiers have been developed close to 1 μK, and amplifiers for microwave parametric transducers have long been available with $T_n \sim 10$K. The microwave parametric transducer on NIOBE at UWA has achieved about 1 mK noise temperature, while the SQUID transducer on NAUTILUS has achieved similar noise performance. It is not obvious which type of transducer will ultimately be the most successful.

Johnson and Bocko [106–108] and Tobar *et al* [100] have presented designs for quantum-limited microwave transducers, while Richard and the Legnaro group have presented design for optical transducers [109, 110]. See [94, 98, 111, 112] for further discussion of these issues.

A sensitive transducer and a low-loss resonant mass are not sufficient to create a sensitive gravitational wave antenna. There is a major problem at the interface: mechanical impedance matching. The impedance mismatch ratio (introduced as the coupling factor β) arises because the mechanical output impedance of the bar is very high, characterized by the elastic stiffness of the bar itself, whereas the mechanical impedance of the electric or magnetic field which couples this motion into the transducer is not large. The solution is to create an acoustic transformer at the end of the bar. Such a transformer is analogous to acoustic horns used in loudspeakers, or to the mechanisms in the human ear that couple the motion of the air into the fluid of our cochlea.

All successful impedance matching schemes have consisted of low-mass secondary acoustic resonators tuned to the antenna frequency. This creates a two-mode resonator with a pair of normal modes. The acoustic energy beats between the high-mass resonator and the low-mass resonator, while the transducer is coupled to the low mass. The scheme can be generalized to multimode transformers, consisting of nested sets of resonators reducing in mass by a geometric progression.

Three secondary resonator configurations have been used successfully on antennas: diaphragms (first developed by Paik at Stanford [113]), mushrooms (developed by the Rome group [114]) and bending flaps (developed at UWA [115]). Pang and Richard [109], Hamilton *et al* [116] and Tobar [63] have proposed and tested 3–5 mode systems but these have yet to be implemented. Four of the systems are illustrated in figure 23. The antenna NIOBE uses a 400 g bending flap (figure 23(a)). The bending flap is a convenient form of secondary resonator, which has open geometry suitable for an attachment of a microwave re-entry cavity parametric transducer readout. The microwave readout system consists of a carrier suppression interferometer, and a microwave amplifier followed by a demodulation stage. This achieves reasonably high coupling to the microwave transducer, as demonstrated by the fact that the elastic forces provided by the transducer are sufficient to detune the mechanical oscillator by

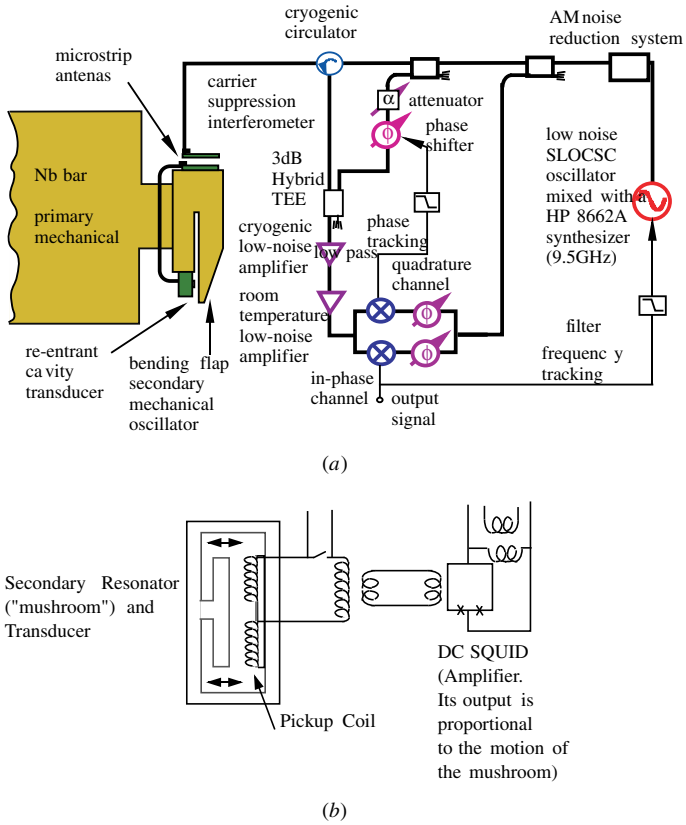

Figure 23. Bar antenna transducer readout systems. (*a*) Bending flap [115]; (*b*) mushroom [114]; (*c*) diaphragm [113]; (*d*) multimode transducer [116].

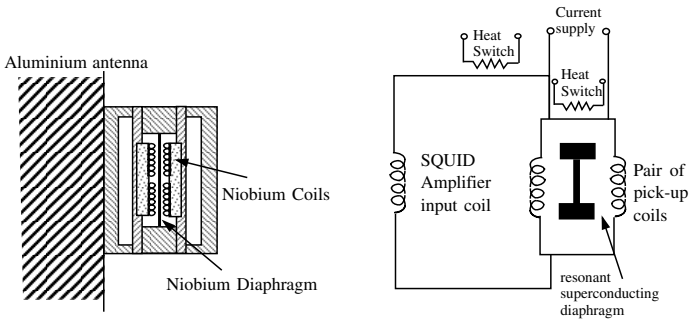
several Hz. The following three configurations, (*b*) the mushroom, (*c*) the diaphragm and (*d*) a multimode transducer, use similar SQUID amplifier readout circuits. The moving mass modulates the inductance of a flat coil, which by flux conservation leads to a modulated current through a SQUID amplifier. The Rome group has used capacitive readout for a mushroom, in which case currents are induced by charge conservation in capacitor. The multimode transducer uses a massive 'diaphragm' coupled to a small tertiary mass plate supported by small niobium cantilever springs.

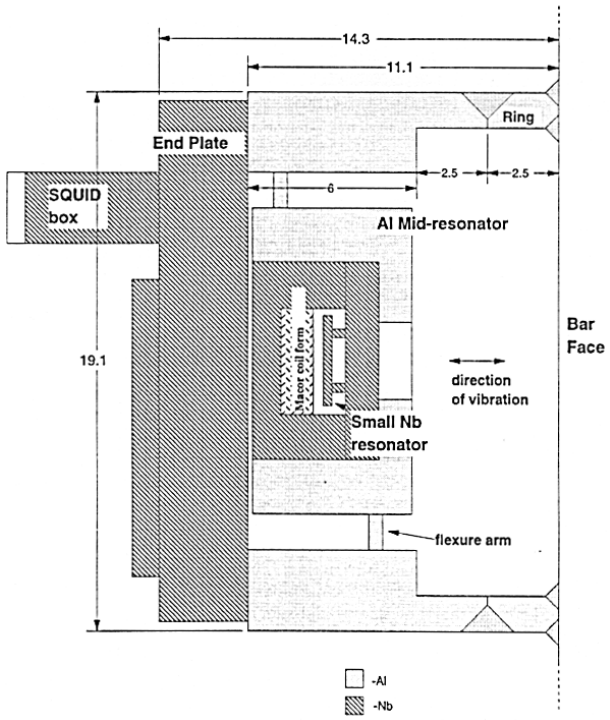
4.5. Antenna materials

An ideal resonant bar would consist of a piece of nuclear matter, with high density and a velocity of sound comparable to the velocity of light! Since this is not available except in neutron stars, we must find a form of molecular matter which, to maximize coupling to gravitational waves, combines high velocity of sound v_s, and high density ρ. To reduce the thermal noise we require a low acoustic loss Q^{-1}.

For an antenna limited by thermal noise the best antenna material (at a practical frequency) will have the largest value of $Q\rho v_s^3$. This quantity is proportional to the ratio of energy absorbed ($\sim\rho v_s^3$) and the thermal noise in the antenna ($\sim Q^{-1}$). Of the three controlling parameters, only the Q-factor can be modified significantly in a particular material, depending on its preparation



(*c*)



(*d*)

Figure 23. (Continued)

and suspension.

Table 2 lists the values of ρ, v_s and ρv_s^3 for various materials, along with the maximum achieved Q-value to date, and the signal-to-noise ratio figure of merit, $Q\rho v_s^3$. The table shows that nearly one order of magnitude improvement is obtained (at a given frequency) in ρv_s^3 by changing from aluminium or niobium to sapphire, and when the Q-factor is included the very low losses in sapphire make it about 500 times superior to Nb or Al (at a given operating temperature). Silicon is more than 100 times better than Nb and Al. Unfortunately, at present silicon and sapphire are not available in sufficiently large masses for these apparent advantages to be useful. Note that a lower Q-factor can always be compensated for by sufficient

Table 2. Comparison between antenna materials.

Material	ρ(g cm^{-3})	v_s(km s^{-1})	Q	ρv_s^3 (10^{13} kg s^{-3})	$Q\rho v_s^3$ (10^{20} kg s^{-3})
Aluminium 6061	2.7	5.1	5×10^6	36	18
Aluminium 5056	2.7	5.1	7×10^7	36	250
Niobium	8.57	3.4	2.3×10^8	34	800
Silicon	2.33	8.5	2×10^9	140	2.8×10^4
Sapphire	3.98	9.4	3×10^9	330	10^5
Lead	11.36	1.1		1.5	
Tungsten	18.8	4.3		150	
Copper(94)/Al(6)	8.0	4.6	2×10^7	77.8	155

cooling, so that fundamentally only the ρv_s^3 term need be considered. Copper-based alloys have been selected as preferred materials for very-high-mass spherical antennas, chiefly because superconducting materials (for which the thermal conductivity becomes very low) are very difficult to cool to ultralow temperatures.

For comparison, table 2 also shows lead and tungsten. Lead is very poor, because of its low sound velocity, whereas tungsten is comparable to silicon. If massive high-Q tungsten masses could be obtained, they would have the significant advantage that the cryogenic system necessary to house the antenna would be smaller (and cheaper and simpler) than that needed for lower-density materials.

4.6. Antenna suspension and isolation systems

Typical *seismic noise* has the spectrum of $x_s = \alpha f^{-2}$ m Hz$^{-\frac{1}{2}}$ in the frequency range 1 Hz to a few kilohertz, where f is the frequency and α is a constant. Measurements by gravitational wave research groups at various sites have shown that the constant varies between 10^{-6} and 10^{-9} (e.g. [117–119]). A vibration isolation system is needed to isolate seismic noise to well below the signal level at the antenna resonant frequency. A variety of metallic suspensions have been developed for resonant gravitational wave detectors (e.g. [120–122]). All are designed to have the normal-mode resonant frequencies of the isolator well below the antenna frequency, and the internal modes of the isolator elements above the frequency range of interest. In general, the normal modes define a set of low-frequency resonances. Internal modes of the mass and spring elements are generally at high audio frequencies. Such isolators therefore have good isolation above a low-frequency corner, and also below the high-frequency internal resonances. For resonant-bar antennas, the isolation band required is from a few hundred hertz to a few kilohertz. In principle, it is fairly easy to realize a mechanical isolator which will attenuate the seismic motion at 1 kHz ($\sim 10^{-12}$ m Hz) by 10^{10} (e.g. [121, 122]). However, practical problems such as nonlinear up-conversion can degrade the performance [123].

Figures 24 and 25 illustrate two of the resonant-bar antennas constructed to date. For antennas operated at 4 K the bar is supported by a low-loss multistage suspension in an experimental chamber with which the antenna has no direct contact. A room temperature vibration isolation stage suspends the cryogenic suspension stage. In the case of NIOBE, vibration can only act on the antenna by traversing the entire 18 stages of vibration isolation, or through transmission through the residual gas in the experimental vacuum. There are no wires connecting to the antenna (which can transmit vibration) because the transducer is

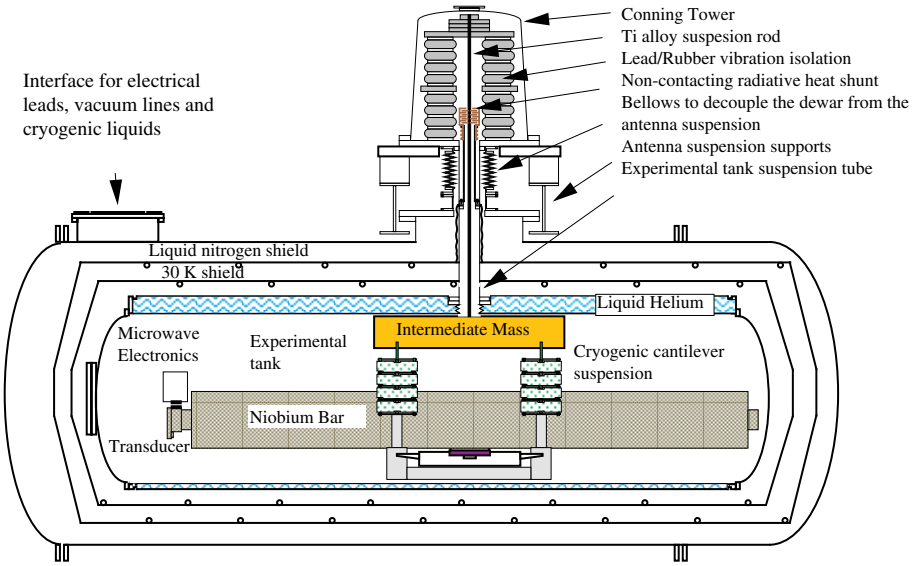


Figure 24. Cross section of the NIOBE antenna. The cryostat is 5 m long and 3 m high.

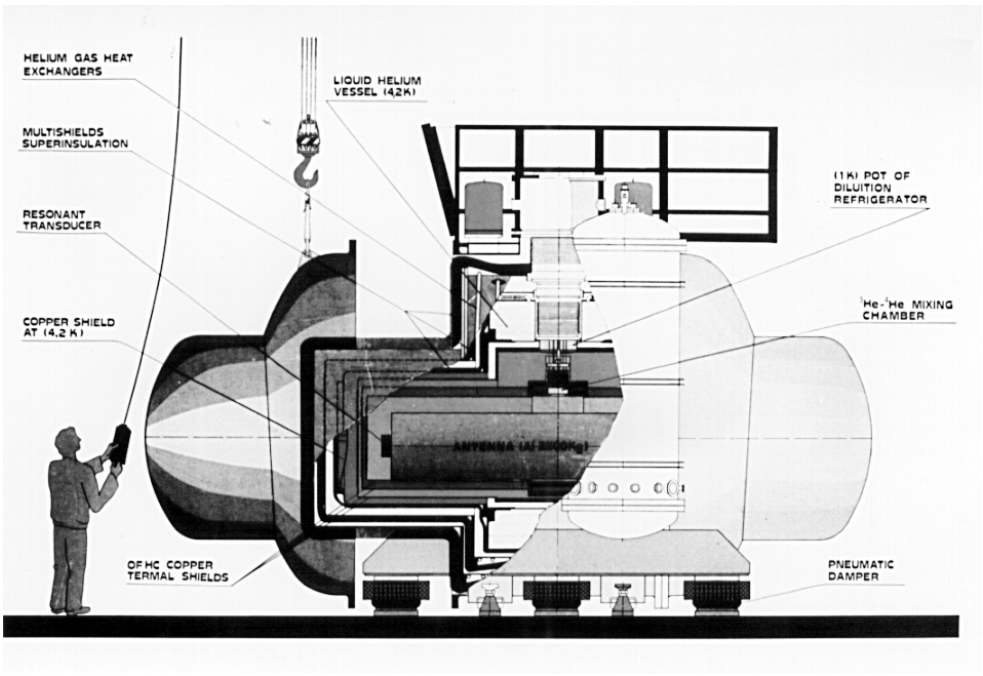

Figure 25. View of the ultracryogenic antenna AURIGA showing cryogenic shields and the Al bar.

interrogated entirely by radiative contact. In the case of antennas using passive transducers superconducting cables can act as transmission lines to conduct vibration, so that great care must be taken to isolate cables using *Taber isolators* [124], consisting of additional mass spring stages (using thin wires as springs) to which the cables are bonded.

The *cryogenic suspension and isolation stage* of an antenna is one of the most critical components. It must isolate against the noise which bypasses room temperature isolation, as well as the thermal noise of the room temperature stage. In addition, it must suspend the antenna using low-loss elements so as to maintain a high antenna quality factor. It is essential that the cryogenic stage, at least, does not have any resonant modes near the antenna frequency. Several different systems have been used with reasonable success. Traditionally, cable suspensions have been used: a cable slung around the belly of the resonant bar. This method has the risk of introducing vibration by the violin string mechanism: slip–stick frictional transitions associated with the motion of the belly cable at the point of tangential contact with the bar. This process arises because of the seismically driven low-frequency pendulum motion of the bar. Such boundary condition effects can be avoided if the antenna is somehow bonded or clamped to the bar at the tangent point. The now defunct Stanford group and the LSU group used welded rods instead of wires to avoid this problem. The third method consists of a cantilever suspension. High Q-factor curved cantilever springs such as the Catherine wheel used on NIOBE support the bar from below. This can have well defined contact points to the antenna to minimize nonlinear processes, and has given the highest Q-factor ever observed in a metal [125]. A fourth method, first suggested by Coccia [126], is the use of a nodal point suspension. In the case of a bar or sphere, the nodal point for the fundamental mode is located at the centre of mass. This means boring a hole to the centre and attaching a rod or cable. While this has many advantages in reducing sensitivity to external noise, it has not been used in a full-scale antenna.

Antennas cooled to ultracryogenic temperatures (below 100 mK) have a particular problem to contend with. Helium exchange gas can no longer be used at such temperatures (the vapour pressure is too low) so the antenna must be cooled by conduction. This means that there must be direct cryogenic conduction paths to the antenna from the dilution refrigerator. Pure and nonsuperconducting metals must be used (such as OFHC copper). Yet the thermal conduction must exist without significant vibration conduction, especially since the dilution refrigerator is likely to be a substantial source of vibration.

Ultracryogenic detectors used to date have exhibited excess sensitivity to local vibration, due presumably to the inadequate performance of the thermal conduction/vibration isolation system. However, recently both NAUTILUS and AURIGA have yielded improved performance, down to a noise temperature of 1 mK.

4.7. Present status of resonant-mass detectors

At the time of writing five resonant-mass gravitational wave detectors are in operation. These consist of three liquid helium temperature detectors, ALLEGRO, EXPLORER and NIOBE at Louisiana State University, CERN (operated by the University of Rome Group) and the University of Western Australia, and two ultracryogenic detectors, NAUTILUS and AURIGA at INFN Frascati and INFN Legnaro, Italy. The latter detectors have been successfully cooled to below 100 mK. Table 3 below summarizes the basic parameters of these antennas. The noise performances quoted are typical/best rms noise levels for the detection of broadband bursts.

As well as undertaking long periods of operation, the antennas are all in the process of upgrade, either through installation of improved transducers, or through installation of improved vibration isolation. Due to the large size of the cryogenic systems, resonant antennas have a rather long cycle time (several months) of cooling and warm-up. Combined with the probability of malfunction in experimental apparatus (a particular problem during the 1980s) the rate of progress has been slower than predicted.

Table 3. The resonant mass detectors which belong to the international Gravitational Events Collaboration.

Antenna	Location	Material	Temperature	Noise Temperature (mK)	Frequency (Hz)	Strain sensitivity
ALLEGRO	Baton Rouge	Al	4 K	6	900	7×10^{-19}
EXPLORER	CERN	Al	2 K	6	900	7×10^{-19}
NIOBE	Perth	Nb	5 K	1	700	5×10^{-19}
NAUTILUS	Frascati	Al	100 mK	4	900	6×10^{-19}
AURIGA	Legnaro	Al	100 mK	1	900	3×10^{-19}

4.8. Performance of resonant bars

The long-term operation of cryogenic resonant bars has been invaluable in characterizing their instantaneous performance, and evaluating various possible filtering techniques for extracting events from a long data record in the presence of excess noise. With regard to instantaneous performance it has been important to verify that the noise performance is consistent with the noise parameters of the bar, transducer and readout system. In nearly all cases extremely good agreement has been obtained, such as illustrated in figure 26. In the case of parametric transducers their performance can be characterized not only by noise spectra, but also by their variable interaction with the antenna, as discussed in section 4.5.

From the experimentally observed noise spectral density, such as figure 26, one can determine the sensitivity of the antenna to various signals such as stochastic background, CW signals and bursts. Figure 27 shows the calibrated burst sensitivity of NIOBE during a 24 h period. The data are presented as mean noise temperature (bottom curve) and the largest noise temperature observed in 100 s. This allows the antenna performance to be quickly assessed, including the presence of excess noise. Figure 28 presents the same data in the form of Brownian motion noise histograms. From the single antenna data there are clearly few events above 10 mK, corresponding to $h \sim 10^{-15}$ (all of these could normally be eliminated by coincidence analysis.

The resonant-bar detector network has recently been able to set new upper limits to the strength and event rate of gravitational wave burst signals from coincidence analysis of three- and four-antenna data. Figure 29 shows this result in comparison with previous upper limits [127].

We saw in section 4.2 that the noise energy for burst detection is reduced by the factor τ_i/τ_a, where τ_i is the signal integration time and τ_a is the antenna ring-down time. The reduction of the noise with τ_a is a manifestation of the fluctuation dissipation theorem. In the case of CW signal detection the noise energy reduces proportional to $(\tau_i \tau_a)^{-1}$. This means again that the best detector is one with very high Q-factor, and that very long integration times improve the amplitude sensitivity as $\tau_i^{1/2}$. Figure 30 presents an FFT analysis of one month's data from the ALLEGRO detector in the search for pulsar signals form the globular cluster 47 Tucanae. In this case the deep integration, over a narrow frequency band, has set limits for CW pulsar signals $\sim 10^{-23}$. The analysis has been repeated for various directions in the two low-noise bands of ALLEGRO.

For the detection of stochastic backgrounds one simply has to multiply the output of two nearby detectors and integrate the result. However, as discussed in section 3, the detectors need to be sufficiently close that the incoming waves are correlated. Their space should be within about $\lambda/3$ where λ is the gravitational wave wavelength c/f. Cross correlation between the detectors NAUTILUS and EXPLORER (as mentioned in section 3) have yielded a limit to

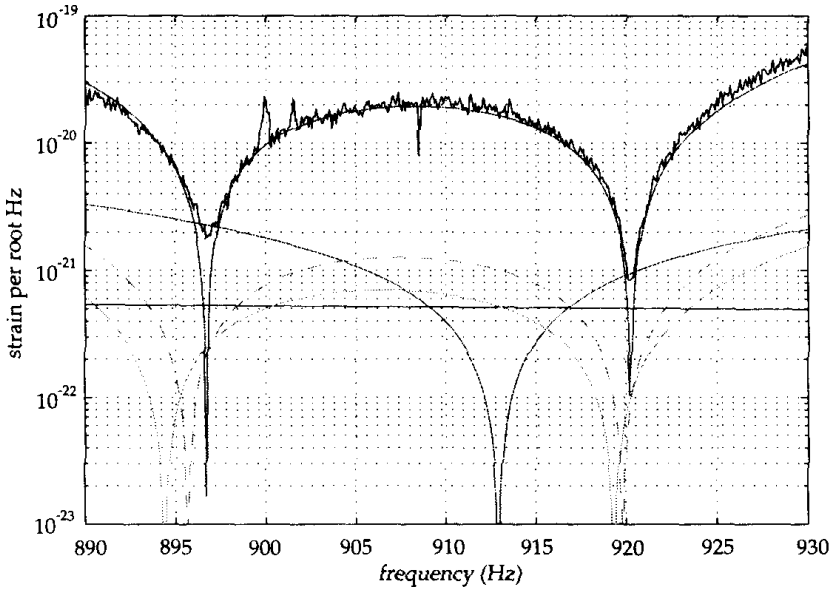

Figure 26. The measured strain noise of ALLEGRO, shown as the irregular trace. The various noise contributions estimated from the noise model are shown as smooth curves. The noise is dominated by the SQUID's wide-band and the transducer's narrow-band noise [71].

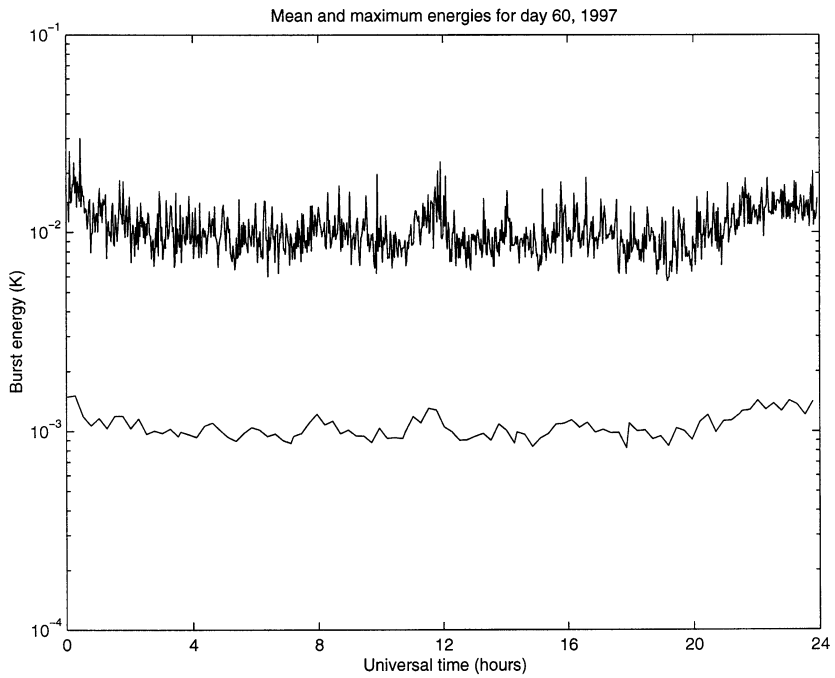

Figure 27. The calibrated burst sensitivity of NIOBE during a 24 h period. The data are presented as mean noise temperature (bottom curve) and the largest noise temperature observed in 100 s [78].

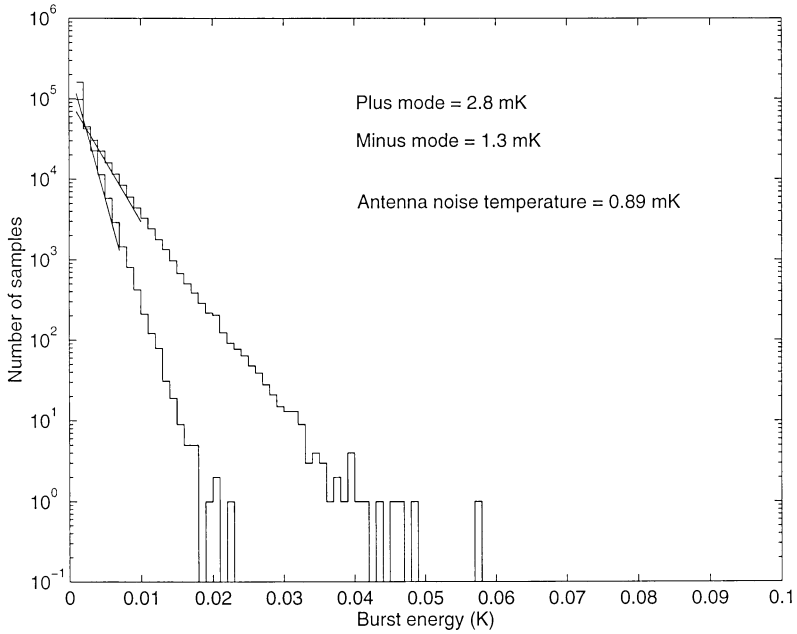

Figure 28. Histogram of the noise of NIOBE after optimal filtering for burst signals, showing the expected Boltzmann distribution. When the weighted mean of both normal modes is evaluated the overall system noise temperature is 0.89 mK.

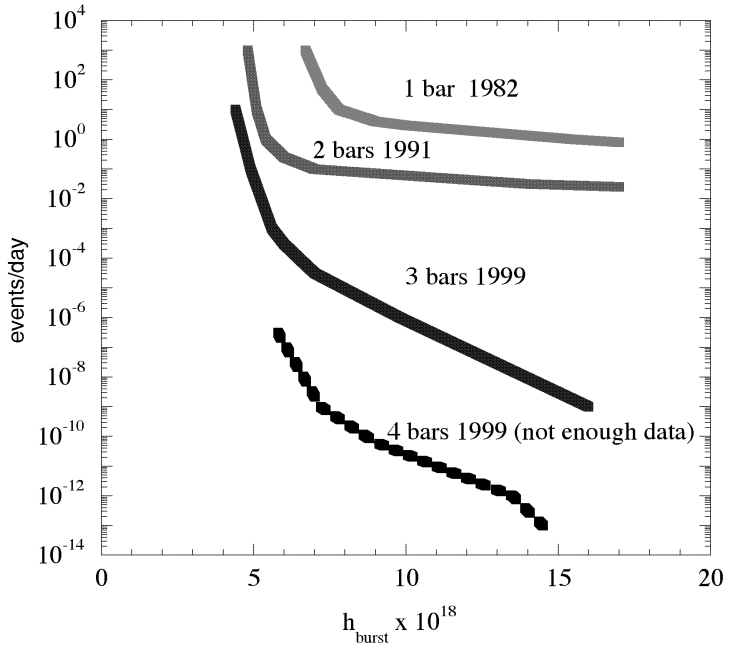

Figure 29. The rate of burst events versus strain amplitude set by one-two-three- and four-antenna experiments. The 4-antenna result is based on a short period of data and hence has weaker significance.

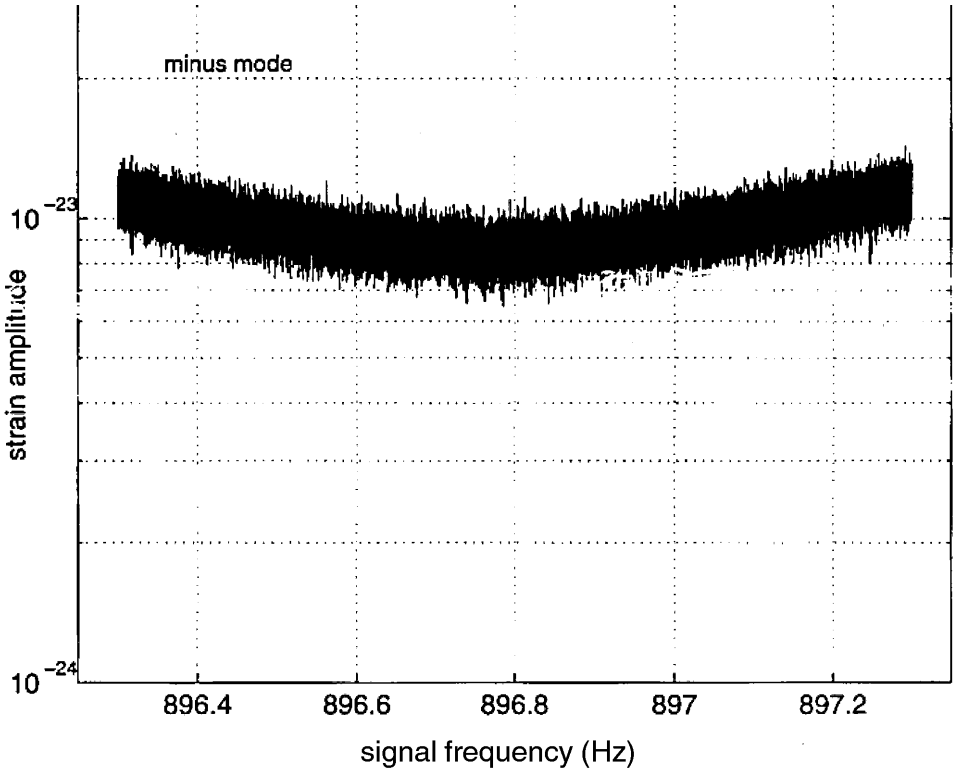

Figure 30. Search for narrow-band continuous waves from possible pulsars in 47 Tucanae [71]. Over about 1 Hz range no CW signal is visible above a strain amplitude $\sim 10^{-23}$.

stochastic gravitational waves of $\sim 10^{-22}$ at 900 Hz. The results achieved were limited because the detectors were too far apart. Vitale *et al* [128] have shown that NAUTILUS and AURIGA can be expected to achieve improvement of more than two orders of magnitude over this figure. However, they should be located within about 100 km of each other to achieve best sensitivity. This would bring the sensitivity to within the range of possible stochastic signals from the era of early star formation.

4.9. Multiple antenna correlation

In the future we can expect detailed correlation experiments to take place between a worldwide array consisting of both resonant-mass and laser interferometer gravitational wave detectors. The analysis would take into account the relative amplitude of the signals observed by detectors with different orientations relative to an incoming signal, and the phase delay due to the propagation time of signals through the Earth. Such a combined analysis would allow source direction and polarization to be accurately determined. Today we are still far from achieving this goal. Here we will discuss the analysis performed to date on data from a far less optimal array.

Besides seismic noise excitation, all cryogenic antennas have shown evidence of excess noise of indeterminate origin [81], as mentioned in section 3. Low noise performance may be achieved for considerable periods of time; but interspersed are periods of excess noise which

is not identifiably correlated with known noise sources. This can degrade performance by many orders of magnitude. While there are opportunities (as discussed above) for nonlinear up-conversion driven by low-frequency pendular modes, and also for thermal-stress-driven excitation as regions of the cryostat vary in temperature, no firm correlation is generally apparent. Thus the seismic, acoustic, electromagnetic pulse and cosmic ray shower detectors that are generally used to discriminate possible noise signals are not sufficient to eliminate excess noise, and much careful work still needs to be done. It has been shown that at a noise temperature of $\sim$1 mK about 2 cosmic ray events will occur per day, and this increases to 103 events per day at the 1 μK noise sensitivity [129]. The Rome group has convincingly demonstrated the presence of cosmic ray excitation events in their data [130].

Multiple antenna coincidence correlation can minimize the effects of excess noise, as demonstrated by many coincidence experiments (e.g. [131]), which sets new lower limits on the gravitational wave flux. When four or more antennas are operated in coincidence the rate of accidental coincidences becomes extremely small, as we discuss further below.

Candidate gravitational wave events consist of either unknown environmental perturbations, occasional rare Gaussian high-energy excursions, and possibly real gravitational wave signals. These may be idealized as an independent set of background events, occurring at a constant rate R per unit time. There is evidence that the background events are not entirely independent but to some extent are clustered. This can occur if a local vibration source acts over a period of time. In spite of this, the data are generally well described by a Poisson distribution.

The probability of a background event in one antenna during the antenna resolving time τ_r is given by

$$P_1 = R\tau_r. \tag{4.20}$$

Now if there are N independent antennas, the probability of accidental coincident excitation of all N antennas in a coincidence window τ_c that must always satisfy $\tau_c \geqslant \tau_r$, is given by the product

$$P_N = \tau_c^N \prod_{i=1,N} R_i. \tag{4.21}$$

If we simplify by assuming that all antennas experience the same background at the rate R, equation (4.21) becomes

$$P_N = R^N \tau_c^N. \tag{4.22}$$

From this it follows that the mean number of accidental coincidences during a coincidence experiment of duration $t_{\rm tot}$ is given by

$$N_{ac} = R^N \tau_c^{N-1} \cdot t_{\rm tot}. \tag{4.23}$$

Table 4 summarizes the mean number of accidental coincidences for experiments with one or more detectors, assuming various coincidence windows. The coincidence window depends on several factors. It cannot be smaller than the poorest clock precision of the detectors in the experiment. Second, it depends on the timing resolution of the optimal filters in the antenna readout. The latter depends on the signal size, but for the typical thresholds used to extract candidate events it is about 0.1 of the optimum integration time. At the improved antenna sensitivity expected in the near future, cosmic ray events could produce one event per 100 s (10^3 events per day). To detect rare events such as gravitational waves from supernovae in our Galaxy, we should be looking for $N_{ac} < 1$ in any coincidence experiment. The probability that a single coincidence is accidental is given roughly by the value of N_{ac} (for N_{ac} less than 1).

Table 4 emphasizes that multiple antenna operation is essential to reduce the background coincidence rate. Two-way coincidence experiments to date have been meaningful because

Table 4. Mean number of accidental coincidences for $R = 10^{-2}$ s^{-1} in a four-month (10^7 s) coincidence experiment.

Number of antennas	Coincidence window (s)			
	1	0.1	0.01	0.001
1	10^5	10^5	10^5	10^5
2	10^3	10^2	10	1
3	10	0.1	10^{-3}	10^{-5}
4	0.1	10^{-4}	10^{-7}	10^{-10}
5	10^{-3}	10^{-7}	10^{-11}	10^{-15}

$R < 3 \times 10^{-4}$ has usually been achieved. At the increased rate of candidate events expected due to cosmic rays as sensitivity improves towards $h \sim 10^{-20}$, it will be difficult to obtain significant data unless at least three detectors are used, or else if separate vetos can eliminate the cosmic rays themselves. The very low probability of accidental coincidences achievable with four- and five-antenna arrays apparent in table 4 demonstrates that with high time resolution it is possible to eliminate a substantially larger background than the assumed value of R. For example, even if R was increased to 1 s^{-1}, the probability of a five-way accidental coincidence using the smallest assumed window is 10^{-5} in a four-month experiment. Note that if the antennas have different resolving times, the τ_c used in equation (4.23) must be greater than the longest resolving time.

The issue of multiple antenna coincidences is not as simple as indicated above due to the fact that the antennas have varying orientations on the surface of the globe. The angular dependence of the signal S observed in a single resonant-bar antenna is given by

$$S(\theta, \phi, \varepsilon) = (0.5(1 - \varepsilon) + \varepsilon \cos^2 2\phi) \sin^4 \theta, \tag{4.24}$$

where θ is the angle of the incoming plane wave relative to the cylinder axis of the antenna, and ϕ is the polarization angle of the wave measured relative to the plane of the antenna and the source. The polarization fraction ε measures the fraction of linear polarization of the wave. For $\varepsilon = 0$ the wave is circularly polarized, whereas for $\varepsilon = 1$ the wave is 100% linearly polarized, with polarization angle ϕ.

To assess the probability of multiple antenna coincidences we must investigate the antenna pattern of a set of antennas on the globe. Since all antennas are horizontal, their orientation with respect to the sky is largely determined by their locations on the Earth, and considered as a whole this leads to a complex antenna pattern when the responses S as given by equation (4.24) are combined into a synthetic multiple antenna pattern. Antenna patterns for one and two resonant-bar antennas have been analysed by Frasca [132] and Nitti [133]; Blair and Frasca *et al* have analysed multiple antenna arrays [134], while Schutz and Tinto [135] have analysed antenna patterns for pairs of laser interferometers.

An analysis of antenna patterns for the geographical locations of four antennas [134] shows that four antennas are sufficient to obtain near-100% sky coverage for two-way coincidences. That is, if we are content with only two antennas being suitably aligned for a random source, we can observe practically 100% of the sky. On the other hand, if we are to demand four-antenna coincidences then we require the antenna orientations to be adjusted such that they optimally search the same part of the sky, and the sky coverage is reduced to about 50%. With eight operating antennas one can achieve near-100% sky coverage and a minimum of four antennas in coincidence for any one event. Note, however, that since spherical antennas have 100% sky coverage, such an eight-antenna array could be replaced by three or four spherical antennas, thus avoiding the sky coverage problem.

We now return to the practical problems of the existing array of bars. We have seen that the presence of local sources of background noise lead to the minimum detection requirement that a two-antenna zero time delay coincidence be observed. With unknown source direction we can apply no constraint on the signal based on the relative size of the signal observed in each antenna. However, it is possible to utilize the fact that the rotation of the Earth causes the antenna sensitivity to be strongly modulated for specific source directions. For example, it may be reasonable to consider that the nearest sources (such as coalescing black holes) will be concentrated near the galactic centre. Under this assumption one can reject data when the antenna sensitivity in this direction (defined by equation (4.24)) is below some predetermined value. Due to the $\sin^4\theta$ factor in equation (4.20) this provides a rather steep angular cut-off and in practice one can eliminate $\sim$50% of data by applying such a *direction filter*. This automatically reduces the number of accidental coincidences (since these occur randomly in sidereal time) and increases the statistical significance of any zero time delay excess). Such a procedure is statistically dangerous, however. The reason for this is that there will always be some direction in which an apparent excess is statistically significant. The direction and the cut-off threshold must always be preset before the analysis.

A second means of improving the statistical significance of the data rests on the fact that the energy distribution for true signals (such as gravitational waves or calibration pulses) is different from the distribution of excess noise events. This is easy to verify experimentally. Astone *et al* [136] have shown that the energy resolution achievable in a typical resonant bar with a threshold for candidate events about 10 times the mean noise energy is uncertain within a range typically 0.3–3 (for signal energy $= 1$). This uncertainty has been verified experimentally, indicating that the use of relative amplitudes to determine source direction can only be used effectively at large signal-to-noise ratio [137]. While this energy spread is large, the energy spread of accidental coincidences is always much larger, typically spanning up to two orders of magnitude. This follows immediately from the high effective temperature of the excess noise distribution (see figure 17). As a result one can apply an energy ratio filter to coincidence data, thereby eliminating from consideration any coincidences for which the energy ratio exceeds a predetermined value. (This depends on the relative orientation of the detectors, and on their excess noise distribution.) Appropriate criteria can be set for such filters based on the measured distribution of non-true-time coincidences. In practice this scheme allows about 50% of the total coincidences to be excluded, again allowing substantial improvement in the statistical significance.

In an unpublished NIOBE–EXPLORER coincidence experiment a total of about 25 zero time delay coincidences was reduced to a total of seven coincidences by the application of both an energy ratio filter and a galactic centre direction filter. This figure was substantially above the background, but timing uncertainties and the fact that these filters were developed during the data analysis period ruled out attribution of statistical significance to the result. If it had been a blind experiment and there had not been timing uncertainties the probability of the zero time delay peak occurring by chance would have been improved from $\sim$0.01 to $\sim 3 \times 10^{-4}$. Future experiments can utilize one or both of the above filters to improve statistics. It is a technique that is likely to be applicable in the search for burst sources in laser interferometer detectors.

4.10. Future prospects

4.10.1. Spherical gravitational wave detectors. Spherical gravitational wave detectors have been analysed extensively by Coccia and co-workers [138–143], Johnson and Merkowitz [34, 144], Zhou and Michelson [145] and Stevenson *et al* [146–149]. A spherical detector consists

of a large approximately spherical mass instrumented with five or more transducers to read out the orthogonal quadrupole modes and the gravitational wave insensitive monopole mode. Such a detector has a high cross section for gravitational waves and omnidirectional sensitivity. A spherical detector can be suspended close to its centre of mass to achieve quite good decoupling of the suspension from the antenna normal modes. This cannot be perfect however, because of another problem: the matching of transducers to the large normal mode masses. All operating resonant-bar transducers use a secondary resonator to match the antenna normal mode mass (about one tonne) to the transducer (see section 4.4). Typically, the secondary resonator (such as the UWA bending flap, figure 23) has a mass of several hundred grams. This is roughly the maximum mass that can be coupled to existing transducers with electromechanical coupling coefficient in the range $1–10^{-3}$.

In the case of a 100 tonne sphere aiming for high sensitivity to bursts in the kHz range, the impedance matching problem is more complex. The maximum effective bandwidth of a two-mode system is set by the beat frequency between the two normal modes. This is given by $\Delta f = f_0(M_1/M_2)^{1/2}$. For a 1000:1 mass ratio this represents a bandwidth of 3%. Since bandwidth translates directly into burst sensitivity, it is necessary to reduce this ratio, which can best be done with a multistage impedance matching network. A reasonable choice is a factor of about 30, which gives a fractional bandwidth of $(\frac{1}{30})^{1/2}$, or about 18%. However, to match to a transducer using such mass ratios between a 50 tonne normal mode mass and a 50 g transducer coupling mass requires the use of four stages, with the second-stage resonator exceeding 1 tonne, a third-stage resonator of tens of kilos, coupled to the final low-mass transducer stage. The sphere becomes a rather hairy sphere, possessing not five fundamental quadrupole modes that couple to gravitational waves, but 20. Care must be taken that there are no adverse couplings between the normal modes, since perfect orthogonality will be difficult to achieve in such a complex structure. Negligible cross-coupling can easily be achieved by deliberately choosing coupling mass parameters such that all modes are offset from each other by a few Hz.

A scheme for creating some of the additional resonators required on a sphere is illustrated in figure 31. It makes use of bending flaps, which have the advantage that they have low surface-to-mass ratio (to minimize surface losses), simple geometry for fabrication, and minimum wasted volume. The first intermediate mass is realized by simple machining of the sphere. The second could be welded or cast *in situ*, or it could also be cut from the first intermediate mass by suitable machining (the latter would save more space but has been omitted in the figure for clarity). Just two of the necessary five resonator structures are shown here. This design concept ensures that the antenna and most of the impedance matching system can be fabricated with complete mechanical integrity, thus avoiding unmodelled losses from bolts or glue joints. Here it is worth pointing out that the presence or absence of cylindrical symmetry is not an issue in antenna design, as demonstrated in the NIOBE bending flap at UWA. For large mass ratios the symmetry breaking creates a very small torsional reaction at the suspension point, which could only modify losses if the suspension itself had very large differences in acoustic losses for different degrees of freedom. In reality, suspension systems must be designed to isolate all linear and rotational degrees of freedom since intrinsic cross-coupling always occurs, determined by the Poisson ratio which has a value $\sim$0.3 in all pure homogeneous materials.

The final transducer stage on a spherical antenna can follow the noncontacting microwave parametric transducer concept to avoid the need for cable isolation and save space in the ultracryogenic volume. The transducer could be a sapphire transducer [150–152] or it could be a superconducting re-entrant cavity, as shown in figure 23. For ultralow-temperature applications it is necessary that the transducer have low power dissipation, generally below 1–10 μW. This requires the transducer losses to be lower than niobium transducers demonstrated

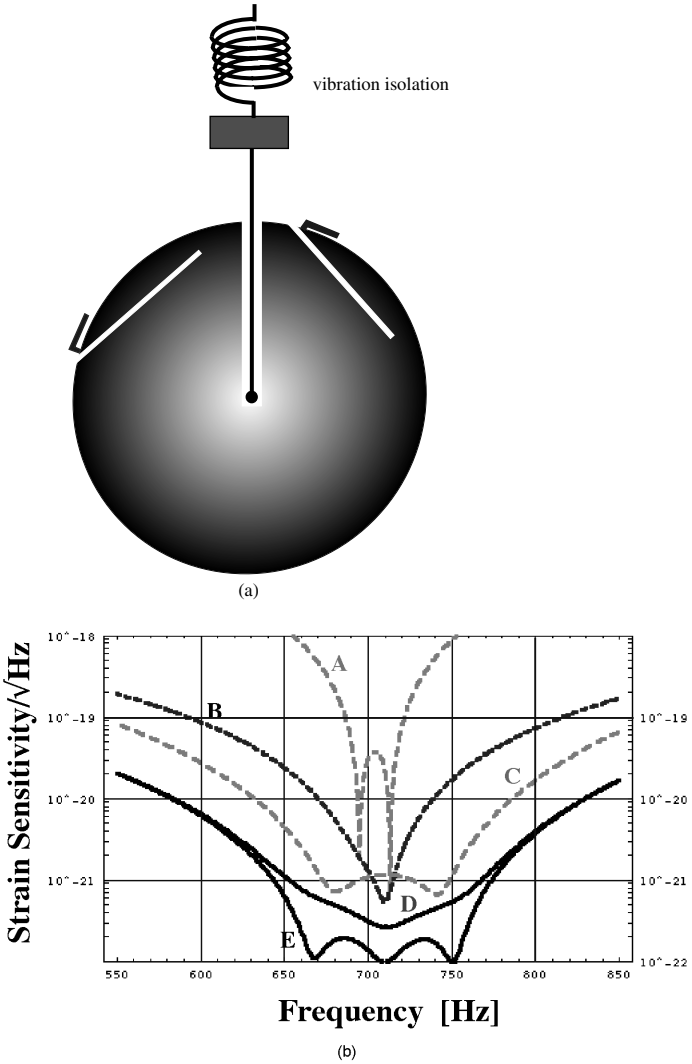

Figure 31. (*a*) A 100 tonne spherical antenna with two of the five cuts required to create ∼1 tonne secondary resonators to readout the orthogonal normal modes. To each secondary resonator is bonded a bending flap ∼30 kg to create the third normal mode of the impedance matching network. The fourth resonator (too small to show here) would consist of an additional bending flap of mass ∼50 g. A parametric transducer could read out such an antenna using radiative coupling thus avoiding vibration coupling through wires. (*b*) [153] Noise performance of a similar spherical detector. Curves A–E show the increasing bandwidth as the number of secondary resonators increased from 1 to 5 respectively.

so far. However, this can easily be achieved by using a larger gap spacing, and a frequency below 10 GHz. In the case of sapphire transducers, sideband pumping allows the dissipated power to be reduced below 1 μW. Figure 31(*b*) [153] shows that broadband noise performance ∼250 Hz can be achieved with a four-mode transducer on a large sphere. The bandwidth is significantly degraded as the number of modes is reduced.

At the transducer it becomes necessary to make a materials transition from the Al or Cu–

Al antenna material, to niobium or sapphire. No definitive solutions for such transitions have been defined, but shrink fitting (by thermal differential contraction), glue bonding or brazing are likely to allow suitably low-loss assembly. It will be important to develop bonding systems in small-scale tests before construction of large-scale spheres.

Spherical detectors cooled to ultralow temperatures can offer difficulties in cooling due to their small surface-to-mass ratio. Frossati has determined that forced convective cooling is essential if the cooling time is to be reasonable. If the material is superconducting, thermal conductivity freeze-out makes this a much more severe problem. For this reason Cu–Al and Be–Cu have been proposed for the antenna material.

4.10.2. Arrays of small high-frequency detectors. A part of the gravitational wave spectrum that has had insufficient attention is the high-frequency band between 2 and 20 kHz. In this band one expects gravitational waves from stellar mass black hole formation and their normal modes. At high frequencies, laser interferometers lose sensitivity due to shot noise, while resonant-mass detectors lose sensitivity due to the smaller size required for such high resonant frequency. Frasca and Papa [154] has proposed a solution consisting of phase coherent arrays of short stumpy antennas, designed so that that all five lower quadrupolar modes (the longitudinal mode, the two discoidal modes and the two 'pantograph' modes) have comparable quadrupole moment and sensitivity. Using five transducers, such stumpies can be read out similarly to the five quadrupole modes of a sphere, and thus have omnidirectional sensitivity. In principle, the total energy sensitivity increases linearly with the total detector mass, so that an array can be enlarged arbitrarily by simply adding additional identical elements.

Whereas a large sphere achieves high sensitivity in a single device, but at the expense of a rather low resonant frequency, the array of stumpies is claimed to achieve the same sensitivity at an arbitrarily high frequency, chosen by astrophysical considerations. It can have cost advantages too, through replication of identical elements.

Such an array obviously requires the individual elements to be sensitive to the same part of the spectrum. However, with adequate impedance matching the stumpies should have bandwidth $\sim$15% similar to that achievable in spheres and bars. This means that there is minimal difficulty in tuning individual detectors.

However, the practical limitations to achieving high sensitivity, such as the limits imposed by noise, have yet to be demonstrated. Further research in this area would be very valuable, including an in-principle demonstration of the concept using calibration signals. The array of stumpies provides an opportunity to achieve great increases in high-frequency sensitivity in the future, but will probably not be implemented until positive results are obtained with existing detectors, or astrophysics provides a very strong justification for improved high-frequency sensitivity.

4.10.3. Transducer developments and prospects. The implementation of improved transducers and impedance matching structures is essential to increasing the bandwidth and burst sensitivity of resonant-mass detectors. Successful transducers have been developed based on capacitative or inductive modulated superconducting circuits with RF or DC SQUID amplifiers, as well as microwave parametric transducers based on superconducting cavities and cryogenic GaAsFET amplifiers. Both systems have comparable sensitivity and a variety of advantages and disadvantages.

The sensitivity of a SQUID-based transducer depends on the SQUID noise performance, and on the mechanical and electrical quality factors of the superconducting elements. A persistent problem has been AC electrical losses in the niobium superconducting coils used for

sensing and coupling transformers in passive transducers. It has sometimes been difficult to obtain sufficient trapped persistent current in inductive sensing circuits, and sufficient electric field across capacitative sense elements. AC losses introduce thermal noise, while low current or electric field reduces the forward transductance, reducing the electromechanical coupling and increasing the antenna noise temperature.

A critical factor for SQUID transducers is the SQUID noise. Recently there has been progress in this area. Two groups have created SQUIDs with noise measured to be below about $30\hbar$, one to two orders of magnitude better than commercial devices. However, recent results [155] indicate that noise is degraded in a transducer environment due probably to trapped flux.

Parametric transducer performance also depends on the mechanical and electrical quality factor of the transducer structure. This is less of a problem however, since the simpler mechanical structures used have shown Q-factors $\sim 10^7$, and electrical Q-factors $\sim 10^5$–10^6, both of which are high enough to be negligible noise sources at current sensitivity. Microwave amplifiers have for many years been shown in radio astronomy to have near-quantum-limited noise, but in the only successful such implementation the amplifier noise contribution is in excess of this [156]. Critical to achieving excellent amplifier noise is very low signal levels, requiring excellent carrier suppression, since otherwise pump power reflected from the cavity greatly exceeds the signal sidebands.

Another critical problem is pump oscillator phase noise. The NIOBE transducer required an ultralow phase noise microwave oscillator to be especially developed.

To achieve sensitivity near to the quantum limit with a parametric transducer will require a higher Q-factor electrical resonator and a lower noise pump oscillator. Fortunately, oscillators 30 dB better than that used on NIOBE have now been developed, and a sapphire transducer with mechanical and electrical Q-factor exceeding 10^8 should allow this technology to advance to within a factor $\sim$30 of the quantum limit [100, 152, 157].

4.11. Vibration isolation and suspension developments

The vibration isolation and suspension system for resonant-mass detectors has always consisted of both room temperature and cryogenic isolation stages such as those discussed above. In the case of ultracryogenic detectors there has been greater emphasis on cryogenic isolation but careful isolation of the cryostat structure itself has been necessary to prevent local disturbances. It is tempting but incorrect to consider the vibration isolation problem solved, since improvements of more than 1000-fold in energy sensitivity are projected, and already detectors show signs of inadequate isolation. In the case of NIOBE there are signs of variable noise temperature by about a factor of two which is observed as degrading mode temperature without change to the wideband noise. Sometimes diurnal variations associated with human activity are observed. This can be understood as arising from vibrational short circuits, perhaps due to a small piece of superinsulation or whiskers of solid air crossing the narrow spaces in the radiative cooler in the suspension tube, or residual conduction through the low pressure (10^{-5} torr) gas in the experimental volume.

EXPLORER is operated at 2 K, below the helium superfluid transition to eliminate the vibrational effects of boiling liquid helium, which otherwise causes degraded performance. NAUTILUS operates well only when local activity is low, again indicating inadequate vibration isolation. Thus it appears that all currently operating detectors are operating close to a vibration isolation limited noise floor, at which improved antennas and transducers will not provide the anticipated noise advantages.

In principle, isolation can be easily improved by further isolation stages, such as the

cantilever spring stages used at UWA. However, short circuits can easily occur, especially through unmodelled resonances in components such as masses, springs or wires, which can cause catastrophic degradation of performance. Not only great care, but excellent design and deep understanding of complex mechanical structures is essential. One point in favour of advanced detectors such as spheres is the advantage of near-nodal-point suspension achieved using centre of mass suspension [126], which can improve isolation by 40–60 dB depending on the proximity of the suspension point to the node. As already emphasized, this can never be perfect due to the finite size of suspension elements and the multimode nature of detectors.

4.12. Conclusion

Resonant bars have been brought to a high level of development. There is now an excellent understanding of the technology and clear proposals for substantial future advances. In particular, it is likely that large spherical detectors will be found to be the best solution for obtaining high sensitivity in the 1–10 kHz range. Meanwhile, an extremely vigorous research effort in laser interferometer detectors is underway, as discussed in the next section.

5. Interferometer detectors

5.1. History

The Michelson interferometer has long been known as an extremely sensitive instrument to measure length changes. The idea of using a laser interferometer as a gravitational wave detector was suggested as early as the 1960s [65, 158] and experimentally investigated in the 1970s [66, 159, 160]. But the first experimental attempt, giving high sensitivity to the displacement of test masses was due to Forward [161]. Forward used a retro-reflector to reflect a beam to a beamsplitter and used active control for locking the interferometer to a fringe. He obtained a spectral strain sensitivity of 2×10^{-16} Hz$^{-\frac{1}{2}}$. The state of the art in sensitive interferometers at the time of writing is represented by three prototype instruments of 10 to 40 m in arm length. These are at Garching [162], Glasgow [163] and CalTech [164]. The 30 m delay line interferometer at Garching has achieved test mass differential position sensitivity of 2.5×10^{-18} m Hz$^{-\frac{1}{2}}$ dominated by shot noise between 1 and 6 kHz. The 10 m Fabry–Perot interferometer at Glasgow has reached $\sim 7 \times 10^{-19}$ m Hz$^{-\frac{1}{2}}$ from 500 Hz to 3 kHz and is close to being limited by shot noise. The 40 m Fabry–Perot interferometer at CalTech has achieved its best displacement sensitivity of 3×10^{-19} m Hz$^{-\frac{1}{2}}$ near 450 Hz. The broadband noise background (neglecting the narrow peaks which can be removed by appropriate filtering of the data) between 300 and 1000 Hz gives a rms differential displacement of less than 10^{-17} m, corresponding to an rms gravitational strain noise level of 2×10^{-19} which is comparable to the sensitivity of current resonant-bar detectors.

In pursuit of increasing the interferometer sensitivity, several optical schemes have been invented. *Power recycling*, proposed by Drever [165], reuses the otherwise unused laser power from the interferometer bright fringe. The light is reflected back towards the beamsplitter, thus increasing the total light power entering the interferometer. *Dual recycling* proposed by Meers [166] allows both laser power and signal power to be recycled, thus increasing sensitivity at the expense of signal bandwidth. Various other schemes such as synchronous *recycling* [165], *detuned resonant recycling* [167], and *resonant sideband extraction* [168, 169] provide various advantages. In general, recycling schemes allow high power built-up in the interferometer arms (which may or may not contain optical cavities) to increase the sensitivity while controlling the signal sideband storage time to maintain detection bandwidth.

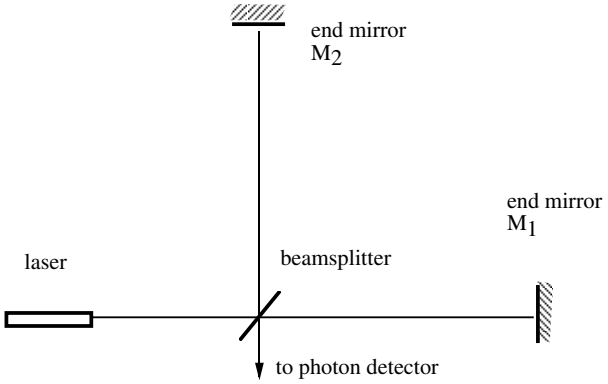

Figure 32. Simple Michelson interferometer.

Power recycling has been demonstrated on both tabletop [170–172] and suspended interferometers [173, 174] with success. Power recycling factors of 300 and 450 have been achieved [173, 174]. The broadband and tuned signal recycling has been demonstrated on tabletop by ANU group [175]. Dual recycling has been tested experimentally by both Glasgow [176] and Max Plank groups [177].

Long-baseline detectors are under construction at: Hanford, Washington and Livinston, Louisiana, USA (American LIGO project) [32], Pisa, Italy (3 km Italy/France VIRGO project) [178], Hannover, Germany (600 m British/Germany GEO project) [179] and Tokyo, Japan (300 m TAMA project) [180].

During the past few years the development of diode-pumped Nd:YAG lasers and ultralow-loss optical coatings has offered greatly improved performance in laser interferometer devices. Nd:YAG lasers are intrinsically stable and efficient. Low-loss coatings (for mirrors working in the infrared frequencies) offer very high recycling gain. Development of polishing techniques for sapphire means that improved material less susceptible to thermal lensing is becoming available. New ideas in suspension and isolation means that it appears likely that future interferometers need only be limited by fundamental limits, while there remains substantial room for future advances.

5.2. Configurations

5.2.1. Simple Michelson. A simple Michelson interferometer detector is shown schematically in figure 32. The interferometer consists of three 'free masses'—one beamsplitter, and two test masses at right angles to form the end mirrors. These masses are vibration isolated and suspended so that at frequencies well above resonance they can move freely as inertial test masses in the direction of the optical path of the interferometer in the frequency range of interest. When a gravitational wave passes it creates relative displacements of the test masses. The relative motion of the end mirrors is read out as intensity variations in the interferometer output, giving information about the incoming gravitational wave.

For simplicity, consider the case of an incident gravitational wave perpendicular to the plane of the interferometer with a polarization direction parallel to the interferometer arms. The passing wave will make one arm of the interferometer shorter and the other longer in half of the wave period, and reverse the contraction–elongation process in the other half-period. The relative change of optical length of the two arms $\Delta L = L_2 - L_1$ can be described as a

phase shift,

$$\Delta F = 2\pi \Delta L/\lambda. \tag{5.1}$$

This results in a change in the interference pattern at the output of the beamsplitter. The relative difference in optical path ΔL is proportional to the arm length $\Delta L = hL$. Generally, an interferometer is sensitive to a linear combination of the two polarization fields, and h in the above equation is

$$h = F_+ h_+ + F_\times h_\times \tag{5.2}$$

where F_+ and $F_\times$ are coefficients depending on the direction to the source and the orientation of the interferometer.

Because the gravitational signal is extremely small, it is very difficult to monitor the small time-varying changes in the interference pattern due to the passing gravitational wave. In practice, the phase difference arising from the optical arm length variations is obtained by the so-called 'nulling method'. The idea is to always keep the light returning from the two arms 180° out of phase so that its output is a dark 'fringe'. When the end mirrors are moved by the passing gravitational waves, the error signals applied to end mirrors to maintain the dark fringe contain the information of the gravitational wave signals. In this way the effect of power fluctuations in the laser beam can be minimized, and the shot noise level can be reduced.

Since the detection of gravitation waves with an interferometer is achieved by measuring the relative optical path (phase) change between the two arms, and since this path difference is proportional to the optical path L, it is clear that the size of the signal can be increased by lengthening the optical path of each arm. However, there is an optimum length $L_{\rm opt}$. At such a length the storage time of the light within the interferometer arms is equal to half the period of the gravitational wave. For arms longer than $L_{\rm opt}$, the gravitational wave signal will change sign during the light travelling time in the arm and the effect will partially cancel out. For example, for a gravitational wave signal of frequency $f_g \sim 1$ kHz, the optimum arm length is $L_{\rm opt} = c/(2f_g) = 150$ km. Such a long optical path length can be easily realized in a space-based interferometer (see section 3.2). In an Earth-based interferometer this is made possible by using multi-pass techniques. One such technique is the multi-pass Michelson interferometer in which an optical delay line [66] is inserted in each of the interferometer arms. The other is a Fabry–Perot Michelson interferometer [181] in which a second mirror is inserted in each arm to form a Fabry–Perot cavity.

5.2.2. Delay line Michelson interferometer. A delay line Michelson interferometer is shown schematically in figure 33. The two beams coming out of the beamsplitter are reflected many times between the beamsplitter and the end mirrors before they are recombined. For example, a 3 km long interferometer can have an optical length of 150 km by having 50 bounces. Apart from the restriction that the optical path length be shorter than $L_{\rm opt}$, the useful number of reflections is in practice limited by the reflection losses at the mirror.

A practical difficulty of the delay line Michelson interferometer configuration is the scattered light problem. The delay line uses a large number of beams zigzagging back and forth between mirrors. It is easy for light to scatter from the mirrors or from the side of vacuum pipes into the main beam at the photodetector. This scattered light could have a large phase difference $\alpha = 2\pi f \delta l/c$ with respect to the main beam, where f is the laser light frequency and δl is the path difference from the main beam. When the scattered light interferes with the main beam, it results in a phase shift β of the recombined light given by $\beta \sim a \sin\alpha$, where a is the fraction of the scattered light. This change of phase will be sensed by the output photodetector when combined with the beam from the other arm. It can be seen that any fluctuation of

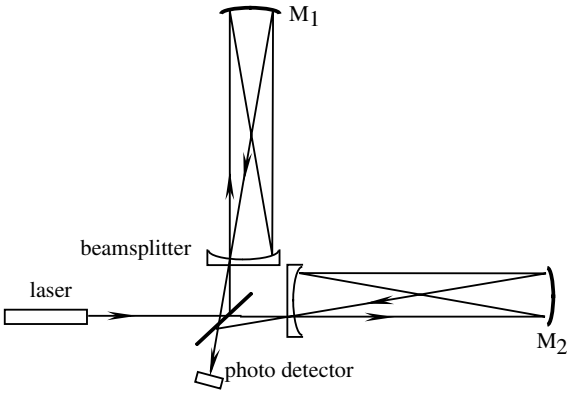

Figure 33. Schematic diagram of a delay line Michelson interferometer.

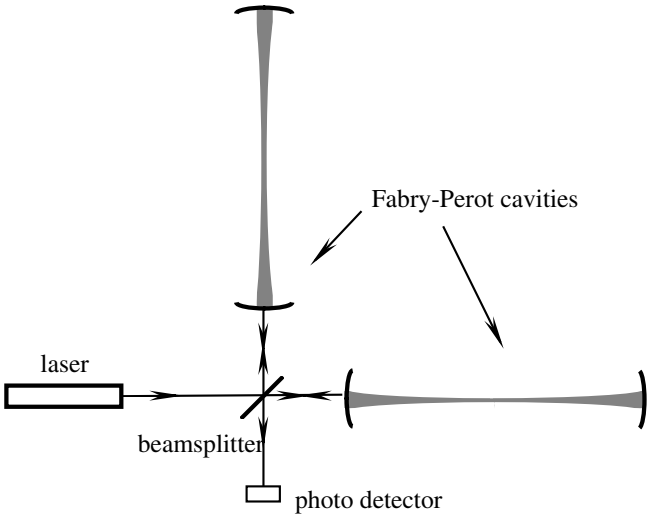

Figure 34. Schematic diagram of a Fabry–Perot cavity interferometer.

laser frequency or vibration of the vacuum pipes (which results in a change of δl) will cause a phase fluctuation of each beam, and thus a fluctuation in the final signal. This effect can be reduced by stabilizing the laser frequency. Modulation of the laser light [182] can improve the performance to some extent. This is done by changing the laser frequency f such that over a certain measurement time the scattered light phase difference α changes from 0–$2n\pi$. The average effect of the scattered light is then zero. This technique is limited by the dynamic range of the modulation. Another disadvantage of a delay line Michelson interferometer is that it needs large mirrors. However, excellent sensitivities of the order $h \sim 10^{-19}/\mathrm{Hz}^{1/2}$ have been obtained using a delay line Michelson interferometer of arm length 30 m [183].

5.2.3. Fabry–Perot cavity interferometer. The Fabry–Perot cavity interferometer gravitational wave detector was first introduced by Drever *et al* [181]. The idea is to add two additional mirrors near the beamsplitter, as shown in figure 34.

The near mirror and the end mirror in each arm form an optical cavity. Light travelling

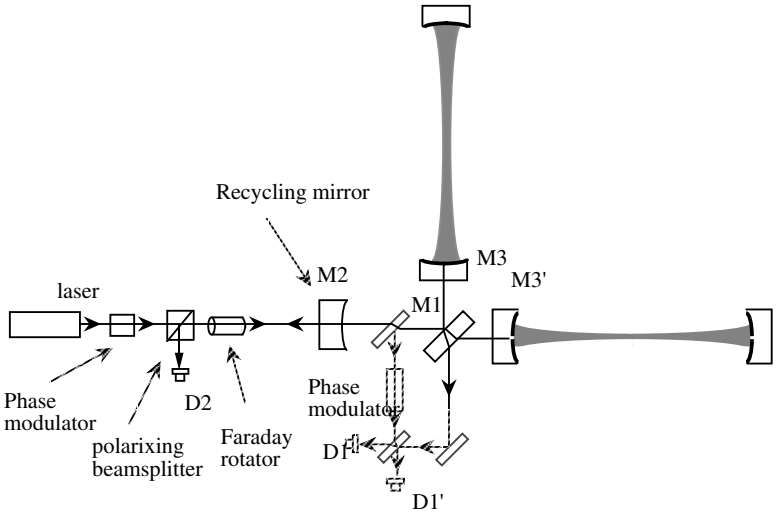

Figure 35. Basic arrangement of a Fabry–Perot interferometer system [324].

in one arm is reflected between the same pair of spots on the two mirrors, forming a sharp resonance. This Fabry–Perot cavity is very sensitive to the changes in cavity length, and to the change in frequency of the light. Because no laser has achieved the required stabilization level to directly detect the change in cavity length induced by gravitational waves, two cavities are needed to detect differential changes. The light from a single source passes through a beamsplitter and illuminates the cavities in the two arms of the interferometer. By looking at the differential phase change of the two arms, the effect of frequency fluctuations of the light source can be eliminated, and the signal is a measure of the passing of a gravitational wave. The size of the suppression of the laser frequency fluctuation noise depends on the balance of the two cavities. Typically, with a highly stabilized laser, the cavities must be balanced to one part in 10^3 or better.

Another approach is to lock the laser in wavelength to one of the cavities, and then to lock the second cavity to the laser wavelength. The locking signal of the second cavity then gives the relative cavity length change with respect to the first cavity, due to the passing gravitational wave. A practical arrangement of a Fabry–Perot cavity interferometer with such a readout system is shown in figure 35.

The Fabry–Perot cavity interferometer has the advantage of having smaller mirror size, and thus smaller vacuum pipe size, than that in a delay line Michelson interferometer. Also, the scattered light problem can be reduced greatly in a Fabry–Perot cavity arrangement because the scattered light is made to travel the same path as the main beam in the cavity.

5.2.4. Sagnac interferometer. A Sagnac interferometer is schematically shown in figure 36 in which light beams travelling in opposite directions experience common optical paths. With its common-path nature, the Sagnac interferometer is insensitive to a range of noise sources that affect other interferometers. Noise from low-frequency mirror displacements, laser frequency and intensity fluctuations, laser beam pointing fluctuations, thermally induced birefringence, and reflectivity asymmetry in the arms are all suppressed. This means that the Sagnac configuration can have a simplified control system and reduced optical tolerance requirements. Low-temporal-coherence illumination can be used in a common-path interferometer to reduce

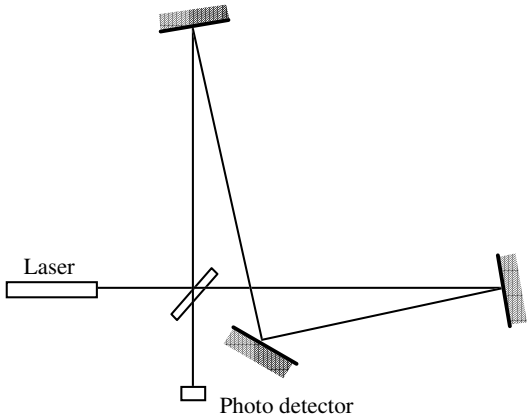

Figure 36. Schematic diagram of a Sagnac interferometer.

the noise caused by parasitic paths introduced by scattered light. In 1986, Weiss proposed an open-area Sagnac interferometer for gravitational wave detection. Recently, the zero-area Sagnac interferometer shown in figure 36 has been analysed and experimentally investigated as a topology for an advanced gravitational wave detector [184,185]. For 4-km 20-bounce (storage time of 0.53 ms) LIGO-scale interferometers illuminated with a 1064 nm Nd:YAG laser, the Sagnac interferometer has its first peak response at 690 Hz with 3 dB bandwidth from 220 to 1250 Hz [184], as shown in figure 37. Proper setting of the storage time allows the peak response frequency to be tuned to the gravitational wave band of interest. A shot-noise-limited phase sensitivity of 9×10^{-10} rad $\mathrm{Hz}^{-1/2}$ has been achieved on a tabletop Sagnac interferometer [185]. It has been demonstrated that precision phase measurement can be performed with a laser bearing a substantial amount of frequency and amplitude noise [185]. The Sagnac interferometer with resonant sideband extraction has been demonstrated on the tabletop [186].

The comparison between the Sagnac and Michelson interferometers is detailed by Mizuno [187] and colleagues. Their conclusion is that, once cavities are used either in the arms or for power- or signal-recycling, the advantages of the Sagnac interferometer over the Michelson interferometer disappear. Without power recycling, $\gg$1 kW laser with quite high stability is required to achieve the desired sensitivity for Sagnac interferometer.

5.2.5. All-reflective interferometer. Extremely high light power incident on the beamsplitter is needed to reduced the photon shot noise which is a major limiting factor in the high-frequency regime ($\sim$1 kHz) in laser interferometers. However, high light power poses problems for transmissive optics such as beamsplitters and the input/output mirrors of Fabry–Perot cavities, because there is always some optical absorption causing heating. The optical components are heated both by absorption in the substrate and in the reflective coatings. Heat from both regions leads to thermal lensing and birefringence in the substrate, and also to distortion of the optical surfaces. The Sagnac interferometer might alleviate these problems since the counterpropagating laser beams in principle share the same optical path.

A more certain method of reducing adverse thermal effects is to eliminate transmissive optical components completely. The losses in optical coatings are generally less than absorption losses, so by using reflective diffractive components instead of lenses and beamsplitters, it should in principle be possible to make interferometers much more tolerant of high optical powers. The idea of an entirely diffractive reflective interferometer has

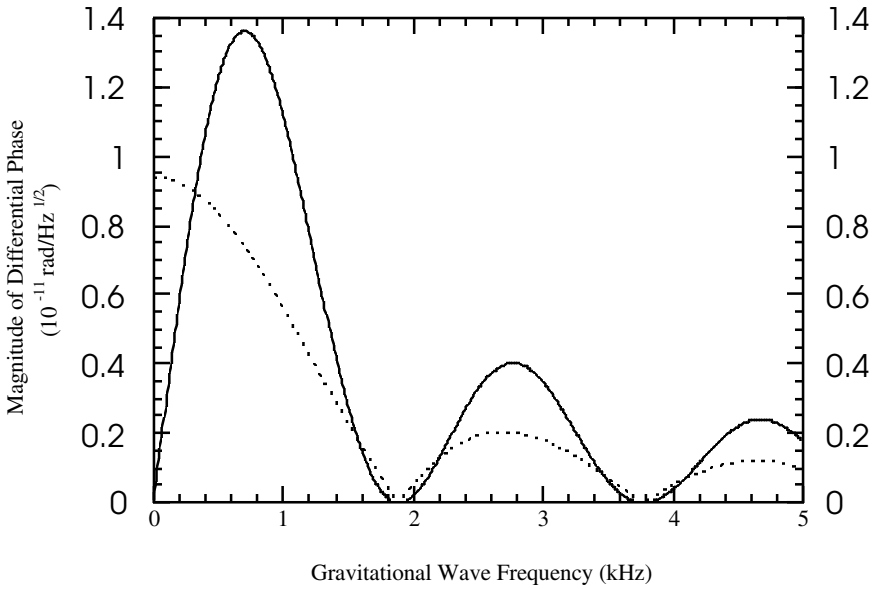

Figure 37. Theoretically calculated differential phase generated by a gravitational wave with strain $h_g \sim 10^{-23}/\sqrt{\text{Hz}}$, in a 20-bounce delay line, 4 km arm length Sagnac interferometer illuminated by a 1064 nm laser. The Michelson interferometer response (dotted curve) is shown for comparison [184].

been discussed by Drever [188]. The concept would allow test masses to be created using nontransmissive materials such as silicon or niobium, where low thermal noise did not have to be combined with excellent optical properties. One possible interferometer configuration using a diffractive beamsplitter is shown in figure 38. Veitch *et al* [189] have reported tests of a holographic beamsplitter used to remove optical aberrations and guarantee high fringe visibility and complete destructive interference at the interferometer output even in the presence of aberrations. An experimental demonstration of various grating beamsplitter tabletop interferometers (Michelson, Sagnac and Fabry–Perot) has been performed at Stanford [190]. For a practical diffractive interferometer it will be necessary to perfect reflective diffractive elements. If optical cavities are to be used, the mirror coatings will have to include a diffractive coupling beam. For example, a mirror may be required that has 99.999% reflection, and 0.001% coupling into a beam that leaves the mirror at a suitable angle. This problem sets a challenge for optics in the next decade, which can lead to major improvements in gravitational wave detection in the future.

5.3. Recycling

5.3.1. Power recycling. The sensitivity of an interferometer is ultimately limited by shot noise due to photon quantum statistics. The standard quantum limit for an interferometer can be obtained from the balance of two competing quantum noise sources as described by Caves [191, 192], Braginsky *et al* [112] and others. The first is the photon-counting error due to $N^{1/2}$ fluctuations in the number of output photons from the interferometer. The second is the radiation-pressure error. This arises from the perturbations on the end mirrors produced by fluctuating radiation-pressure forces which also scale as $N^{1/2}$. As the input laser power P increases, the relative photon-counting error decreases as $N^{1/2}/N$, while the radiation-pressure

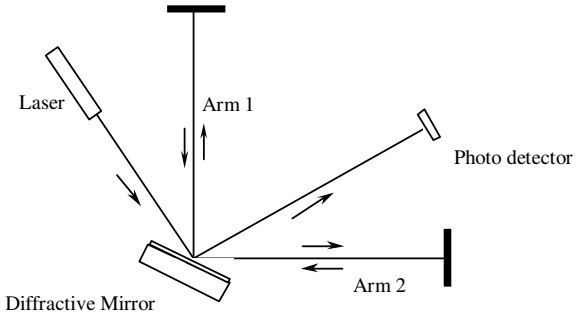

Figure 38. Schematic diagram of a Michelson interferometer based on the use of reflective diffraction grating as a beamsplitter.

error increases as $N^{1/2}$. Minimizing the total error with respect to P yields a minimum error of order of the standard quantum limit and an optimal input power for a simple Michelson interferometer,

$$P_{\text{opt}} = \frac{\lambda mc}{8\pi\tau^2\sqrt{\eta}}, \tag{5.3}$$

at which the minimum error can be achieved. Here, m is the mass of an end mirror, λ is the wavelength of the light, τ is the measurement duration, and c is the light velocity.

With a reasonable set of values for interferometer parameters, $m \sim 10^2$ kg, $\tau \sim 10^{-3}$ s, $\lambda \sim 1\ \mu$m, the optimum laser power P_{opt} is approximately 6×10^7 W—a power far higher than the power of present CW lasers. The low available input power means that the interferometer for use as gravitational wave detectors will be limited not by the standard quantum limit, but rather by photon-counting statistics (shot noise) which scales inversely to the square root of incident power at beamsplitter.

As mentioned above, the technique of power recycling [165, 166] can be used to increase the power incident at the beamsplitter and improve the sensitivity of interferometer detectors. The basic idea is that because the interferometer detector operates at a dark fringe output, almost all of the light (reduced only by losses in mirrors and beamsplitters) is reflected back towards the laser, and can therefore be used again as long as it is phase coherent with the input laser beam. This technique is realized by inserting a recycling mirror M_2 in between the laser and the beamsplitter as shown in figure 35. The position of the recycling mirror (or the laser frequency) is then carefully adjusted so that the recycling mirror combined with the two main cavities and the beamsplitter form a large resonant optical cavity containing the interferometer. By doing so, an effective laser power perhaps 1000-fold larger than the original laser may be built up inside this cavity, thus reducing the shot noise.

5.3.2. Resonant recycling. The resonant recycling technique [165] uses a mirror arrangement such that after each half gravitational wave period, the light in the two arms exchange arms instead of recombining at the output photodetector. In this way, the light of each beam always experiences phase shift in the same direction. The phase shift builds up during the total storage time over many gravitational wave cycles. In the end, a large phase difference between the two arms can be detected at the output of the interferometer. This technique can be used in both delay line Michelson interferometers and in Fabry–Perot interferometers. Figure 39 shows resonant recycling arrangements for both delay line interferometer and Fabry–Perot cavity interferometer.

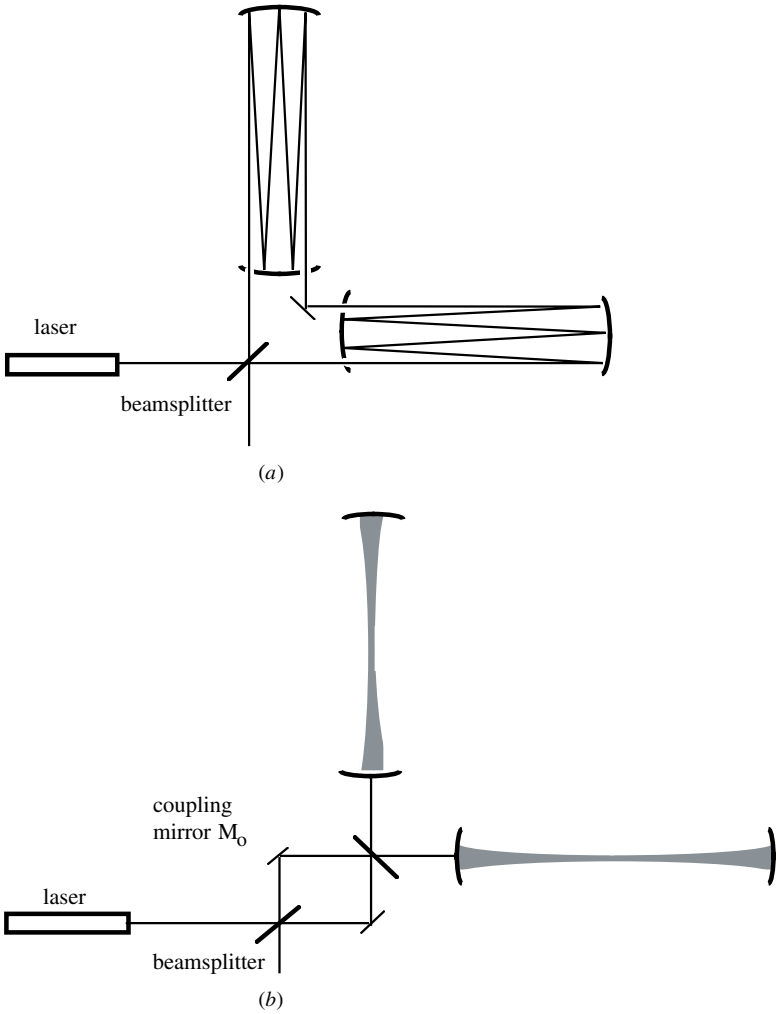

Figure 39. (*a*) Resonant recycling arrangement for a delay line interferometer. (*b*) Resonant recycling arrangement for a Fabry–Perot cavity interferometer.

In the case of resonant recycling in a Fabry–Perot cavity interferometer, it is considered that the two cavities are coupled through the high-reflectivity mirror M_0. This coupled system then has two modes of oscillation. The interferometer is tuned so that one of the modes of the coupled optical cavity system matches the frequency of the laser light and the other matches the frequency of the optical sideband produced by the motion of the end mirrors due to an incident gravitational wave. Both the laser light and the sideband signal produced by gravitational wave are enhanced at the output. In principle, resonant recycling gives better sensitivity for detecting periodic signals of known frequency. The total storage time is limited by the losses of the mirrors.

5.3.3. Dual recycling. A simple arrangement for dual recycling [193] is shown in figure 40. In addition to the power recycling mirror M_3, a new signal recycling mirror M_4 is placed at the output of the interferometer. Generally, the light at laser frequency (carrier) cannot

reach M_4 when the interferometer is locked on a dark fringe. However, when the gravitational wave arrives, it modulates the interferometer arm length difference and generate sidebands at frequencies offset from the laser frequency by the gravitational wave frequency. The sidebands leak from the interferometer output towards M4 as gravitational wave signal. So M_4 has no effect on the carrier but reflects the signal sidebands back to the interferometer. If we adjust the position of the mirror M_4 to allow the reflected signal sidebands and the signal in the interferometer arms to be in phase, the signal power (sensitivity) will be increased. The relative position of the recycling mirror M_4 determines the tuning frequency of the dual recycling. The bandwidth is determined by the reflectivity of the signal recycling mirror and the loss of the two arms. The dual recycling with tuning frequency at zero is called broadband dual recycling. The relative signal-to-noise ratio of a 3 km, 16-reflection delay line interferometer with different degrees of tuned dual recycling is shown in figure 41. The central frequencies are at 200 and 1000 Hz respectively. Even a relatively short arm interferometer can obtain impressive sensitivity. For example, figure 42 shows the predicted shot-noise-limited strain sensitivity of a 400 m, four-pass delay line [194]. The input power is 5 W. The tunned frequency is at 200 Hz. Curves (a) and(c) are based on application of recycling factors (450) already achieved in the laboratory [174], curves (b) and (d) employ somewhat higher factors.

5.3.4. Simple dual recycling instruments. The advantage of the Fabry–Perot Michelson interferometer is that high laser power and low mechanical noise requirements are predominantly restricted to optical cavities. Thus one needs only four very-high-performance components (the main Fabry–Perot mirrors) while the beamsplitter and other components are far less critical. When this scheme is extended to dual recycling as shown in figure 43. The interferometer consists of nested cavities, a pair of Fabry–Perot cavities within the overall power recycling and signal recycling cavities. This requires rather complex control systems.

A much simpler arrangement would be a four-pass dual recycling Michelson interferometer (GEO project) as illustrated in figure 43 [195]. Such a system utilizes only two cavities. Now, to regain the sensitivity of the Fabry–Perot Michelson, the interferometer must use high levels of power recycling, plus moderate signal recycling. Because of the thermal lensing problem [196], this arrangement requires excellent mechanical and optical performance of the beamsplitter.

It appears that very-low-loss silica beamsplitters may allow recycling factors up to 10^4 [197]. An alternative would be to use sapphire beamsplitters, which have intrinsic advantages associated with their high rigidity, and high thermal conductivity. However, the disadvantage of sapphire is its optical birefringence which requires control of the orientation of the crystal relative to the input and output beams.

5.3.5. Resonant sideband extraction. Resonant sideband extraction [168, 169] is a similar configuration to dual recycling for laser-interferometric gravitational wave detectors with Fabry–Perot cavities in the arms. This scheme reduces the thermal load on the beamsplitter and the coupling mirrors of the cavities and allows one to adapt the frequency response of the detector to a variety of requirements.

To obtain a good sensitivity in interferometric gravitational wave detectors one requires high light power in the arms of the interferometer to increase the photon shot-noise-limited signal-to-noise ratio. This can be done by increasing the finesses of the arm cavities. But since high finesse cavities have narrow bandwidth, (i.e. long optical storage time) this sets a limit to the detector bandwidth. The same power build-up can equally be obtained in principle by using power recycling to compensate for the limitation to the power enhancement in the

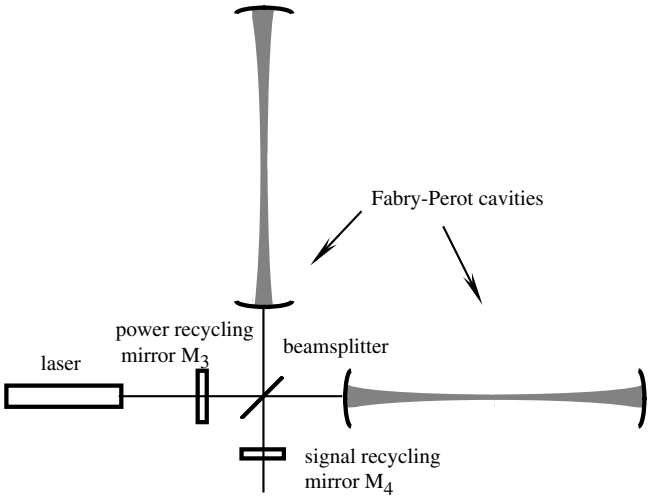

Figure 40. Dual recycling arrangement of an interferometer.

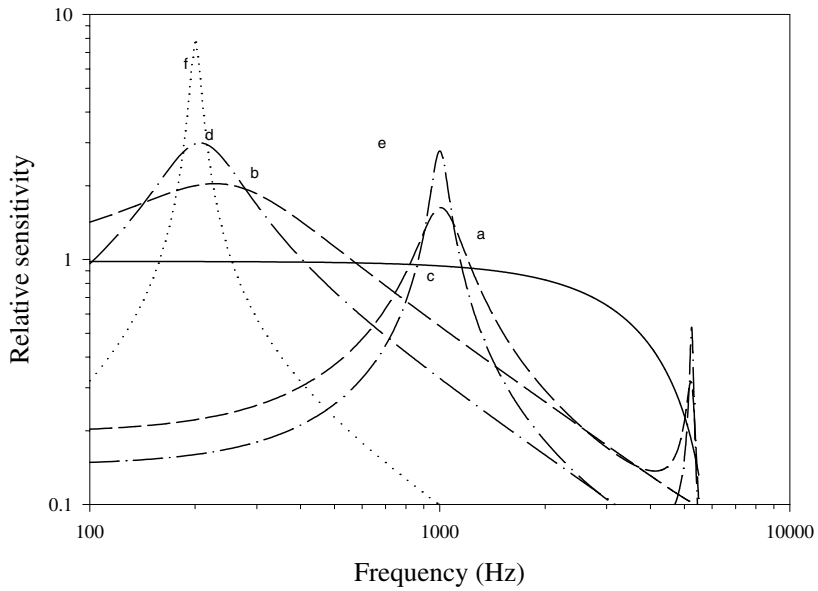

Figure 41. Relative signal-to-noise ratio of a 3 km 16-reflection delay line with different degrees of tuned dual recycling. The tuning frequencies are at 200 Hz and 1 kHz respectively. The vertical axis is in arbitrary units. The solid curve is for power recycling only; the dashed curve is for signal recycling mirror reflectivity, $R_s = 75\%$; the dash-dotted curve for $R_s = 90\%$; the dotted curve for $R_s = 99\%$ [325].

arm cavities. However, in practice the power recycling gain achievable is likely to be limited by imperfect contrast as well as losses in the beamsplitter and the coupling mirrors of the arm cavities. Furthermore, as already discussed, high power may induce thermal lensing and birefringence in the beamsplitter.

Resonant sideband extraction allows this dilemma to be avoided in an interferometer with

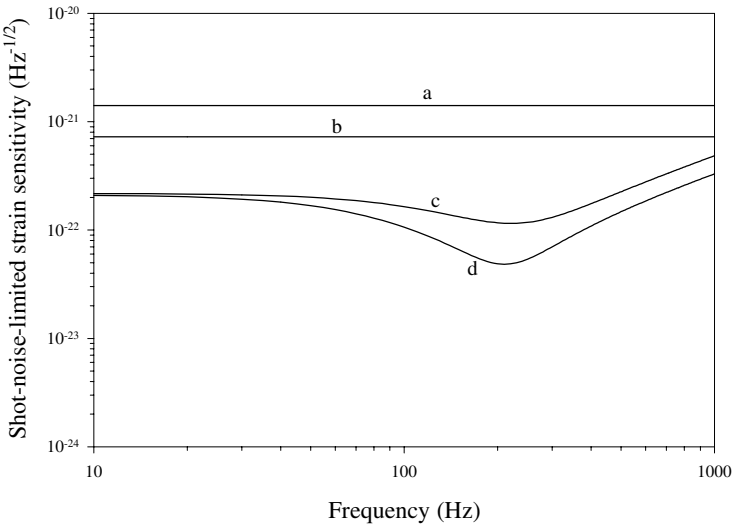

Figure 42. Frequency response of a 400 m interferometer. Input power is 5 W. Curve (*a*) power recycling factor of 450, no signal recycling; curve (*b*) power recycling factor of 1700; curve (*c*) dual recycling with power and signal recycling factors of 450; curve (*d*) power recycling factor of 1700, signal recycling factor of 800 [194].

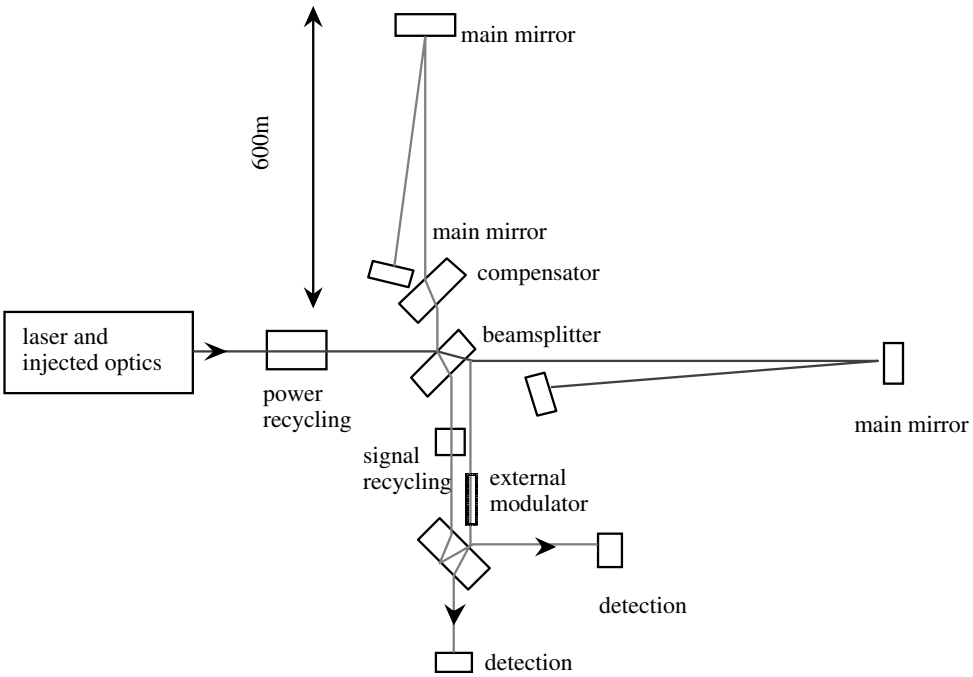

Figure 43. Schematic diagram of a four-pass delay line interferometer with both power and signal recycling (i.e. dual recycling). The angles and lengths are not to scale. The test masses of the interferometer are formed by the main mirrors and the beamsplitter [195].

arm cavities. The scheme resembles signal recycling, but uses a *signal extraction mirror* between the beamsplitter and the photo-detector. The purpose of this mirror is to *decrease* the storage time of the signal sidebands and therefore increase the detector bandwidth. This is achieved because the signal extraction mirror and arm cavities form a three-mirror-coupled cavity. Because the interferometer is locked to dark fringe the signal extraction mirror has no effect on the carrier. The signal extraction cavity formed by the signal extraction mirror and the coupling mirrors of the arm cavities forms a compound mirror which has frequency-dependent transmittance and reflectivity. Tuning the signal extraction cavity allows the transmittance for the signal frequencies of interest to be higher than that of arm cavities alone. For these frequencies the storage time in the three-mirror cavity is shorter than that in the unmodified arm cavity. In this case, the reduction of the storage time results in an increased detection bandwidth and unchanged high-finesse arm cavities for the carrier. In principle, the power enhancement in the arm cavities could be so great that no power recycling would be required. Yet the power passing through the beamsplitter and the coupling mirrors of the arm cavities could be low enough to have little thermal load. Figure 44 shows the frequency response of 3 km arm length interferometer with resonant sideband extraction configuration at various conditions [168].

5.4. Vibration isolation

At Earth-based sites for gravitational wave detectors, the ground is continuously vibrating with a rms amplitude of $x_s \approx \alpha f^{-2}$ m Hz$^{-\frac{1}{2}}$, where $\alpha \approx 10^{-6}$–10^{-9}. This is far greater than the signals we want to measure. Thus it is of great importance that terrestrial gravitational wave detectors, both resonant-bar and laser interferometers, are isolated from the seismic noise background. High-performance mechanical vibration isolation systems are required for this purpose. An ideal vibration isolator would not only cut out all significant seismic vibration in the pass band of the gravitational wave detector, but also cut out the seismic noise at much lower frequencies, so that the suspended test masses were effectively stationary with respect to the laser light field. If the total rms motion were much less than an optical fringe width, the servo control requirements would be minimized: components would be as stable as if rigidly attached to an optical table, or placed in interplanetary space. Operation of an interferometer would then be very simple. We show below that total rms motion from all frequencies above 0.2 Hz can in principle be reduced to about 1 nm.

This ideal level of isolation has not yet been achieved but there are various approaches that when combined, should approach the ideal performance discussed above. We subdivide the approaches to this problem under the headings passive isolation, active isolation and pre-isolation.

5.4.1. Passive mechanical isolation. Passive mechanical vibration isolators are mass–spring low-pass filters. For a multistage isolator, each stage of the isolator with resonant frequency f_0 will attenuate vibration by a factor $(f_0/f)^2$ at frequencies $f \gg f_0$. The total attenuation of the multistage isolator at frequencies above the *corner frequency* (the highest normal mode frequency of the isolator) is $(f_1 f_2 \ldots f_N/f^N)^2$, where N is the number of stages.

Figure 45 shows the typical behaviour of such an isolator. The figure shows a typical transfer function of a five-stage isolator with $f_0 = 2$ Hz. Below the corner frequency the normal modes amplify the seismic noise, while above it the isolation improves as the tenth power of the frequency ratio.

Traditionally, vibration isolators for gravitational wave detectors were based on industrial vibration isolators, using systems such as alternating layers of lead (or steel) and rubber [5].

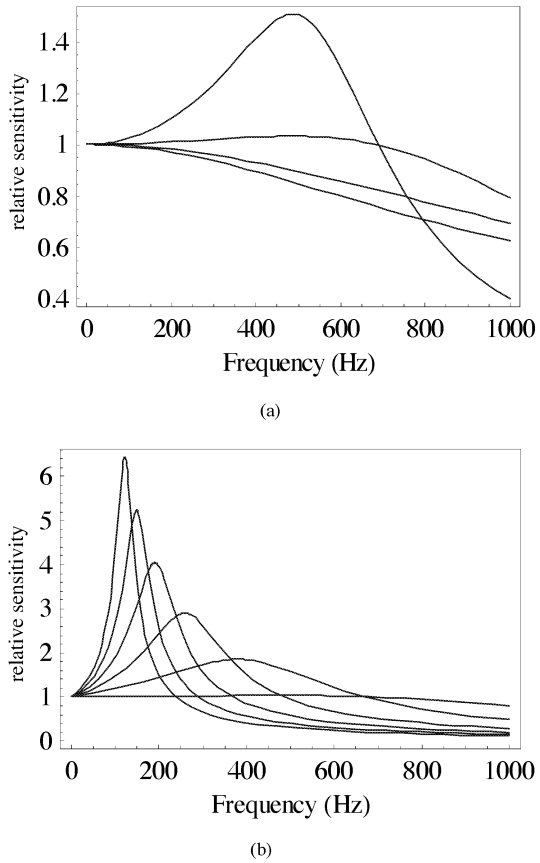

Figure 44. Typical frequency response of a 3 km arm length interferometer with resonant sideband extraction configuration. (*a*) Dependence of the frequency response on the length of the sideband extraction cavity (SEC) when the carrier is resonant in SEC. The curves, in order of increasing response at 400 Hz, are for SEC length of 1 m, 30 m, 100 m, 300 m. (*b*) Dependence on the tuning of SEC to carrier. The broadest response corresponds to the carrier resonant in SEC, and the others are detuned from it (carrier resonant condition). The length of SEC is 100 m, and detuning is by steps $2\pi/1000$. In both figures, the vertical units are arbitrary [168].

Isolators of this type have been used for room temperature vibration isolation in both resonant-mass gravitational wave detectors and prototype laser interferometer detectors. The disadvantage of these isolators is that they are not suitable for use in high vacuum (unless the rubber is outgassed or packaged in metal bellows); moreover, they are not suitable for uses at low temperatures where elastomer materials harden. In addition, this type of isolator generally shows large temperature coefficients and drift, due to the properties of the rubber, as well as having a relatively high corner frequency, limited by the compressive yield of the elastic elements.

Ideally, a multistage pendulum could be used to provide sufficient horizontal isolation for a laser interferometer gravitational wave antenna. Several groups have used double or triple pendulum suspensions combined with rubber and steel isolation stacks [198–201]. However, the curvature of the Earth creates intrinsic cross-coupling between the horizontal and vertical directions, due to the fact that the laser beam in an interferometer can only be perpendicular to the local vertical at one location. In a large-scale laser interferometer detector, the magnitude

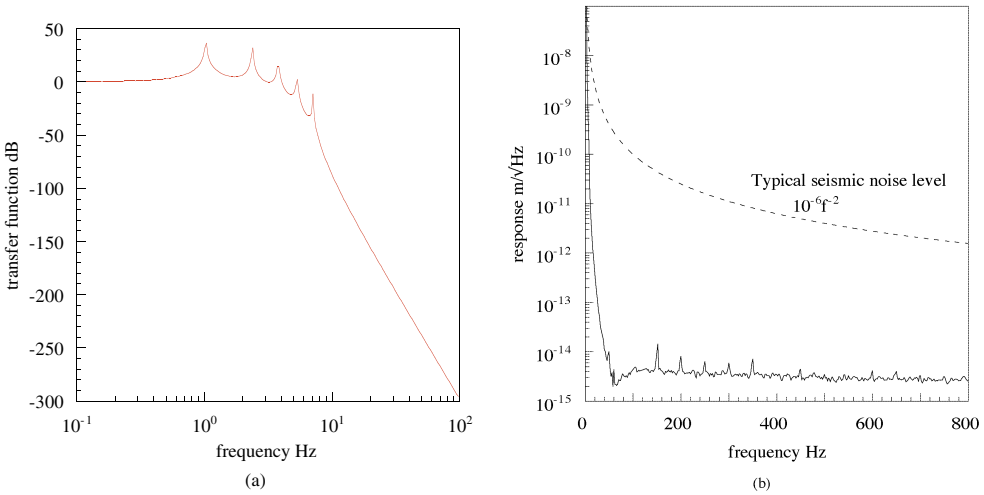

Figure 45. (*a*) Theoretical transfer function of a five-stage vibration isolator. Each stage has a natural frequency of 2 Hz. (*b*) Experimental upper limit of performance of a five-stage isolator [326], with a typical seismic curve of $10^{-6} f^{-2}$. At high frequencies the isolation reaches the noise floor of the sensing transducer of 3×10^{-15} m Hz$^{-1/2}$. Below 58 H the mechanical resonant frequency of the transducer, the sensitivity of the transducer degraded. Practically all the data above 50 Hz are transducer noise.

of the cross-coupling in ideal circumstances is $\sim 10^{-3}$. In real isolators the cross-coupling is likely to be degraded by mechanical imperfections. Thus it is important that the vertical vibration isolation should also be very high. The isolators must also be strong enough to support a total weight $\sim 10^2$–10^3 kg.

In interferometer antennas, the corner frequency needs to be pushed as low as possible to create the broadest possible bandwidth for observations. There is a great advantage in operating an interferometer antenna at the lowest possible frequencies. Not only does it extend the range of sources accessible to the detector, but for specific sources such as binary neutron star coalescence events, it increases the number of cycles of the coalescence that can be observed, thus allowing the signal-to-noise ratio to be increased. Giazotto pioneered the development of low-frequency vibration isolation. A very-large-scale multistage low-frequency superattenuator based on a gas spring was developed at Pisa [202, 203]. It had a high load-bearing capacity and a corner frequency of 2–3 Hz. However, gas springs have strong temperature coefficients, and so such isolators have problems of thermal stability and complexity. At the University of Western Australia, tapered metal cantilever spring vibration isolators [118], were developed, which showed excellent performance but somewhat higher corner frequency. The Pisa group replaced gas springs with similar tapered cantilevers and reduced the mechanical frequencies by use of magnetic antisprings, created by using magnetic repulsion between like poles of permanent magnets. This allowed low-frequency behaviour similar to the gas spring system to be achieved [204].

5.4.2. Active isolation. Active isolation techniques have been investigated extensively in gravitational wave research [205–210]. The basic idea is simple, as shown in figure 46: the relative displacement between the test mass to be isolated and the suspension point (the error signal) is sensed and fed back to an actuator to servo the suspension platform so that the motion of suspension point follows the motion of the test mass. In this way, the motion of the

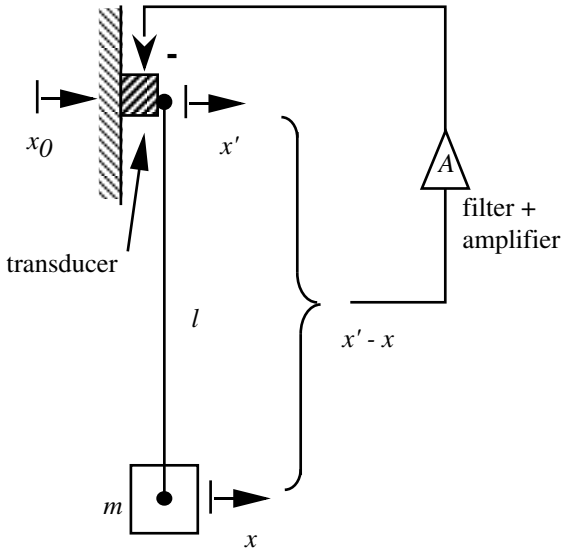

Figure 46. Schematic diagram of an active pendulum [205].

suspension platform is reduced and hence the motion of the test mass. If we look at the simple case of figure 46, the equation of motion of the mass is (for simplicity we ignore the damping term)

$$\ddot{x} = \omega_0^2(x' - x_0), \qquad \omega_0^2 = \frac{g}{l}. \tag{5.4}$$

Assuming the error signal is fed back to the suspension point so that $x' = x_0 - A(x' - x)$, then the transfer function of the system is

$$\frac{x}{x_0} = \frac{\omega_0^2}{-\omega_2(1+A) + \omega_0^2} = \frac{\omega_0^2/(1+A)}{-\omega^2 + \omega_0^2/(1+A)}. \tag{5.5}$$

It can be seen that this system behaves like a pendulum with an equivalent resonant frequency of $\omega_0/\sqrt{(1+A)}$. At frequency $f \gg f_o$, the attenuation is $[f_o/f/(1+A)]^2$ instead of $(f_o/f)^2$. This means that the isolation of mass m is improved by a factor of $(1+A)$.

The basic arrangement for vertical active isolation is shown in figure 47. The final transfer function is slightly complex. However, from the block diagram (figure 48), it can be seen that

$$x = G'x', \qquad G' < 1, \tag{5.6}$$

$$x' = G[xo - H(x' - x)] \qquad G < 1, \tag{5.7}$$

where GG' is the passive transfer function of the system and H is the loop gain of the feedback. The closed loop transfer is then

$$\frac{x}{x_0} = \frac{GG}{1 + H(G' - G'G)}. \tag{5.8}$$

The performance of this active system is improved by a factor of $[1 + H(G' - G'G)]$. However, it is impractical to assume very large gain H to obtain high-performance isolation. There are several limitations. One is the presence of internal resonances of the isolation structure. At each resonance there will be a phase shift added to the loop transfer function which can make the servo unstable. To ensure stability, the gain of the servo should be within the limit that

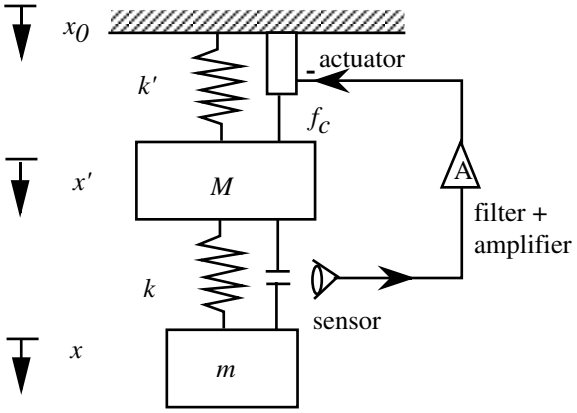

Figure 47. Schematic diagram of the active isolation model [206].

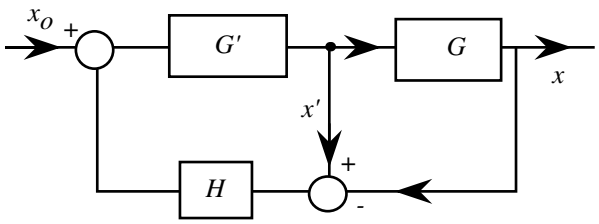

Figure 48. Block diagram of the active isolator [209].

all the internal resonant peaks are below unity gain. Another limitation is the noise in the sensor. This noise is treated the same by the servo system as the error signal between test mass and suspension platform. This noise will be amplified and fedback to the platform to create a displacement. At low frequency, where the attenuation of the test mass from the platform is not high, sensor noise plays an important role since the test mass tends to follow the movement of the platform.

5.4.3. Residual motion and the need for ultralow-frequency pre-isolation. A suspended test mass in a laser interferometer is required to be very precisely located to within $\leqslant 10^{-6}$ of an optical wavelength. Residual motion of the test mass in interferometers operated to date is typically ∼few microns. This has caused two problems. First, it makes it difficult to acquire lock, because very large forces must be applied to decelerate the test mass and locate it within operating range. Second, it makes it impossible to act directly on the test mass (by say a magnetic actuator) because the electronic noise of the actuator circuit is never less than 10^9 times smaller than the maximum signal which can be applied. (This is the dynamic range of a low-noise amplifier.) If the maximum signal is able to correct 10^{-6} m of motion, then the noise level will create noise motion just 10^9 times smaller, i.e. 10^{-15} m. This is unacceptably large.

There are two possible solutions to the problem. One is to create a more complex servo system and, in particular, to apply control forces to the stage above the test mass. All detectors constructed to date use this approach. The second possibility is to greatly reduce the residual motion.

Residual motion, and in particular residual accelerations, can be greatly reduced if a

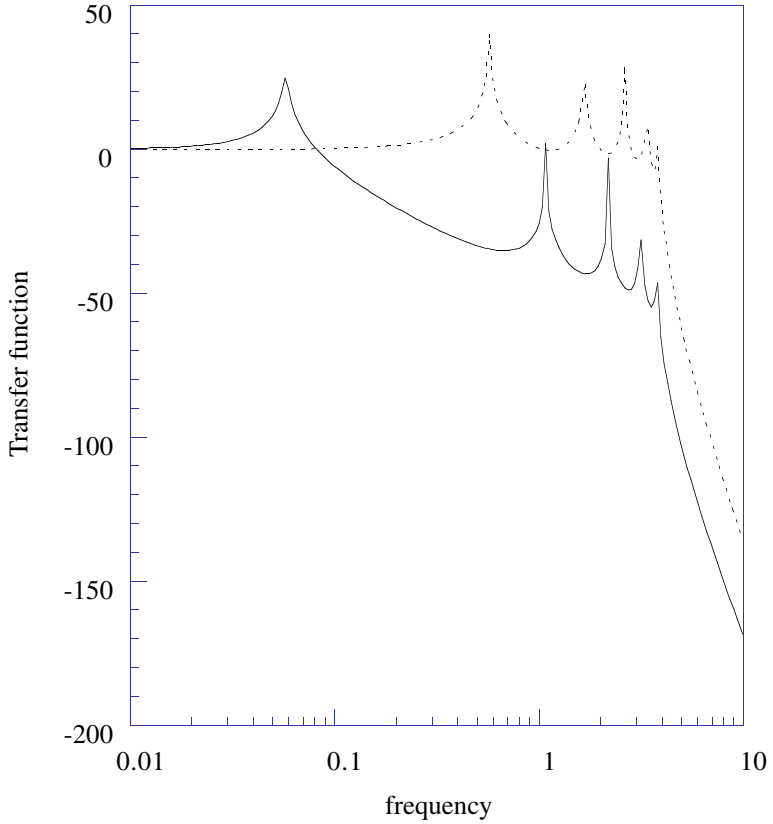

Figure 49. Comparison of transfer functions of a multistage isolator with and without an ultralow-frequency stage. Dotted curve: five-stage 2 Hz isolator, solid curve: four-stage 2 Hz isolator plus a 0.1 Hz ultralow-frequency pre-isolator.

conventional isolator is suspended by a pre-isolator with a much lower resonant frequency. This is illustrated in figure 49, where the addition of a single low-frequency stage reduces the amplitude of the normal mode peaks by about 50 dB. To realize this advantage requires the development of ultralow-frequency (ULF) mechanical suspension stages. As mentioned before, the isolation performance of an isolator with resonant frequency of f_o above the corner frequency is $(f_o/f)^2$. Thus the lower the resonant frequency f_o, the better isolation performance and the lower the corner frequency. This does not guarantee that with one or several ULF stages one can obtain very high isolation performance at high frequency. The problem is that internal mechanical resonances usually occur at frequencies that are typically about 10^2–10^3 times the fundamental resonant frequency of the mechanical resonant structures. Thus, for example, a stage with 10^{-1} Hz resonant frequency is likely to have an internal resonance from 100 Hz upwards and these will corrupt its isolation performance.

As a result, ULF stages are best used as pre-isolation stages in conjunction with low-frequency isolators. For an N-stage isolator, there are N normal mode peaks with amplitude up to 100 times the seismic background, depending on the Q-factor of the isolation elements. It is predominantly these normal modes which make it difficult to control and lock the interferometer. As discussed in section 5.4.1, different methods have been used to damp the normal modes, such as magnetic eddy current damping [200,211] and vibration absorber [212].

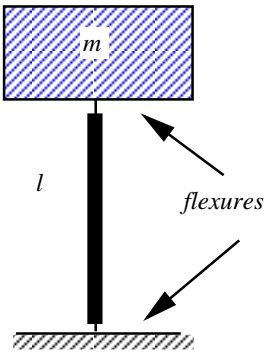

Figure 50. Simple model of an inverted pendulum.

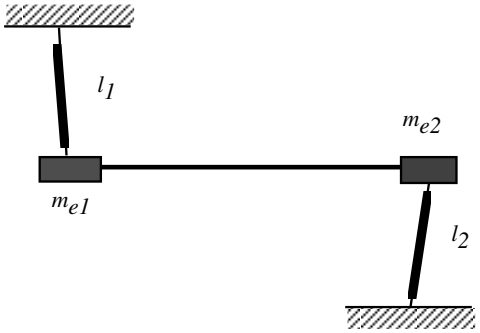

Figure 51. Simplified diagram of a folded pendulum.

A ULF-stage pre-isolator efficiently and passively reduces the normal mode amplitude as shown in figure 49. All the normal modes are on the cut-off slope of the ULF stage and are greatly reduced, leaving one very-low-frequency mode which is easy to control. This greatly simplifies the control system of the interferometer.

There are two main approaches to achieving very low frequency. One is to use a negative spring or antispring. A simple version is the inverted pendulum [213,214] as shown in figure 50. The resonant frequency of an inverted pendulum is given by

$$\omega_0 = \sqrt{\frac{k}{m} - \frac{g}{l}}, \tag{5.9}$$

where k is the spring constant of the flexure elements, m is the mass and l is the length of the inverted pendulum. Gravity provides a negative spring constant. The device has a low frequency when $g/l \sim k/m$, and it becomes unstable for $g/l > k/m$. Inverted pendulums for gravitational wave detectors were first investigated in UWA [213]. Because a mechanical Hooke's law spring is being used to counter a gravitational spring, and because the temperature coefficient of length differs from the temperature coefficient of Young's modulus, such antispring devices generally have relatively large temperature sensitivity. Thus servo control is needed to maintain a stable operating position. A full-scale inverted pendulum pre-isolation stage about 6 m high has been built for VIRGO's supperattanuator [215], and a 1 m stage has been developed at UWA [216].

For horizontal isolation, more elegant devices minimize the contribution of mechanical springs. One such device is the folded pendulum [217–219]. It combines a positive and negative pendulum as shown in figure 51. The resonant frequency of the folded pendulum is given as

$$\omega = \sqrt{\frac{1}{M_e}\left(\frac{m_{e1}g}{l_1} - \frac{m_{e2}g}{l_2}\right) + \gamma}, \tag{5.10}$$

where γ is a small additional term which takes into account elastic contributions from the flexures, $M_e = m_{e1} + m_{e2}$ is the equivalent mass of the pendulum and l_1, l_2 are the lengths of the positive and negative arm respectively. This device has low temperature sensitivity and has achieved a resonant frequency of 15 mHz [220]. With a resonant frequency of 17 mHz, this device gives isolation of more than 90 dB at 10 Hz. Above 15 Hz, the attenuation is degraded due to internal resonances of the isolator structure, as discussed above.

Another type of ULF stage is the X-pendulum [221, 222]. It uses two cross-wire linkage arrangements that mimic the motion of a very long pendulum. A resonant frequency of

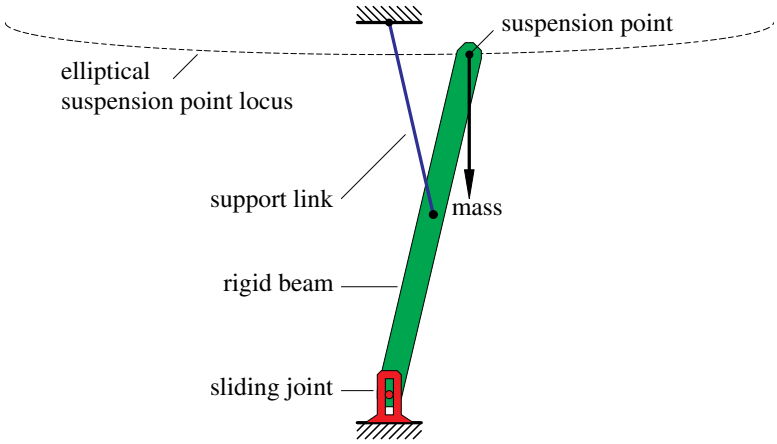

Figure 52. Scott–Russel linkage.

50 mHz has been demonstrated. With a resonant frequency of 0.21 Hz, the X-pendulum has demonstrated 30 dB isolation at 3 Hz. Above 3 Hz, the internal resonances dominate.

Both the folded pendulum and X-pendulum are most easily implemented as one-dimensional isolators. Although they can be cascaded to form a two-dimensional horizontal isolator, there are significant construction problems. Winterflood and Blair [223] have used the Scott–Russel linkage, shown schematically in figure 51. This device mimics the motion of a very long conical pendulum, achieving two-dimensional horizontal isolation in one single stage. A full-size prototype pre-isolator [224] has demonstrated a resonant frequency of 7 mHz and with a resonant frequency of 17 mHz, it achieves an isolation exceeding 75 dB at 0.5 Hz.

It is interesting to note that only one of the four horizontal stages discussed above is dependent on a carefully designed spring. This is the inverted pendulum, where a gravitational antispring balances on angular mechanical spring. In the other cases, mechanical springs are eliminated, except in so far as being an intrinsic, but small, component of a flexure suspension. All the linkage-based devices have the advantage that the temperature coefficients and nonlinearity of springs are minimized.

As mentioned above, cross-coupling requires a high level of isolation for both horizontal and vertical isolation. Thus there is little point in building an isolator with excellent horizontal pre-isolation unless it also has good vertical pre-isolation. Since the vertical isolation must always counteract a large gravitational force, it is almost impossible to avoid the use of large mechanical springs for vertical load bearing. However, several practical means of counteracting the spring constant have been demonstrated. The first is the magnetic antispring, demonstrated at Pisa [204, 225]. Pairs of magnets in a repulsive arrangement create a potential hill in the middle line of the magnet pairs. The negative spring constant represented by the potential hill partially cancels the positive spring constant, substantially reducing the total stiffness of the spring. Unfortunately, most magnets have high temperature coefficients, so that the magnetic antispring must be very carefully temperature controlled.

An alternation which avoids magnets is the geometric antispring. This was first demonstrated by LaCoste in his seismometer design [226], in which a zero length coil spring suspends a horizontal arm by acting on it at an angle (figure 53). The torsion crank linkage developed by Winterflood and Blair [224] uses a different geometrical antispring concept, as illustrated in figure 54. This design makes use of the nonlinearity produce by the torsion arm connected to a suspension link. It is arranged so that the effective spring constant

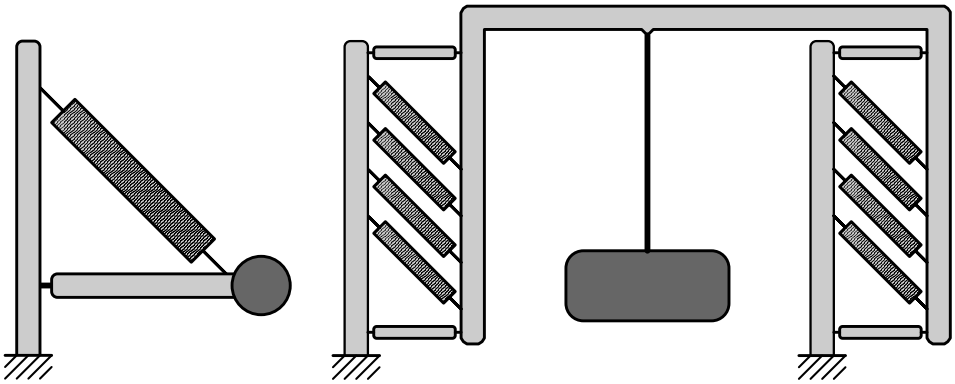

Figure 53. (*a*) LaCoste linkage. (*b*) Vertical preisolation using LaCoste linkage.

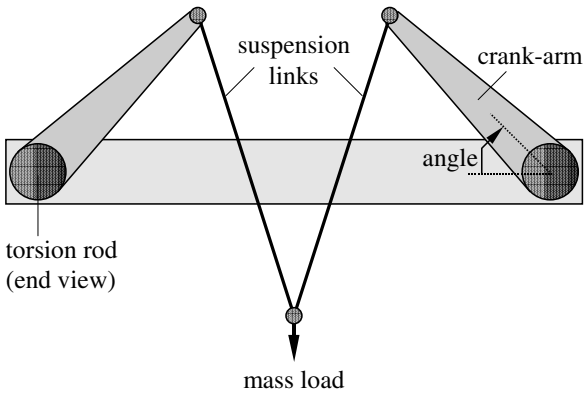

Figure 54. The torsion crank linkage arrangement [224].

$k = \partial_F/\partial_y (F = \text{force}, y = \text{vertical displacement})$ is almost zero and constant in a certain range. In a simple model, the torsion crank achieved a resonant frequency of 50 mHz. This vertical ULF stage can be combined with a Scott–Russel stage to create a three-dimensional pre-isolator as shown in figure 55.

De Salvo has demonstrated a geometric antispring based around a pair of cantilever blade springs [227]. The torsion rods of figure 54 are replaced by cantilever blades, and using appropriated angled suspension wires the same geometry effect causes nulling of the spring constant for a certain deflection angle.

Figure 56 shows the residual motion predicted for a passive isolator being developed at UWA [216]. This system utilizes passive eddy current damping, as well as seismic tilt control. The predicted performance is 10^{-9} m rms above 0.2 Hz. If such an isolator can be realized, interferometer operation will be greatly simplified.

5.5. Thermal noise

Once the seismic noise cut-off is lowered sufficiently through the use of high-performance vibration isolators, thermal noise will become the critical source of noise. From the fluctuation–

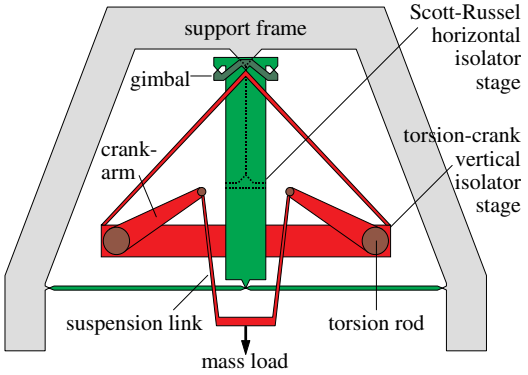

Figure 55. Three-dimensional pre-isolation stage, consisting of a torsion crank vertical stage and a Scott–Russel horizontal stage.

dissipation theorem [90] the general power spectrum of the minimal fluctuation force is

$$F_{\mathrm{th}}^2 = 4k_{\mathrm{B}}TR(\omega), \tag{5.11}$$

where k_{B} is the Boltzmann constant and $R(\omega)$ is the real part of the impedance of the system. Using $Z = F/v$, the above equation can be expressed as

$$x_{\mathrm{th}}^2 = \frac{4k_{\mathrm{B}}T\sigma(\omega)}{\omega}. \tag{5.12}$$

$\sigma(\omega)$ is the real part of the admittance $Y(\omega) = 1/Z(\omega)$. For a simple harmonic motion system with spring constant k, mass m and a damping r, the thermal noise displacement power spectrum is [228]

$$x_{\mathrm{th}}^2 = \frac{4k_{\mathrm{B}}Tr}{(k - m\omega^2)^2 + r^2\omega^2}. \tag{5.13}$$

If a damping mechanism of structural damping is assumed, which can be described with a complex modulus of elasticity [229], $k = k_0[1+\mathrm{i}\varphi]$, $\varphi =$ constant (i.e. $r = k\varphi$), equation (5.18) becomes

$$x_{\mathrm{th}}^2 = \frac{4k_{\mathrm{B}}Tk\varphi}{\omega[(k - m\omega^2)^2 + k^2\varphi^2]} = \frac{4k_{\mathrm{B}}T\omega_0\varphi}{\omega m[(1 - \frac{\omega^2}{\omega_0^2})^2 + \varphi^2]}, \tag{5.14}$$

where $\omega_0 = \sqrt{\frac{k}{m}}$ is the angular resonant frequency.

In a laser interferometer gravitational wave detector, thermal noise is mainly divided into two classes—the suspension thermal noise and the internal thermal noise of the test mass.

5.5.1. Suspension thermal noise and Q-factor of the pendulum. Suspension thermal noise is mainly the Nyquist noise of the test mass pendulum of the interferometer. The Q-factor of a pendulum suspension can in principle be very high because the energy storage is predominantly in the effectively loss-less gravitational field. However, some elastic energy must always be stored in the flexure which supports the pendulum. The Q-factor of a pendulum is limited by the losses in this element. The Brownian motion noise amplitude of a simple pendulum at angular frequency ω, for any normal mode at frequency $\omega_p \ll \omega$ is given by

$$x_p^2(\omega) = \frac{4k_{\mathrm{B}}T\omega_{p^2}}{Q_p m\omega^5}. \tag{5.15}$$

The Q-factor of the pendulum is given by $Q_p = \gamma Q_0$, where $Q_0 = 1/\varphi$ is the intrinsic Q-factor of the flexure material, and γ is the enhancement factor, which depends on the geometry and material of the pendulum flexure [228, 230].

Applying equation (5.20) to a simple pendulum, it has been shown that the thermal noise in a simple pendulum scales as [228]

$$x_{\mathrm{th}}^2 \propto m^{1/2}. \tag{5.16}$$

It can be seen that the suspension thermal noise can be reduced by increasing the mass of the pendulum and the quality factor of the test mass pendulum stage. To obtain numerical estimates, consider a typical interferometer with parameters of $L = 3$ km, $T = 300$ K, $m = 30$ kg, $f_p = \omega_p/2\pi = 1$ Hz, and $Q_p = 10^9$. We then have

$$h = \frac{x}{L} \sim 10^{-21}\left(\frac{10\ \mathrm{Hz}}{f}\right)^{5/2} \Big/ \sqrt{\mathrm{Hz}}. \tag{5.17}$$

This shows that extremely-low-loss pendulums are essential. For example, to obtain the sensitivity goals of $10^{-23}/\sqrt{\mathrm{Hz}}$ at 10 Hz, a pendulum Q-factor of 10^{10} is required.

At current sensitivity levels, it is barely possible to measure directly the thermal noise floor for high Q-factor test masses over the frequency range of interest for gravitational wave detectors. The thermal noise has to be inferred from Q-factor measurement of some resonance at other frequencies. However, the Q-factor and frequency relation is model dependent, and the calculated thermal noise floor differs with different damping mechanism assumptions. Frequency-independent Q-factors over a large frequency range have been approximately confirmed in some materials [214, 231–234]. The mechanism of structural damping is now widely accepted. However, it still needs more investigation, particularly to confirm the phenomenon in low-loss single-crystal materials.

Various types of suspension have been studied to obtain a high pendulum Q-factor. Most researchers have assumed that wires are necessary. Suspensions with a thin wire double-loop simple pendulum configuration are widely used [199, 200, 235–237]. A pendulum Q-factor of

$Q \sim 10^8$ with wire suspension is expected [238], assuming reasonable Q-factors for the wires. Pendulum Q-factors exceed 10^7 had been observed with fused silica fibre suspension [239]. The highest pendulum Q-factor reported so far is $>3 \times 10^8$ by Braginsky *et al* [240] with a monolithic silica fibre and a 30 g mass.

The simple pendulum suspension system inevitably will have a set of middle-frequency violin string modes from the suspension wire. Those modes will contaminate the window of gravitational wave detection. The problem of the thermal noise of pendulums suspended by wires has been intensively studied [232–234, 241–243]. Studies have shown that high pendulum Q-factor is related to a high violin string mode Q-factor. So each violin string mode is confined within a very narrow frequency band.

Theoretical analysis has shown that significant improvements can be achieved if the pendulum is replaced by a compound pendulum supported by a thin membrane which acts as a hinge [230]. A pendulum with hinge suspension has been shown to achieve $Q \sim 10^7$ [244]. Using known high-Q materials such as niobium which has a Q-factor $\sim 10^5$ in thin membrane, and assuming that Q is independent of frequency, it can be shown that Q-factors exceeding 10^7 [245] can be expected. Also, since the test mass pendulum is suspended by a very short membrane, the violin string mode will be high enough to be neglected. The membrane flexure can be made much thinner than the wire flexure and thus has lower thermoelastic effect.

5.5.2. Test mass internal resonance thermal noise. The test mass will have many internal resonances. The total thermal noise thermal noise spectral density can be expressed as [228]

$$x_{\mathrm{th}}^2 = \frac{4k_{\mathrm{B}}T}{\omega} \sum_i \frac{\omega_i^2 \varphi_i}{m_i[(\omega_i^2 - \omega^2)^2 + \omega_i^4 \varphi_i^2]}. \tag{5.18}$$

Here i is the index of the ith mode, m_i is the effective of ith mode and $\varphi_i = 1/Q_i$, where Q_i is the quality factor of the ith mode. Typical internal resonances of a test mass are at about several kilohertz. The thermal noise spectral density far below the internal resonant frequency $\omega \ll \omega_i$ (assuming loss factor $\varphi_i = \varphi =$ constant) is given by

$$x_{\mathrm{th}}^2 \frac{4k_{\mathrm{B}}T\varphi}{\omega} \sum_i \frac{1}{m_i \omega_i^2}. \tag{5.19}$$

Although it can be seen from the above equation that the lowest internal resonance contributes most to the thermal noise, detailed theoretical studies [246, 247] has shown that higher-order modes cannot be neglected, especially when the laser beam is not perfectly aligned.

From equation (5.19) it can be seen that to reduce internal thermal noise it is required that the test masses have high internal resonances and very high Q-factors $(1/\varphi)$. Since ω_i is proportional to the velocity of sound, high sound velocity materials are required. It is worthwhile pointing out that the dimensions of the test mass should not be too large so as to keep the frequency of internal resonances as high as possible. This is contradictory to the requirement of using a big test mass to reduce the pendulum thermal noise. There is a compromise in choosing the size and mass of the test mass. High Q-factor materials (such as quartz and silicon) have been investigated in prototype laser interferometer detectors [248]. At present, fused silica test masses are widely used in prototype interferometer detectors. The Q-factor of silica test masses were observed to be of the order of 10^6 [249, 250] with a higher value of $>10^7$ in some resonant modes recently observed by Beilby and Startin [251]. The highest Q-factor of silica was reported by Braginsky of 6×10^7 [252].

Using another high Q-factor material, sapphire, as test mass has been proposed [230]. The excellent thermal and mechanical properties of sapphire makes it a promising material for use in test masses. Compared with silica material, the high thermal conductivity means the thermal

lensing problem can be minimized, while the very high Young's modulus means the internal resonance will be high. The highest reported sapphire Q-factor is 4×10^8 by Braginsky [112] and recent measurements reported a reproducible result of $2–3 \times 10^8$ Q-factors [239, 253]. Theoretical analysis [254] suggests that the thermal noise can improve by a factor of >10 by using sapphire test mass instead of silica test masses.

In practice, the suspension joint to the test mass plays an important role in obtaining both high-Q pendulum motion and high internal Q-resonance. Monolithic suspension systems have been suggested and investigated. These include bonding the silica fibre to the silica test mass using silicate bonding method [255], and bonding niobium flexure to sapphire test mass using active alloy bonding [256] and possibly silicate bonding [257].

5.6. Control systems

As mentioned above, the test masses in the interferometer must be suspended to isolate against seismic and environmental vibration. To achieve operation of an interferometer a feedback system must be used control the test mass position to high precision. Firstly, a local control system is necessary to suppress large-scale motions and align the mirrors to the point where the best interference contrast may be achieved. Secondly, to allow maximum sensitivity, a global control system is required to control the interferometer arm lengths to a relative motion of $\sim 10^{-12}$ m rms [183]. This is achieved by locking the interferometer to a dark fringe.

5.6.1. Local controls. Various damping methods to suppress low-frequency normal mode in vibration isolators have been investigated. Passive damping such as magnetic eddy current damping has been investigated [200, 211]. The problem with this type of damping is that the damping is usually relative to a support structure and can introduce noise into the isolators both through seismic noise and resonant peaks of the support structure. This degrades the high-frequency performance of the isolator.

An alternative method of magnetic damping uses the narrow-band resonant absorber. In this case, individual modes of an isolator can be damped using a tuned resonator which is itself magnetically damped.

The low-frequency normal modes can also be attenuated by active damping [162, 199, 258–261]. A correction force corresponding to the motion of the suspended masses (measured by an inertial or non-inertial sensor) is applied to the appropriate part of the suspension system. A non-inertial sensor such as shadow sensor [162] is widely used on prototype interferometers [162, 163]. It consists of a small vane mounted on the sensed surface, a light-emitting diode (LED) and an opposing photodiode (PD) mounted on the reference surface. The vane is free to move between the LED and PD and develops a signal proportional to the displacement of the vane by partially interrupting the light. The correction forces are applied by a small permanent magnet mounted integrally with the vane, and a coil mounted on the reference surface. The reference surface is usually the support frame, which is attached to the ground. Then the problem arises that the seismic noise can be injected into the servo loop both in sensing and in force actuation. If motion sensing is done with respect to the frame, it is impossible to avoid seismic noise in the sensing. This sensing noise has components in the signal band which must be prevented from driving the test mass and appearing in the signal output. This is readily achieved by electronic filtering of the signal [162, 260]. The noise injection through the coil can be overcome by carefully positioning the coil so that the magnetic field gradient is maximized at the magnet. This results in the best decoupling of the forces applied on the controlled masses [162]. Another way to overcome frame vibration is to use two coils to linearize the field and create a magnetic force which is independent of the position and motion

of the frame [260]. If the reference surface is a reaction mass [262] which is well isolated from the seismic noise, the noise injection will not be such a problem. However, such a sensor will not damp the common-mode motion of the test and reference masses. An inertial sensor such as a mass-loaded piezoelectric accelerometer [263] or a wideband accelerometer [264, 265] can in principle avoid the problem of sensing frame vibrations. Inertial sensing avoids any coupling with seismic noise. Its ultimate sensitivity is set by electronics noise, thermal noise and thermal drifts of the accelerometer and the feedback actuators.

Another kind of non-inertial sensor is the capacitance transducer [266]. A convenient implementation for use on dielectric test mass surfaces consists of two interleaving combs of parallel conductors etched onto a circuit board. The dielectric constant of the sensed surface contributes to the capacitance between the combs. A voltage applied to the capacitor will exert a force on the test mass, while motion of the test mass modulates the capacitance. Thus this system can provide both sensing and feedback forces. There is no need for lossy magnets or vanes to be attached to the test mass, so the test mass acoustic losses need not be degraded [249].

5.6.2. Global controls. It is necessary to extract error signals to control the interferometer lengths or mirror positions to lock the output at the dark fringe and the recycling cavity or arm cavities on resonant with the laser frequency. In order to avoid the noise due to the laser power fluctuations and $1/f$ electronics noise at low frequencies, the measurement has to be shifted to the quieter MHz domain using modulation–demodulation techniques. Various modulation configurations have been proposed and extensively studied. Schemes known as external [176, 267–269] and frontal [270–274] modulation have been particularly investigated because their modulators are outside the interferometer. Thus, as opposed to internal modulation, these schemes avoid introducing losses or wavefront distortion within the interferometer [275]. Although quantum-noise-limited sensitivity has been achieved with internal modulation at low laser power level [276–278], all the proposed large-scale laser interferometer detectors will not use this configuration because it introduces losses and wavefront distortion.

In the external modulation configuration (figure 36), a reference beam from the antireflective coated face of the beamsplitter is extracted, phase modulated and mixed with the main interference as in a Mach–Zehnder interferometer. This configuration needs additional optical components that, in order to avoid noise, must be suspended. The length of the reference Mach–Zehnder arm must be controlled to maximize the phase sensitivity. The modulation index m in the external arm is an independent variable and can be set to maximize $J_1(m)$ when m reaches its optimum value of 1.84 radians. A larger modulation index leads to more power being transferred to higher-order sidebands, which are normally not utilized by the demodulation process. Furthermore, in power-recycling and arm-cavity configurations, another modulation is needed to extract error signals to control the recycling mirror and arm cavities. Because the arm lengths of the interferometer can be equal and because the reference beam extracted from the back face of the beamsplitter has travelled almost the same path length as the main beam, this configuration is insensitive to the laser frequency noise.

In the frontal modulation configuration (figure 57) the interferometer has two arms with a small difference in length. The laser beam is phase modulated before entering the interferometer. The laser field at the interferometer input may be expressed as a superposition of three monochromatic plane waves if the modulation index is not too high: the carrier with the original laser frequency and two sidebands with the frequency shift of the modulation frequency f_m. In the simple Michelson, when the dark fringe condition is fulfilled for the carrier, the sidebands transmitted to the interferometer are maximum when arm length difference is a quarter of the modulation wavelength, $c/4f_m$.

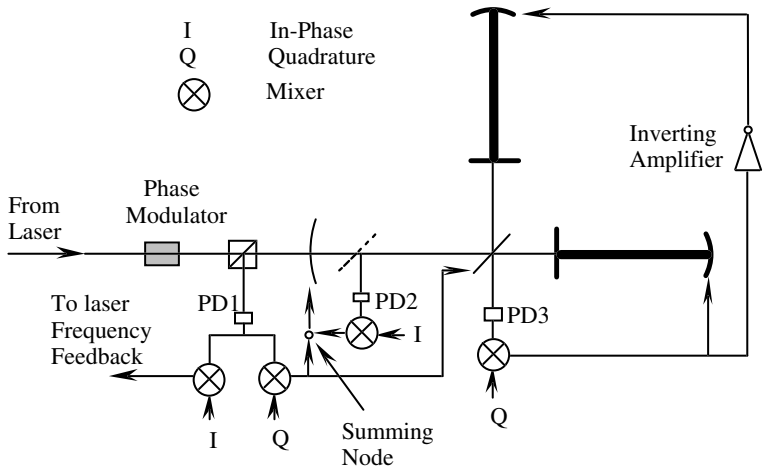

Figure 57. Global control configuration with frontal modulation [272].

If a recycling mirror is added, the modulation frequency and arm length difference must fulfil two conditions. First, the sidebands must resonant in the recycling cavity, otherwise the effective modulation index will be very small. Second, the signal must have maximum phase sensitivity. If R_r and R_m are respectively the intensity reflectivity of the recycling mirror and the interferometer, the modulation frequency f_m and the arm length difference Δl have to satisfy the following condition [273]:

$$\cos\left(2\pi f_m \frac{\Delta l}{c}\right) = \sqrt{R_r R_m}. \tag{5.20}$$

This condition also ensures the optimum enhancement of the modulation index inside the recycling cavity.

Even with cavities in two arms, one modulator is enough to get all the error signals to control each mirror. This configuration is simple and rather easy to realize. But because of the nonsymmetric configuration, the interferometer is sensitive to laser frequency and beam jitter noise. Frontal modulation was first demonstrated by successfully locking a tabletop prototype of a power-recycled Michelson interferometer with Fabry–Perot cavities in the arms [272].

5.6.3. Analogue and digital controls. Implementing the control discussed above can be achieved by either analogue or digital control systems. Analogue control is a well developed technology. Conventional PID servo control techniques can be used. Most prototype interferometers use analogue control for local damping, alignment and fringe locking [279]. The results have been successful, with sensitivity of 3×10^{-19} m Hz$^{-1/2}$ achieved [164] and generally not limited by servo system noise. However, for large-scale interferometers like LIGO and VIRGO, there are a large number of degrees of freedom (more than 200) [280] which need to be controlled and many of them are coupled each other. It is also planned that many error signals will be monitored and archived, to allow cross-correlation with the signal from the interferometer output PD. Many automated features are also required. All of the above points incline towards the use of digital control systems. Since Barone *et al* [281] introduced the idea of digital control into the automatic alignment of a Michelson interferometer, they have demonstrated theoretically and experimentally that all the specification on the noise requirements, the dynamic range and the control bandwidth can be satisfied using all-

digital control systems [282]. A fully digitally controlled interferometer prototype has been successfully operated in Naples, Italy for development and test of some VIRGO subsystems.

Heflin and Kawashima [283, 284] implemented both analogue and digital alignment control for the TENKO-100 DL interferometer. The results indicate that digital feedback control for application onto interferometer systems with target search frequency $\sim$1 kHz or less is a feasible alternative to analogue feedback systems. It has been shown to reproduce many of the same desirable features as the analogue systems.

Improved vibration isolation, especially that with very low residual motion, is likely to allow the undoubted complexity of the control problems discussed above to be substantially simplified.

5.7. Laser stabilization

Laser interferometers are designed to be sensitive to the optical phase difference of two arms, and should not be sensitive to common-mode fluctuations of the input light. But in practice, because of asymmetry between the two arms, fluctuations in the input light will couple into the output signal. In the frontal modulation scheme some asymmetry is unavoidable. In addition, differences in the optical components will cause, for example, intensity fluctuations to give rise to a differential radiation pressure force between both arms. Thus, laser intensity and frequency fluctuations must be strongly suppressed.

5.7.1. Laser pre-stabilization. The laser frequency noise Δf can couple into interferometer phase fluctuation $\Delta\varphi$ via arm length difference ΔL [162]:

$$\Delta\varphi \cong 2\pi\,\Delta f\,\Delta L/c. \tag{5.21}$$

The interference of the scattered light with the main beam can also couple the frequency noise into the output signal [182]. To ensure that frequency noise is sufficiently low that it does not compromise the sensitivity in the signal frequency regime, an active stabilization system is necessary to reduce the laser frequency noise.

An effective method of laser frequency stabilization was proposed by Drever and Hall *et al* [285], modelled on a technique used in microwave systems which was first proposed by Pound [286]. In optics the technique is called Pound–Drever–Hall (PDH) modulation. Light incident on a cavity is frequency modulated. The cavity creates intensity modulation whose phase depends on the relative frequency between the laser and the cavity resonance. The reflected light can be thought of as containing two beams: light simply reflected from the cavity input mirror and the light which has entered the cavity, resonated in the cavity and leaked back via the input mirror. The cavity leakage has a strong phase shift with respect to the directly reflected light from the input mirror, depending on the detuning from the cavity resonance. The interference between these two beams allows the detection of the phase difference, and hence the frequency difference, of the laser frequency compared with the cavity resonant frequency. The light from the laser is usually modulated at a RF frequency to shift the measurement to the quiet high-frequency domain. This helps overcome technical noise such as low-frequency electronics noise.

The schematic diagram in figure 58 shows a typical laser frequency stabilization scheme. A small fraction of laser light is phase modulated at a radio frequency by a Pockel cell (PC) and injected into a reference cavity. The reflected light is detected by a PD and mixed with the RF reference signal. If the laser frequency is tuned to one of the cavity resonances the reflected light has two balanced sidebands with opposite phase and a carrier. The mixer output is zero. If the laser frequency fluctuates the two sidebands will be unbalanced and the mixer will give

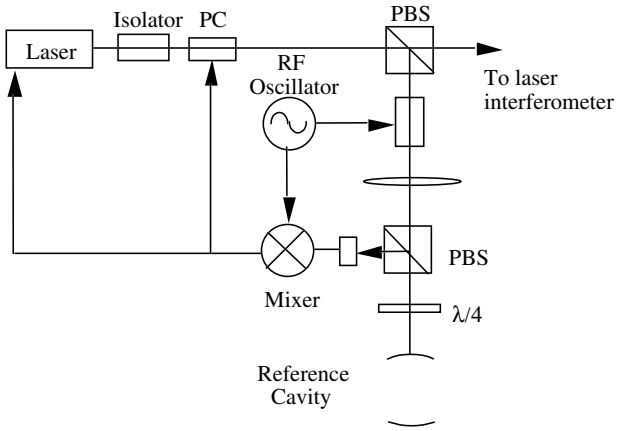

Figure 58. Frequency stabilization.

a signal proportional to the laser frequency difference with respect to the cavity resonance frequency. This signal can be fed back to a piezomirror (for low-frequency correction) and an extra-cavity Pockel cell (for high-frequency correction) to lock the laser frequency to the cavity.

The performance achievable in PDH stabilization is theoretically set by the quantum limit: the balance of shot noise and radiation pressure fluctuations which deform the reference cavity. However, in practice the laser shot noise limit is always dominant. This sets a limit to the frequency noise spectral density Ssn, and if the cavity has no losses this is given by [287]

$$S_{sn}(\mathrm{Hz}/\sqrt{\mathrm{Hz}}) = \frac{\Delta\nu}{J_0(\beta)}\sqrt{\frac{h\nu}{8\eta P_i}}. \tag{5.22}$$

Here $\Delta\nu$ is the cavity linewidth, P_i is the power incident on the cavity, ν is the laser frequency, η is the quantum efficiency of the PD, β is the modulation index, and $J_0(\beta)$ is the zeroth Bessel function.

Every gravitational wave detection group is involved in the development of laser stabilization. A frequency noise on the order of $\sim$10 mHz $\mathrm{Hz}^{-\frac{1}{2}}$ at 1 kHz has been achieved with a diode pumped Nd:YAG laser actively stabilized to a rigid reference cavity [288–291].

Another noise source in PDH locking is the mechanical and thermal noise of the reference cavity. The cavity resonant-frequency fluctuation $\Delta\nu$ is directly linked to the cavity length fluctuations ΔL. That is,

$$\frac{\Delta\nu}{\nu} = \frac{\Delta L}{L}. \tag{5.23}$$

If the reference cavity length is very long the noise contribution from a given cavity length fluctuation is much less than that of a short cavity. For this reason, the laser frequency is often stabilized to one arm cavity [163, 289] of an interferometer for further stabilization of the light frequency, and a frequency noise on the order of $\sim$10 μ Hz $\mathrm{Hz}^{-\frac{1}{2}}$ at 1 kHz has been achieved. In recent designs special-purpose *mode cleaner* cavities have been used [292] (see below) as a reference cavity. The Max Planck group has stabilized to an interferometer's power recycling cavity [173].

5.7.2. Mode cleaners. It is inevitable that the laser beam has geometric fluctuations (beam jitter) because of the vibration of the laser cavity. Vibration of the injection optics may also

introduce the beam jitter. The beam jitter noise will couple into the interferometer output signal if the two arms are not perfectly symmetric. For example, if the beamsplitter is misaligned from the optimal symmetric orientation by a small angle θ the lateral movement Δx of incident beam may produce an effective differential displacement signal Δs given by [293]

$$\Delta s = 4\theta \Delta x. \tag{5.24}$$

A simple way to clean the beam jitter noise of a low-power laser beam is to pass it through a single mode fibre [162]. In a single-mode fibre geometric fluctuations are transformed into fluctuations of the power coupling into the fibre. The problem in that because the core of a single-mode fibre has a small radius (of the order of a few wavelengths) the intensity inside the core is very high and this generates nonlinear effects including stimulated Brillouin scattering [294, 295]. This sets an upper limit on the maximum power that can be transported in a single-mode fibre. In addition, fibres themselves can be subject to vibration which can introduce additional beam jitter.

Another method to suppress beam jitter is to use a long optical cavity in transmission, called a mode cleaner. The geometric fluctuations of the laser beam are suppressed because they are not resonant within the cavity. The geometric beam fluctuations can be described in terms of higher transverse modes of the resonant cavity. In rectangular coordinates Hermite–Gaussian functions can be used to describe the eigenmodes of a cavity to a good approximation. Since the Hermite–Gaussian modes form a complete set, an incident beam with small translational movement Δx, angular fluctuation $\Delta\theta$, beam waist size mismatch $\Delta\omega_0$, and beam waist position mismatch Δb can be expanded in terms of cavity eigenmodes [292] as follows:

$$E_{\rm in} = E_{00}\left(\frac{\Delta x}{\omega_0} + j\frac{k\omega_0}{2}\Delta\theta\right)E_{10} + \frac{1}{\sqrt{2}}\left(\frac{\Delta\omega_0}{\omega_0} + j\frac{\Delta b}{k\omega^2}\right)(E_{02} + E_{20}). \tag{5.25}$$

Here E_{ij} are the amplitudes of the fundamental, first and second eigenmodes, while $E_{\rm in}$ is the amplitude of the incident beam and ω_0 is the beam waist.

For a cavity consisting of two mirrors with radii of curvature R_{c1}, R_{c2}, intensity transmission T_1, T_2, and reflectivity R_1, R_2, separated by a distance L, the fractional transmission of the incident light amplitude through this cavity is [296]

$$T_{mn} = \frac{\sqrt{T_1T_2}}{1-\sqrt{R_1R_2}}\frac{1}{\sqrt{1+(\frac{2\sqrt{R_1R_2}}{1-R_1R_2}\sin((m+n)\Psi))^2}}, \tag{5.26}$$

where $\Psi = \cos^{-1}(\sqrt{(1-L/R_{c1}(1-L/R_{c2})}$.

For the fundamental mode, $T_{00} = \frac{\sqrt{T_1T_2}}{1-\sqrt{R_1R_2}}$. The amplitude attenuation of the higher-order modes compared with the fundamental mode is given by

$$\sqrt{1+\left(\frac{2\sqrt{R_1R_2}}{1-R_1R_2}\sin((m+n)\Psi)\right)^2} \approx \frac{2F}{\pi}\sin((m+n)\Psi), \tag{5.27}$$

where $F = \frac{\sqrt{R_1R_2}}{1-R_1R_2}$ is the finesse of the cavity. Thus a high-finesse cavity mode cleaner can strongly suppress the higher-order modes.

However, the power inside a high-finesse mode cleaner cavity will also be much higher than the incident light power. Thus, thermal damage to the mirror coating becomes a key issue in defining the cavity configuration. If P is the power we want to transmit, and ω is the beam radius on the mirrors, then the power density on mirrors is given by $I = \frac{2FP}{\pi^2\omega^2}$. To avoid optical damage to the coatings of the mirrors, the spot area should be kept above $\pi\omega_{\rm min}^2 = \frac{2FP}{\pi I_{\rm max}}$, where $I_{\rm max}$ is the power density limit of the coatings.

The power transmission of an optical cavity for incident light with frequency offset f from the resonant frequency is given by the well known Lorentzian response: $T_f = \frac{T_0}{1+(2f/\Delta\nu)^2}$, where $\Delta\nu = c/2LF$ is the cavity linewidth. The cavity acts as a second-order low-pass filter. With a large length L and high finesse F the cut-off frequency becomes low. For example, for $L =$ 100 m and $F = 1000$ the cut-off frequency is 1.5 kHz. Since all the laser fluctuations (amplitude and frequency) can be understood in terms of the generation of sidebands, a mode cleaner also acts to suppress such fluctuations at offset frequencies higher than the cut-off frequency.

5.8. Optics

As we have already seen, a fundamental limitation of the sensitivity of interferometric gravitational wave detectors is shot noise, or photon-counting errors. In order to reduce shot noise, high light power must circulate in the interferometer. Because of the limitation of laser power currently available from stabilized CW lasers, power recycling appears to be an indispensable technique for large-scale instruments.

The maximum power recycling factor is determined by the total losses of the interferometer when the transmission of the recycling mirror is properly chosen. The losses of the interferometer may result from energy loss due to absorption or scattering of the mirrors, or by imperfect recombination of the two beams on the beamsplitter due to misalignments and wavefront distortions. Power losses can arise from imperfect mirror surfaces, coating inhomogeneities, diffraction losses through limited apertures, beamsplitter and mirror substrate wavefront distortion and depolarization. The minimization of these losses presents a formidable challenge.

5.8.1. Surface quality. The relevant specifications of the surface figure for optical components has been considered extensively by all of the groups building large-scale laser interferometers [196, 297–299]: see, for example, the discussion by Winkler and coworkers [196], which is based on a requirement for a power build-up in a power-recycled DL interferometer. The surface deformations can be characterized by their amplitude s and spatial wavelength λ_s. Surface deformation with λ_s smaller than the beam diameter (micro-roughness) cause the scattering loss. The relative power loss by scattering due to the micro-roughness is given by

$$\frac{\Delta P}{P} = \left(4\pi \frac{s_{\rm rms}}{\lambda_2}\right)^2, \tag{5.28}$$

in which $s_{\rm rms}$ is the rms value of the micro-roughness amplitude. The tolerable micro-roughness in a DL interferometer with power recycling gain of 100 and 34 reflections is $s_{\rm rms} < \lambda/730$.

Surface deformations with λ_s in the order of the beam diameter contribute to the beam wavefront distortion and the deterioration of the dark fringe of a perfect interference. The tolerable deformation in this scale for the same interferometer is $s_{\rm rms} < \lambda/230$. For surface deformation with λ_s larger than the beam diameter (aberration) the demands are slightly less.

Using the computer-mode-based code of Vinet and Hello [297], LIGO group derived the requirements [299] of the optical components of the 4 km Fabry–Perot Michelson interferometer. The tolerable rms amplitude of the surface micro-roughness is 0.4 nm. The surface figure error (spatial wavelength larger than beam diameter) should be less than 0.8 nm.

Techniques of superpolishing are now well established and mirrors exceeding the tight specifications required have been developed [299–301]. LIGO optics is being polished by General Optics (GO) and Commonwealth Scientific and Industrial Research Organization (CSIRO). Metrology indicated that the polished surfaces with rms deviation (after removeing focus and astigmatism) <1 nm over 20 cm were produced. Surface roughness

measurements showed a micro-roughness of ∼3 Å for CSIRO substrates and ∼0.9 Å for LIGO substrates [299].

The mirror coating is also critical for scattering level and wavefront preservation in the interferometer. VIGO group has reached ∼1 ppm scattering level on 80 mm diameter coated mirror surface. The peak-to-valley coated surface deformation is ∼14 nm on 70 mm diameter [302].

5.8.2. Absorption. Optical absorption may take place at dielectric coatings, or inside the substrate material of transmitting optical components, such as the beamsplitter and the coupling mirror of Fabry–Perot cavities. Apart from losses introduced by the absorption itself, the absorbed light power will heat the local area, and consequently deform the optical components causing wavefront distortion. This arises due to the limited thermal conductivity of the substrate. The local heating forms a temperature gradient inside the substrate and consequently introduces radius of curvature changes on surfaces. Winkler *et al* [196] has analysed the problem and shown that the change δs of the sagitta by the absorption of the reflected beam is given by

$$\delta s = \frac{\alpha}{4\pi\kappa} P_a, \tag{5.29}$$

in which P_a is the absorbed light power, α is the thermal expansion coefficient, κ is the heat conductivity of the substrate material. The crucial quantity for the magnitude of the effect is the ratio α/κ of thermal expansion to heat conductivity. The α/κ of fused silica and sapphire are 33 and 28 respectively [196].

When the beam is transmitted through a material with a temperature gradient, because of a temperature dependence of the refraction index, the refraction indices of the beam axis and the outer parts of the beam are different and thermal lensing may result. The path difference δl between beam axis and outer parts of the beam, introduced by thermal lensing, is approximately [196]

$$\delta l \approx \frac{\beta}{4\pi\kappa} P_a, \tag{5.30}$$

in which $\beta = \delta n/\delta T$ is the temperature dependence of the refraction index and P_a is the power absorption there. It is clear that one wants to keep the ratio β/κ small. The β/κ of fused silica and sapphire are 1000 and 60 [196]. As regards thermal lensing, sapphire is much better than fused silica as a substrate material.

5.8.3. Depolarization. The temperature gradient inside the substrate will also produce a stress distribution. The stresses generate strains in the substrate, which in turn produce refractive index variations (or birefringence) via the photoelastic effect. Stresses may also be introduced during the manufacturing process. The magnitude of the birefringence may be defined by the phase difference δ introduced between orthogonal polarizations. In general, the polarization of the input beam will not be parallel to one of the principal axes of the birefringent component, especially since the birefringence may vary locally.

Power loss occurs due to the depolarization of the original input beam polarization. The measured birefringence of a very homogeneous 10 cm thick Corning 7940 grade 0A fused silica plate is $\delta = 1.2^\circ \pm 0.2^\circ$ in the central area [303] which corresponds to a maximum loss of 10^{-4} per pass. The reported birefringence in sapphire is comparable, about 0.1° cm^{-1} [304]. The lowest birefringences in coatings obtainable today are between 2 to 10 μrad per reflection—but so far only for mirrors and beams with a size of a few cm and mm, respectively [197].

Hello and Vinet [305, 306] have analysed the thermal effects in massive mirrors heated by high-power laser beams. The complete numerical simulation of thermal effects in a GW interferometer [307] indicate that the first-generation detectors using silica components may require substrate absorption coefficients of $\sim$2 ppm cm^{-1} $\pm$ 15%, and coating absorption coefficient of $\sim$2 ppm $\pm$ 10%.These values are within present capabilities for mirror and coating technologies. The reported lowest absorption is a level of less than 1 ppm cm^{-1} for light of 1 μm wavelength in a fused silica sample [308] and a level of 3.1 ppm cm^{-1} in a sapphire sample [309]. The present coating absorption coefficient is $\sim$1 ppm [302]. Recycling factors of 300 [173] and 450 [174] have been achieved with power of $\sim$100 W built up inside the recycling cavity. This corresponds to $>$1 kW cm^{-2} power on the beamsplitter and mirrors. Expected limits due to thermal effects have still not been reached.

Winkler *et al* [196,197] and Strain *et al* [308] with their co-workers at MPI have evaluated the effects of thermal deformation, thermal lensing and thermally induced birefringence on a recycling interferometer. Their model assumes that Gaussian-profile laser beams heat the optical substrates through either uniform bulk absorption or uniform absorption in the coatings, and that the optics has an aperture much larger than the beam diameter. They concluded that the power limit set by thermal lensing is a problem only for advanced interferometers operating at higher power than those presently under development. They find that inherent and thermally induced birefringence will not be the dominant loss mechanism [197] assuming the lowest values for absorption and inherent birefringence reported. They propose that resonant sideband extraction is the best way of reducing the effects of thermal lensing to reach sensitivity appropriate to a 'second-generation' detector [308].

5.9. High-power lasers

The choice of the laser wavelength is an important effect on the design of a long-baseline interferometer. At short wavelengths, the beam diffracts less and thus the diameter of the interferometer mirrors and the vacuum tube can be reduced; thereby reducing the cost of the interferometer. Short wavelengths would also allow a better shot-noise-limited strain sensitivity which is $\propto\lambda^{1/2}$ [189]. Other important factors in the choice of laser wavelength are the losses (absorption and scattering) in the mirrors and beamsplitter, and the availability of suitably quiet and powerful lasers.

Contrasting with prototype interferometers which have used argon-ion lasers, all the long-baseline interferometers will use diode-laser-pumped Nd:YAG lasers ($\lambda = 1064$ nm). The use of Nd:YAG lasers is driven by their much better efficiency and generally quieter characteristics with regard to practically all types of laser noise [293]. Diode-laser-pumped miniature ring lasers can fulfil the requirements of a interferometric gravitational wave detector concerning amplitude and frequency stability [310]. But direct use of these devices in an interferometer for gravitational wave detector is not possible, because the output power of these system is limited to values below 2 W CW in a single axial mode [311].

One possible technique to increase the output power is injection locking which coherently couples a low-power master and a high-power slave oscillator resulting in a high-power output with the frequency characteristics of the master [312]. As shown in figure 59, this is accomplished by injecting the output power from the master laser into the slave laser's resonator. The PDH reflection locking is used to lock the frequency of the slave laser to the master's by adjusting the position of the slave's mirrors according to the error signal [311].

Application of the injection locking technique to Nd:YAG lasers has been extensively investigated [311,313–317]. At Laser Zentrum Hannover (LZH), a maximum single-frequency output power of 20 W has been generated by injection locking to a monolithic ring laser. The

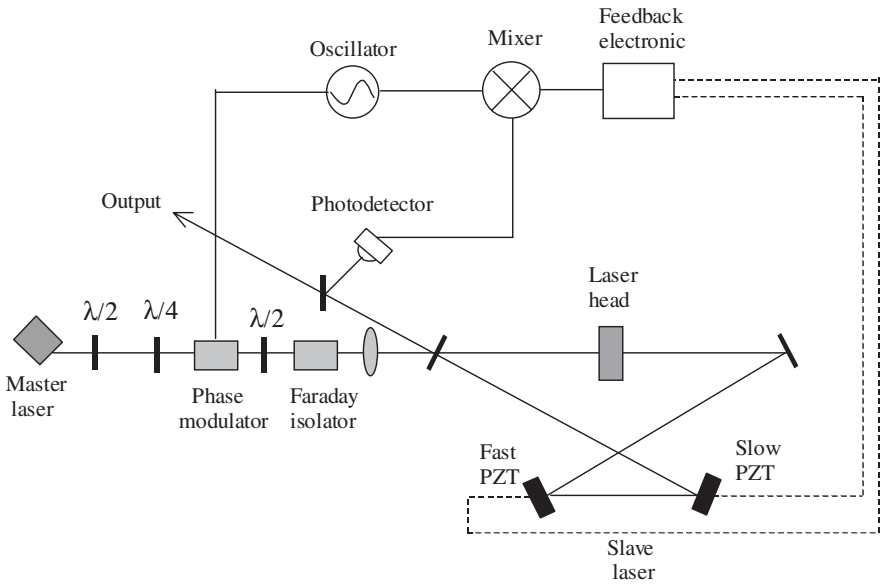

Figure 59. Schematic for injection locking of two lasers [311].

amplitude and frequency stability is investigated. The amplitude noise reaches the shot noise level beyond a few MHz. The relaxation oscillation of the miniature ring laser coupling at ∼700 kHz and the disturbance in the excitation of the slave laser caused by the diode laser power supplies at 80 kHz are two noise sources which could be further stabilized using active amplitude stabilization [318]. Using fibre-coupled diode lasers as pump sources, 62 W CW TEM_{00} mode output has been achieved [319].

At Stanford, an output of 5.5 W single-frequency, 'nearly diffraction-limited', TEM_{00} power was produced by using 50.4 W of pump power. The frequency noise of the unstabilized master laser of ∼20 Hz $Hz^{-\frac{1}{2}}$ at 1 kHz was reproduced at the output of the slave. The relative intensity noise at the output of the slave is $1.7 \times 10^{-6}/\sqrt{\text{Hz}}$ which is 10 times higher that that at the output of the master laser [314]. A 40 W CW, TEM_{00} diode-laser-pumped, Nd:YAG miniature-slab laser has been built and demonstrated with 212 W pumping power [320]. A 10 W laser-diode-pumped Nd:YAG master-oscillator power amplifier is spatially and temporally filtered by a fixed Fabry–Perot cavity, which produced a 7.6 W TEM_{00} beam with 1% higher-order transverse mode content and reduced the relative power fluctuations at 10 MHz to $2.8 \times 10^{-9}/\sqrt{\text{Hz}}$.

At VIRGO, a 10 W laser-diode-pumped Nd:YAG laser has been developed by using injection locking a high-power slave laser to a low power master laster [302]. The master laser is a 700 mW laser-diode-pumped miniature ring Nd:YAG laser operating at single-frequency. The slave laser is Nd:YAG laser transverse pumped on one side by 10 fibre-coupled diodes. TEM_{00} operation has been achieved with a slight contribution of TEM_{01} using a diaphragm inside the X-shaped ring cavity. Using a spatial filter, the TEM_{00} component can be extracted to give a 9 W output power for an effective pumped power of 60 W. The 10 W laser will be frequency pre-stabilized to a reference cavity, and be actively power stabilized.

At TAMA, with 22.3 W pump input from two fibre-coupled laser diodes, combined with 700 mW of power injected by a single-frequency master laser, the injection-locked slave laser emitted 10 W of linearly polarized TEM_{00} beam. The measured relative intensity

noise and the frequency noise are $2 \times 10^{-5}/\sqrt{\text{Hz}}$ and 50 Hz $\text{Hz}^{-\frac{1}{2}}$ respectively. When the frequency of the injection-locked laser is stabilized to an external high-finesse reference cavity, a minimum frequency noise of 40 mHz $\text{Hz}^{-\frac{1}{2}}$ was measured from the locking loop error signal at 1 kHz [313].

At Adelaide, an efficient, medium power, diode-pumped Nd:YAG slab, stable resonator, ring laser based on a new diode-pumping geometry [321] was developed. Using 18 W of absorbed laser diode power (20 W diode output power), 5.8 W TEM_{00} output beam has been produced [189].

6. Conclusion

Gravitational wave researchers have expected to detect gravitational waves 'within the next decade' for the last three decades. Detectors have been dramatically improved and a steadily increasing band of physicists has been able to devote more and more resources to the problem. In the process they have uncovered new physics and new technology. Gravitational wave detectors are the most sensitive devices ever invented.

Like the Great South Land which was rumoured for centuries before it was discovered, the spectrum of gravitational waves is a rumoured continent, first to be detected, and then to be explored. It seems not unreasonable that the exploration will begin within the next decade, but whatever happens the search will continue to motivate physicists and drive a continuing process of innovation.

Acknowledgments

The authors wish to acknowledge the Australian Research Council, which has supported gravitational wave research in Australia for many years, and our colleagues in Perth and around the world with whom we have had rich and rewarding interactions. The field is too large to be able to reference all important papers, and we apologize to those whose work we have failed to reference.

Gravity Waves

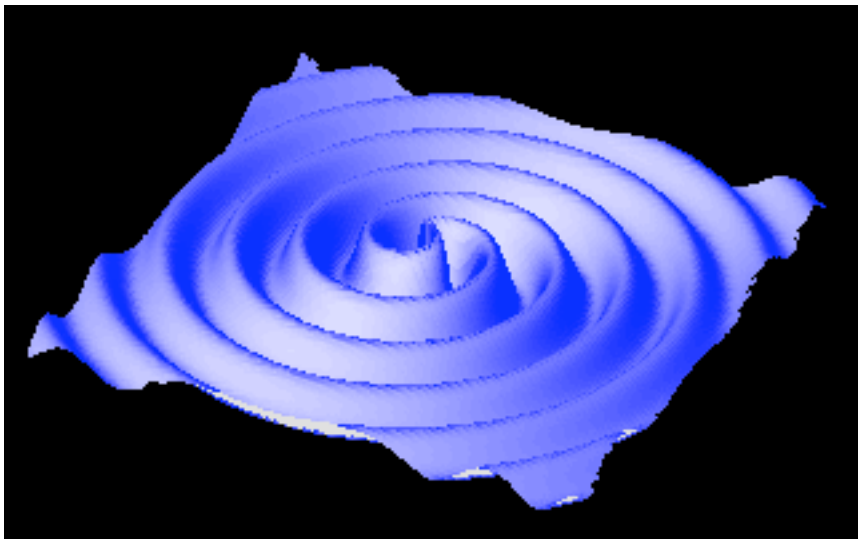
Another new prediction of Einstein's theory of gravity (general relativity) is *gravity waves*, "ripples of spacetime" that travel at the speed of light. Notice that these are ripples *of* spacetime, not ripples *in* spacetime like electromagnetic waves (also called light). Gravity waves are also called *gravitational radiation.* There is no such phenomenon in Newton's theory of gravity.

(Side note: There is a much more ordinary phenomenon also called "gravity waves" in the Earth's oceans and atmosphere: this is simply the fact that if a fluid rises then it will fall again due to gravity. An example is surface waves on the ocean. So when you find an article about gravity waves, check which type they are talking about. From now on, when I say "gravity wave" I mean waves of spacetime as predicted by general relativity)

Gravity waves are generated by the motion of, or changes in, masses in spacetime. For example, if the Sun were to suddenly disappear, the Earth would continue to move in its orbit along the straightest path in the curved spacetime generated by the Sun for eight more minutes. This is because it takes light 8 minutes to get from the Sun to the Earth, so it will take 8 minutes for the change in the spacetime curvature to get from the previous position of the Sun to the Earth. In other words the Earth's orbit would change at the same time that we saw the Sun disappear on Earth, 8 minutes after it actually happened. Don't worry, we're very sure the Sun will not actually disappear.

Actually, the special theory of relativity demands that gravitational changes move no faster than the speed of light, otherwise you could use the gravitational effect of a mass to transmit signals faster than light. This would contradict the understanding of spacetime we have from special relativity.

The detection of gravity waves is an important test of Einstein's general relativity. These waves are very difficult to detect because their effects are very weak for gravity waves generated by most things that happen in the Universe. For example, a rotating spherical mass (like the sun) does not generate any gravity waves at all. Planets orbiting a star generate gravity waves that are far too weak to detect. Normal stars orbiting each other generate gravity waves that stronger, but still too weak to detect from a great distance. Here's a picture of the gravity wave emitted from two stars orbiting each other.



A representation of the gravity waves emitted by two stars orbiting each other.

Only very large masses interacting very close to each other will generate gravity waves that we can hope to detect here on Earth. The strongest gravity waves would be generated by the collision of two black holes. Such collisions are rare, however. More likely is a large mass falling into a black hole such as the one in the center of our Galaxy. This is also rare, but would happen more often than a black hole collision.

Therefore gravity waves are difficult to detect. As I'll describe below, there are several experiments underway to detect them. The best evidence to date, however, is indirect, found by examining the orbit of two very massive but close stars around each other. I'll also describe this below.

What Does a Gravity Wave Look Like?

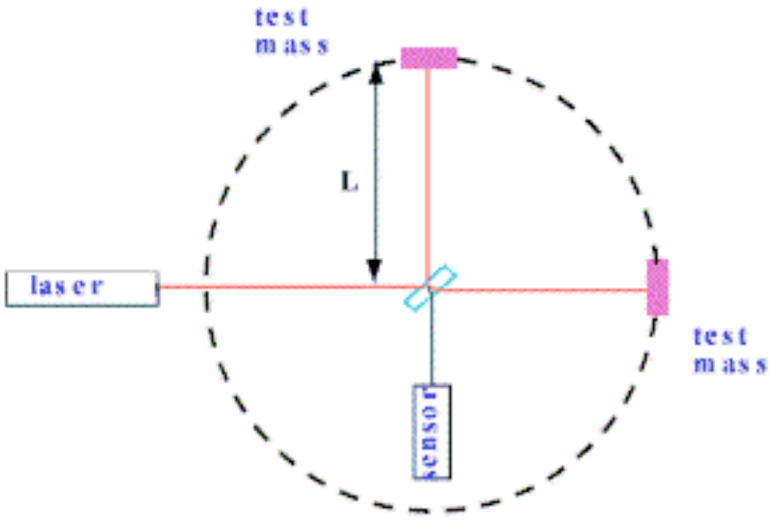
Gravity waves are ripples *of* spacetime, not waves of some material in spacetime. Gravity waves causes space to warp as time passes. Because it is space itself that is warping, everything in that space will warp with it. Therefore you won't see a gravity wave as it passes.

Luckily for physicists, for many gravity waves the warping in one direction will be different from the warping in another direction. We can therefore detect a gravity wave by observing lengths in different directions. If the length changes one way in one direction and a different way in another direction there is a good chance that a gravity wave has passed by.

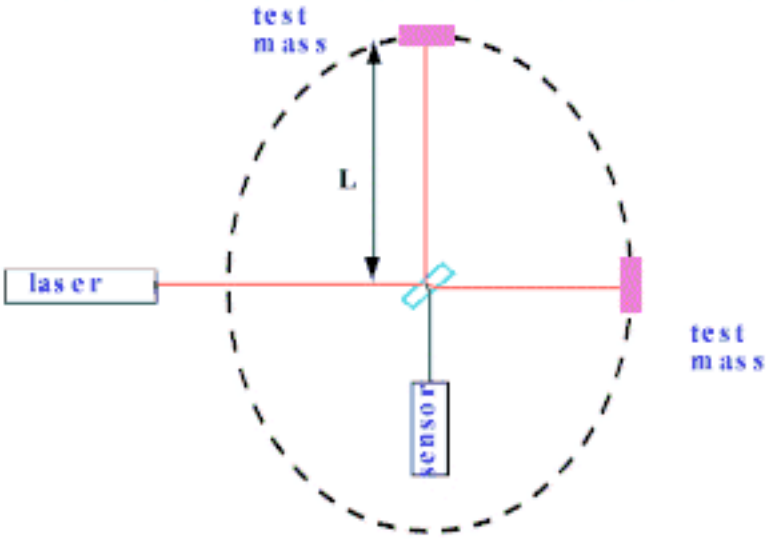
The first attempt to detect gravity waves in this way was by Joseph Webber in the late 60's. He placed very sensitive strain gauges on a large metal bar. If a gravity wave goes by, then the different stretching of the bar in various directions would appear as varying strains. Webber never detected gravity waves, because the bar was not large enough and was subject to too much noise due to changes in temperature and so on.

Joseph Webber and his gravity wave detector.

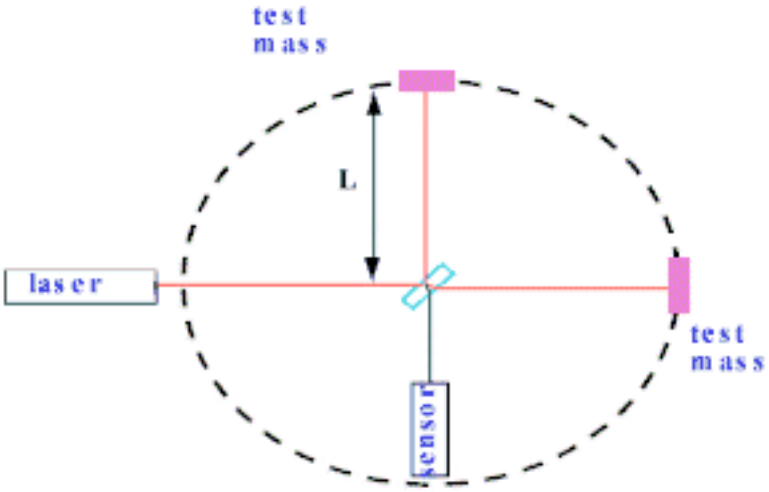
A number of experiments are now coming into operation that try to measure differences in length in various directions by using the interference of light: a laser beam is split in two, sending the two beams along perpendicular paths, then reflecting them back so they can be recombined. The *interference* of the recombined beams will show a length difference as variation in the brightness of the recombined beams. Here's some pictures showing such an experiment in operation:



An interference-based gravity wave detector. The line is the path of the laser beam. This is the picture when no gravity wave is passing.



Here is the situation when a gravity wave is passing: first the beams are stretched in one direction…

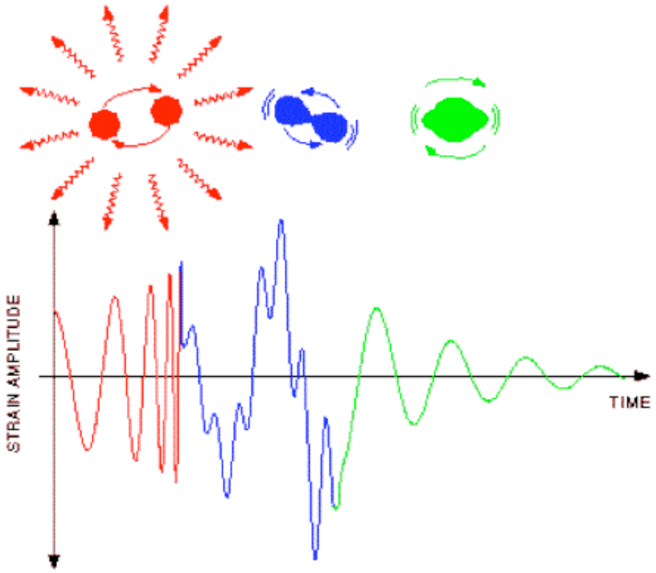


then they are stretched in the other. The sensor will change in brightness in a characteristic way.

Two large interference-based experiments are now operating in the US, one in Livingston, Louisiana and the other in Hanford, Washington. Both are part of the Laser Interferometer Gravity-Wave Observatory (LIGO), run by Cal Tech and MIT. These devices are quite large, with the arm of each laser path (L in the above diagrams) being 2.5 miles. The reason there are two of them far apart is to make sure any signals detected at one is not due to some local noise. A real gravitational wave would be detected at both experiments. LIGO has been taking data since April of this year, with increasing sensitivity over time. Hopefully we'll see an announcement of gravity wave detection soon, though LIGO is just barely at the required sensitivity to detect gravity waves from very large sources.

The LIGO facility in Hanford, Washington, showing one 2.5 mile arm, with the other arm going out of the picture to the left.

Here's a picture of the signal the LIGO experiment may detect from two massive stars coalescing after orbiting each other very closely:

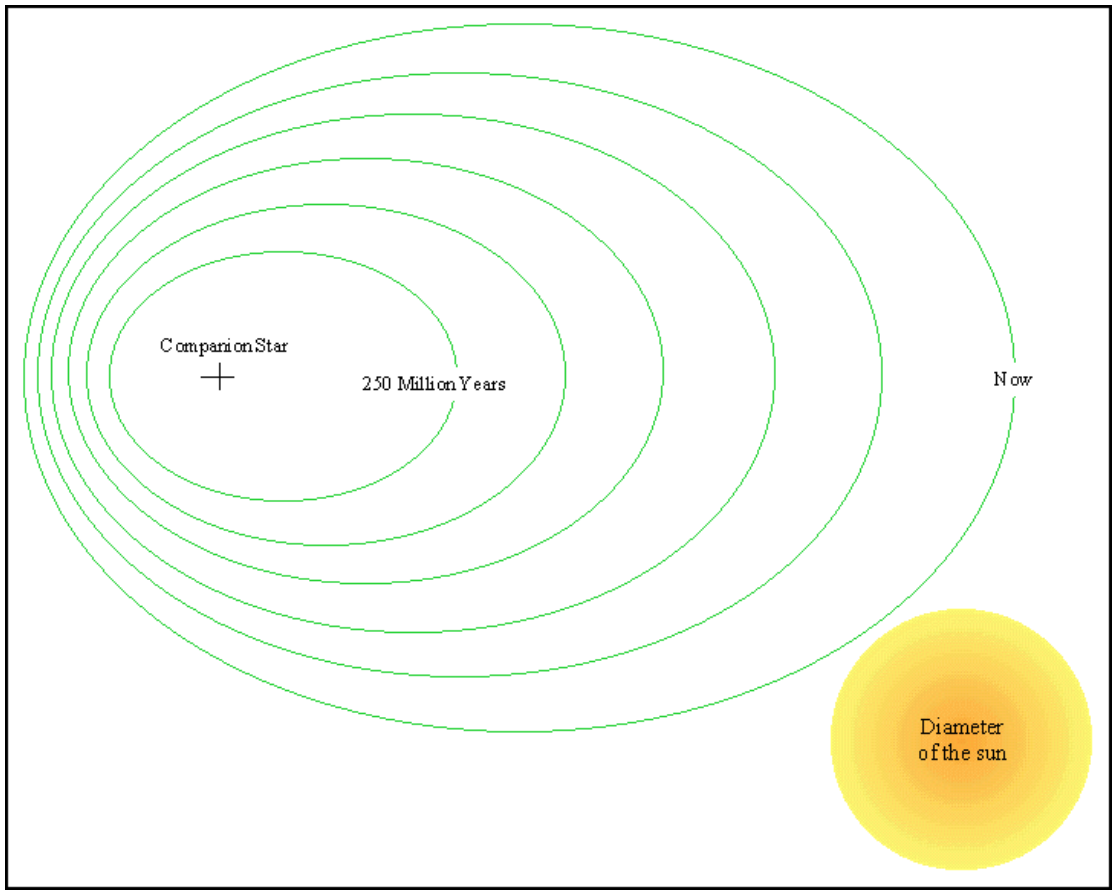


The top of the figure shows two very massive stars coalescing after being in a close orbit. The bottom shows the gravity wave signal that LIGO would detect from this event.

Several other interferometer-based experiments are being built in France, Germany, Japan and one is proposed in Australia. The most ambitious and sensitive proposed interferometer-based experiment is the Laser Interferometer Space Antenna (LISA), a fleet of three spacecraft that would form an equilateral triangle in space, measuring the changes in the length of the triangle with laser beams between the satellites. The sides of the triangle would be about 3 million miles.

The Indirect Detection of Gravity Waves

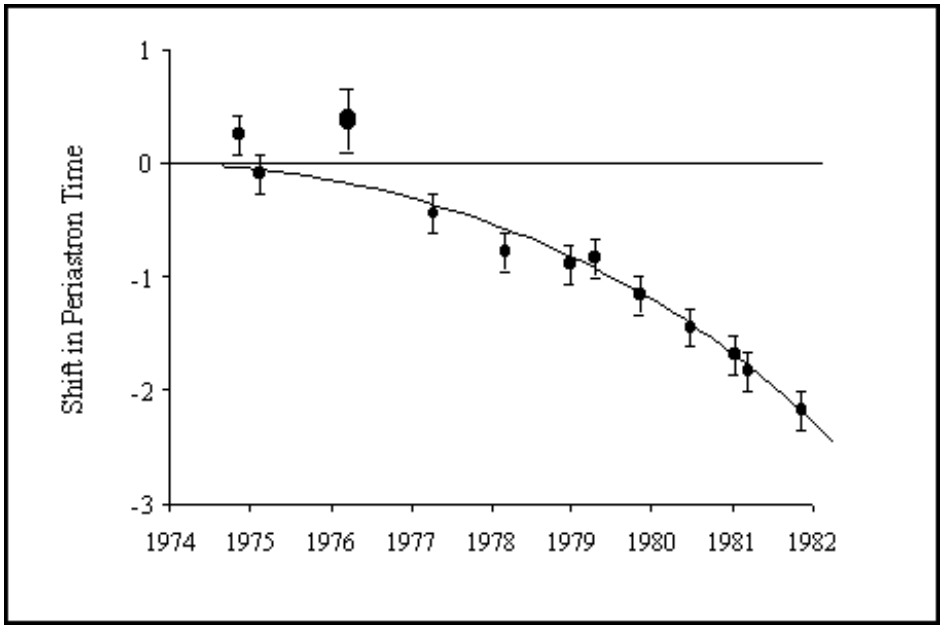
The best evidence for gravity waves to date is indirect, based on observations of the binary star system PSR1913+16. One of the stars in this system is a pulsar, which is a massive star in the last stages of life that has collapsed to a very small size, on the order of 10 miles in diameter. Both stars in PSR1913+16 are about 1.4 times the mass of the sun, and are orbiting very close together. Their orbits are very elliptic, with a closest approach of only 776,000 miles (a little more than the radius of the sun) and a furthest distance of 2 million miles (for comparison, the average distance between the Earth and the sun is about 93 million miles). The orbital period is only 7.75 *hours*.



The orbits of PSR1913+16 (from the point of view of one of the stars) compared with the size of the sun. The ellipse marked “now” is the current orbit. The other ellipses show the future orbits as the stars lose energy by emitting gravity waves, which cause them to slow down and fall into smaller orbits.

Because each star in PSR1913+16 is so massive and they get so close together, their gravitational field is very strong (in other words the spacetime between the pulsars is highly curved). Therefore they emit stronger gravity waves than most objects in the sky. These gravity waves are still too weak to detect even with LIGO, but they carry energy away from PSR1913+16. This energy loss causes the stars in PSR1913+16 to slow down, which causes a change in their orbit that we can detect from Earth. From these observations we can reconstruct the energy loss, and it exactly matches the energy of the gravity waves predicted by general relativity!

If you want a little more detail, here it is. The energy loss is measured by observing the time of closest approach between the stars (which is observed via the very fast pulses of the pulsar). If there were no energy loss then the time between closest approaches would be constant. If energy were being lost due to gravity waves, then the time between closest approaches would become shorter as the stars moved closer together. The closer the stars are together, the larger the gravity waves so the greater the energy loss, which moves the stars closer together still. Detailed calculations from general relativity predict that the time between closest approaches would decrease at an ever increasing rate. When the observations of the closest approach times are plotted over several years, they dramatically match the prediction of general relativity.



The change in time of closest approach of the stars observed over several years (dots with error bars) compared to the prediction of general relativity (curved line). The horizontal straight line (at 0) is the prediction if there were no gravity waves.

Though indirect, this observation is a dramatic vindication of general relativity.

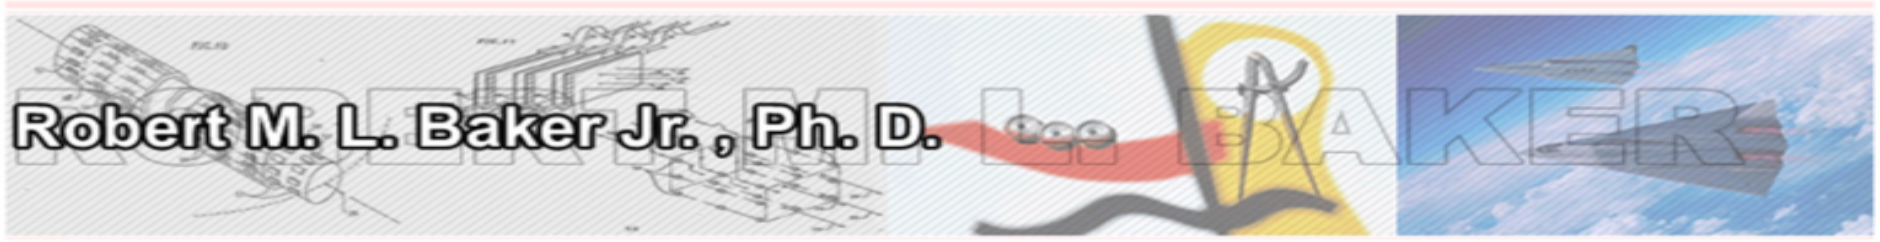
Applications of High-Frequency Gravitational Waves to Aerospace Systems

AIAA ASAT Conference, May 1, 2010



| PHYSICS | ENGINEERING | SCIENCE | ASTRODYNAMICS | MATHAMATICS | ASTRONAUTICS | RESEARCH | HIGH-FREQUENCY GRAVITATIONAL WAVES |

PREFACE

The predictions in this presentation of the benefits of high-frequency gravitational wave based Aerospace applications are theoretical at this time. Evidence of their value is contingent upon laboratory experiments in their generation and detection. Nonetheless, given their potential vital aerospace, strategic military and economic importance, I believe that these possible applications are important motivations for research and development.— Robert M L Baker, Jr.

EXECUTIVE SUMMARY

GRAVWAVE ® LLC.

- For several years the Peoples Republic of China has funded HFGW research programs involving dozens of their scientists and well-known Russian scientists have been involved in HFGW research for over four decades. HFGW detectors have been built by the British, Italians and the Japanese
- Technology developed by GravWave LLC and other institutions overseas can lead to devices, some already constructed overseas, that can generate and detect HFGWs in the laboratory.
- Because of their unique characteristics, HFGWs could be utilized for uninterruptible, very low-probability-of-intercept (LPI) communications among satellites.
- Other potential very theoretical aerospace applications are propulsion, including “moving” space objects and missiles in flight, frustrating anti-missile and anti-satellite systems, surveillance through buildings and the Earth itself, and remote initiation of nuclear events.
- The important potential aerospace applications of this enabling technology are motivations for research and development and such an R&D program in the United States is recommended for immediate initiation.

GRAVWAVE ® LLC.

- First published in 1992. Subsequently the “Li Effect” was validated by eight journal articles, independently peer reviewed by scientists well versed in general relativity, (Li, Tang and Zhao, 1992; Li and Tang, 1997; Li, Tang, Luo, 2000; Li, Tang and Shi, 2003; Li and Yang, 2004; Li and Baker, 2007; Li, et al., 2008; Li, et al., 2009) including capstone papers, Li, et al.(2008) and Li et al. (2009).

- The Li-Effect is *very different* from the classical *(inverse)* Gertsenshtein-Effect. the Li-effect produces a *first-order* perturbative photon flux (PPF), proportional to the amplitude of the gravitational wave (GW) A not A^2 as is the case of the Gertsenshtein-Effect. Thus the Gertsenshtein- Effect is 10^{-30} weaker than the Li-Effect for the detection of relic HFGWs. **The JASON report (Eardley, 2008) confuses the two effects and erroneously suggests that the Li-Baker HFGW Detector utilizes the inverse Gertsenshtein effect.**

Rayleigh scattering mean free path of the EM beam in a Li-Baker HFGW Detector

- $l_{ray} \approx 1/(n\sigma_{ray}) = 1/([N_m P//T][\sigma_{ray}(H_2)] = 1/([1.51\text{x}10^{13}][1.047\text{x}10^{-46}]) = 6\text{x}10^{32}$ cm
- $I = I_0 e^{-z/lray}$,
- I_0 is the initial intensity of the GB = $1.51\text{x}10^{26}\text{s}^{-1}$ photons per second
- $I_{(10)} - I_{(40)} = I_0 (e^{-10/lray} - e^{-40/lray}) \approx (1.51\text{x}10^{26})(-1 + 10/6\text{x}10^{32} + 1 - 40/6\text{X}10^{32}) = 3\text{x}10^{-7}$ photons per second scattered in the 30 cm long GB interaction volume, **which is negligible**.

GRAVWAVE ® LLC.

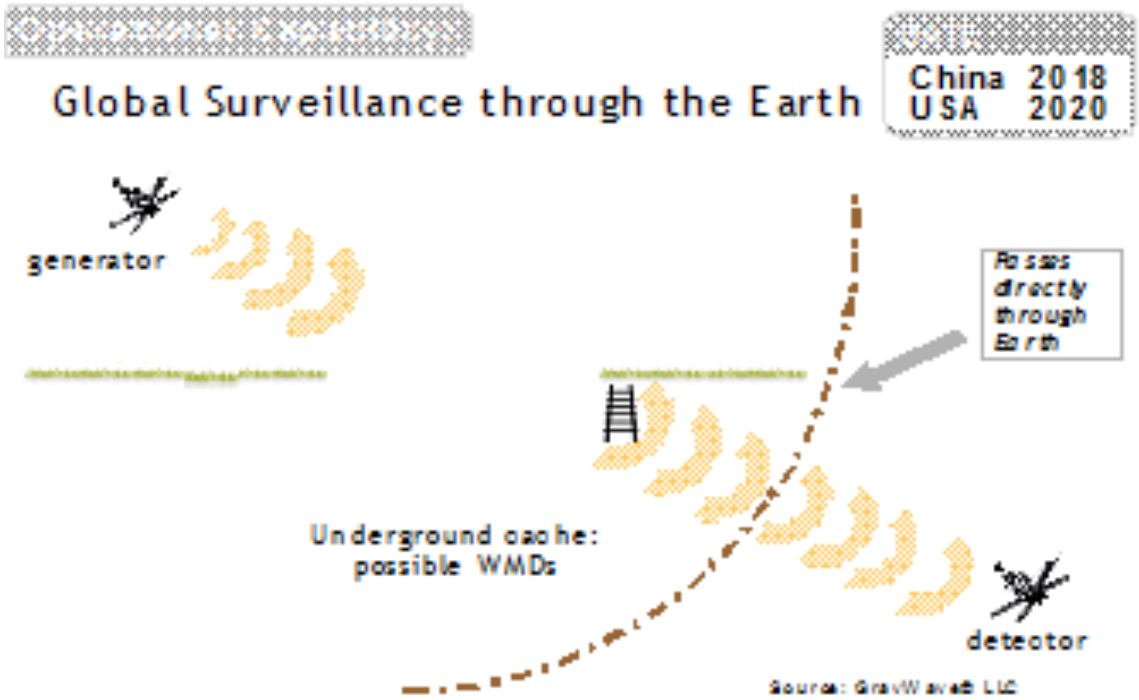
Required Detector-Wall Absorption

- Power db =10 $\log_{10}$ (power out/power in) = 10$\log_{10}$ (6.626x10-27/1000) = -290 db

- Absorption “mat” consisting of four MM layers, each layer a quarter wavelength from the next (in order to cancel any possible surface reflection) and provide a - 45 db -45 db - 45 db = -135 db absorption (Landy, et al., 2008 indicate **no reflection -- only transmission**). Behind these MM layers would be a sheet of 10 GHz microwave pyramid absorbers providing a -40 db absorption before reflection back into the four MM layers. Thus the total absorption would be -135 db -40 db –135db = -310 db.

HFGW Surveillance

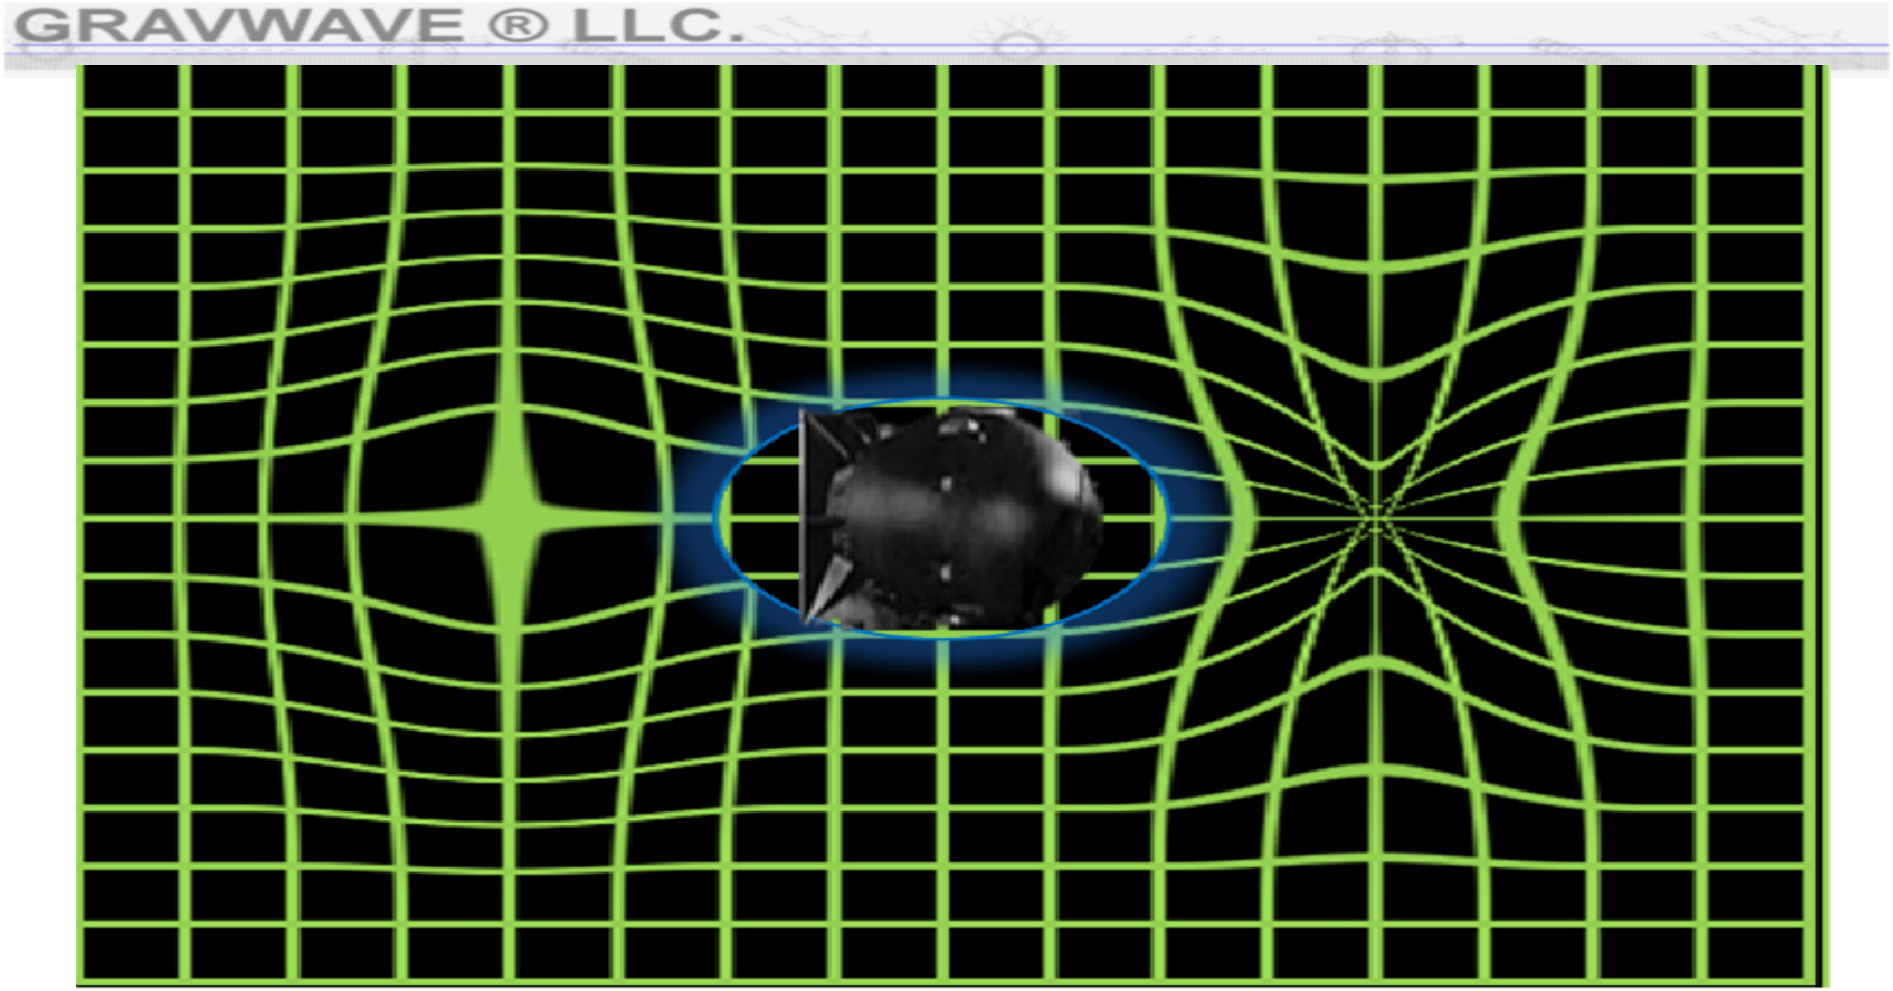
GRAVWAVE ® LLC.



Theoretical Surveillance Application

- Misner, Thorne and Wheeler (1973): “In the real universe there are spacetime curvatures due not only to the energy of gravitational waves, but also more importantly to the material [objects and structures] content of the universe ... its wavelength changes [based on gravitational red shift] and [the gravitational wave] backscatters off the curvature to some extent. If the wave is a pulse, then the backscatter will (change) its shape and *polarization*....” It is extremely difficult to theoretically establish the actual magnitude of the changes, especially at very high frequencies (10^9 Hz and higher) and to quantify them prior to the proof-of-concept HFGW generation/ detection laboratory experiments.

REMOTE DISPLACEMENT OF MASSES



Section 108, page 349 of Landau and Lifshitz (1975)

GRAVWAVE ® LLC.

- "Since it has definite energy, the gravitational wave is itself is the source of some additional gravitational field [static g-field]. Like the energy producing it, this field is a second-order effect in the h_{ik}. ***But in the case of high-frequency gravitational waves the effect is significantly strengthened*****:** the fact that the pseudotensor t_{ik} is quadratic in the derivatives of the h_{ik} introduces the large factor λ^{-2}. In such a case we may say that the wave itself produces the background field [static g-field] on which it propagates. This [static g] field is conveniently treated by carrying out the averaging described above over regions of four-space with dimensions large compared to λ. Such an averaging, smoothes out the short-wave 'ripple' and leaves the slowly varying background metric [static g-field]." (Brackets and italics added for clarity and emphasis.)

Extremely Theoretical Calculations

- Landau and Lifshitz (1975) offer no elaboration of the physics and mathematics behind their assertion; but their textbook reference certainly is based upon some of their analyses or could be derived. In any event, the concept is clear.

- Using the standard astrodynamics equations found, for example, on pages 90 and 91 of Herrick (1971), a computer program yields from a 26.8 to a 2.7 mile perturbative g-field change in missile entry location for 6,200 mile ICBM trajectories (*with 50 to 100 mile length, 0.1 to 0.01 g-field perturbations*). For short-range 1,400 mile trajectories, it yields from a 2.0 to a 0.41 mile perturbative g-field change in missile entry location (*with 25 to 50 mile length, 0.1 to 0.01 g-field perturbations*). Such modest changes would not greatly reduce the damage caused by terrorist ICBM nuclear strikes, but would frustrate anti-missile systems (by perturbing their trajectories) or defend against, for example, surgical strikes against submerged submarine assets.

Conclusions

GRAVWAVE ® LLC.

- High-frequency gravitational wave (HFGW) generators have been proposed theoretically by the Russians, Germans, Italians and Chinese. HFGW detectors are a reality and three have been actually constructed outside the United States by the British, Italians and Japanese.
- A theoretically more sensitive detector than these, the Li-Baker, utilizing metamaterial and off-the-shelf microwave absorbers to eliminate noise, together with a theoretical, multi-FBAR HFGW generator in a double-helix configuration that are discussed, could be utilized for transglobal, low-probability of intercept (PPI) communications. The multi-elements of the transmitter (HFGW generator) are off-the-shelf piezoelectric film-bulk acoustic resonators or FBARs energized by off-the-shelf' modified Magnetrons. In theory a large number of these FBAR elements could lead to HFGW generator-detector communications for a laboratory proof-of-concept experiment.
- Pending the recommended proof-of-concept HFGW experiment other HFGW applications could be of value. These theoretical applications, yet to be quantified, but discussed herein, include surveillance and remote displacement of masses such as missiles and anti-missiles and the remote generation of nuclear fission.

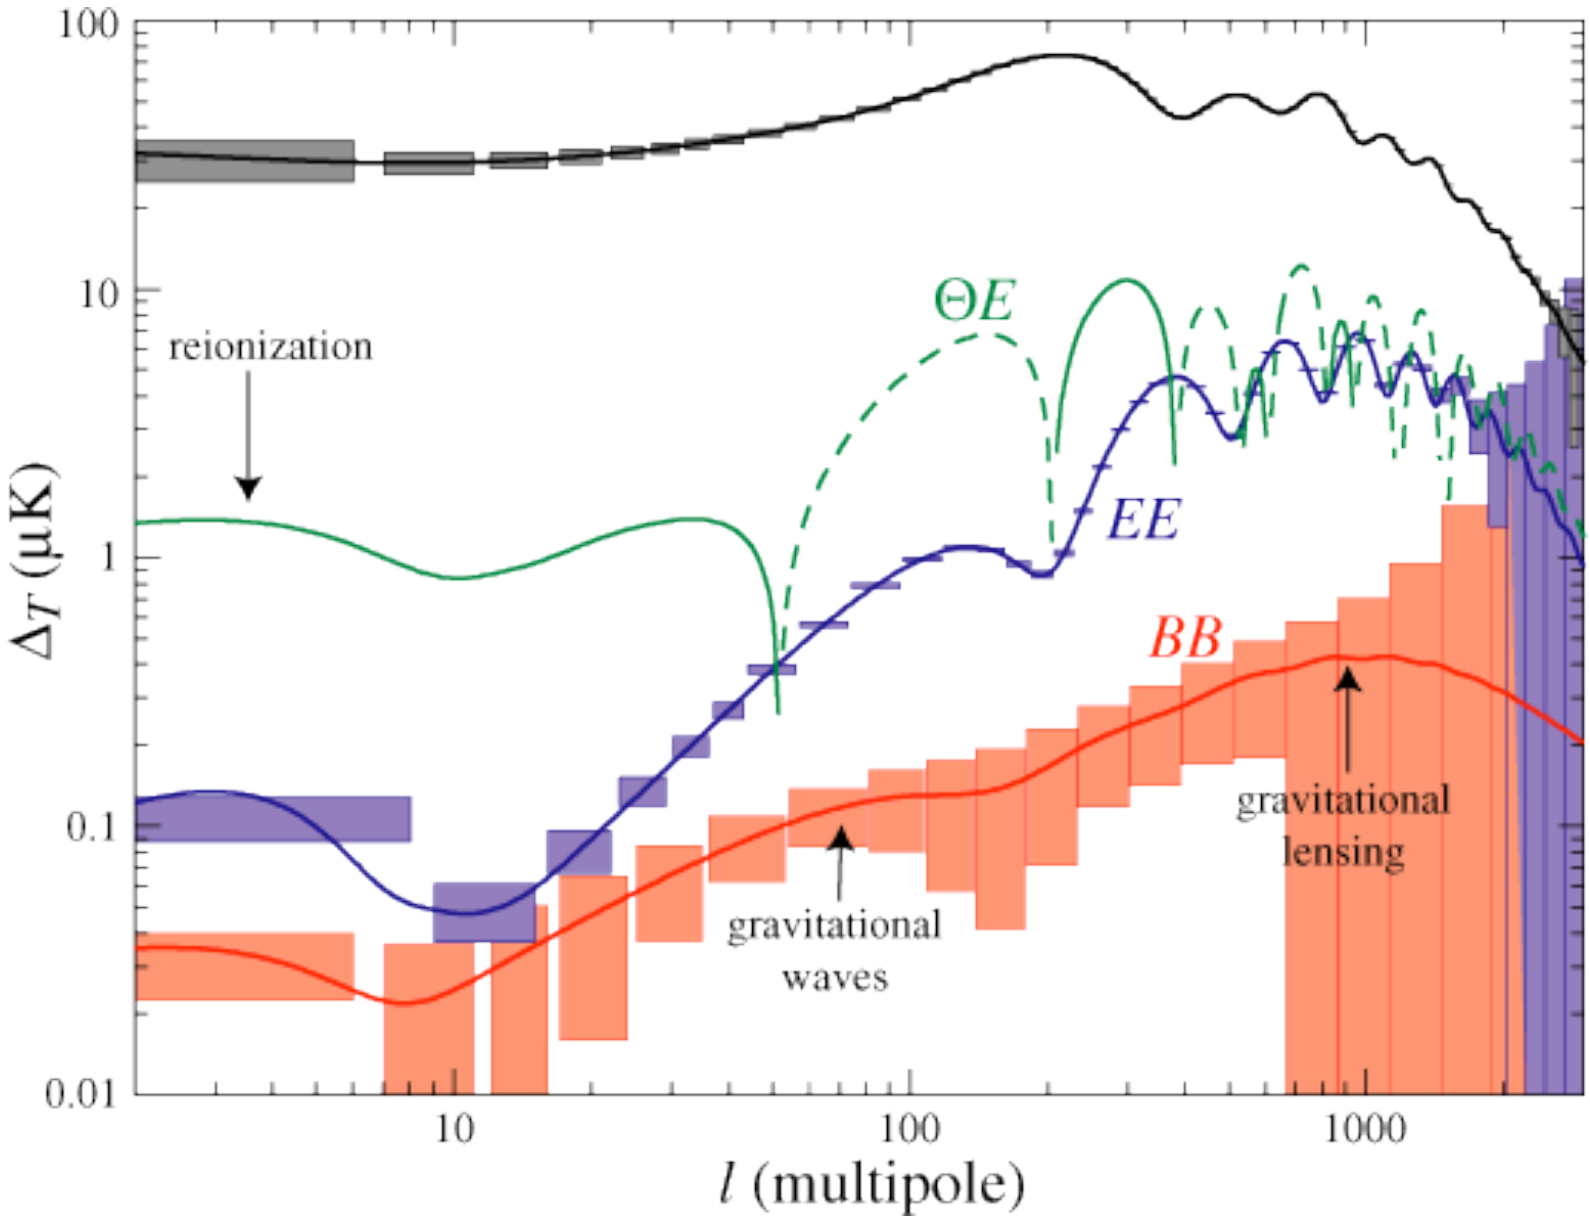
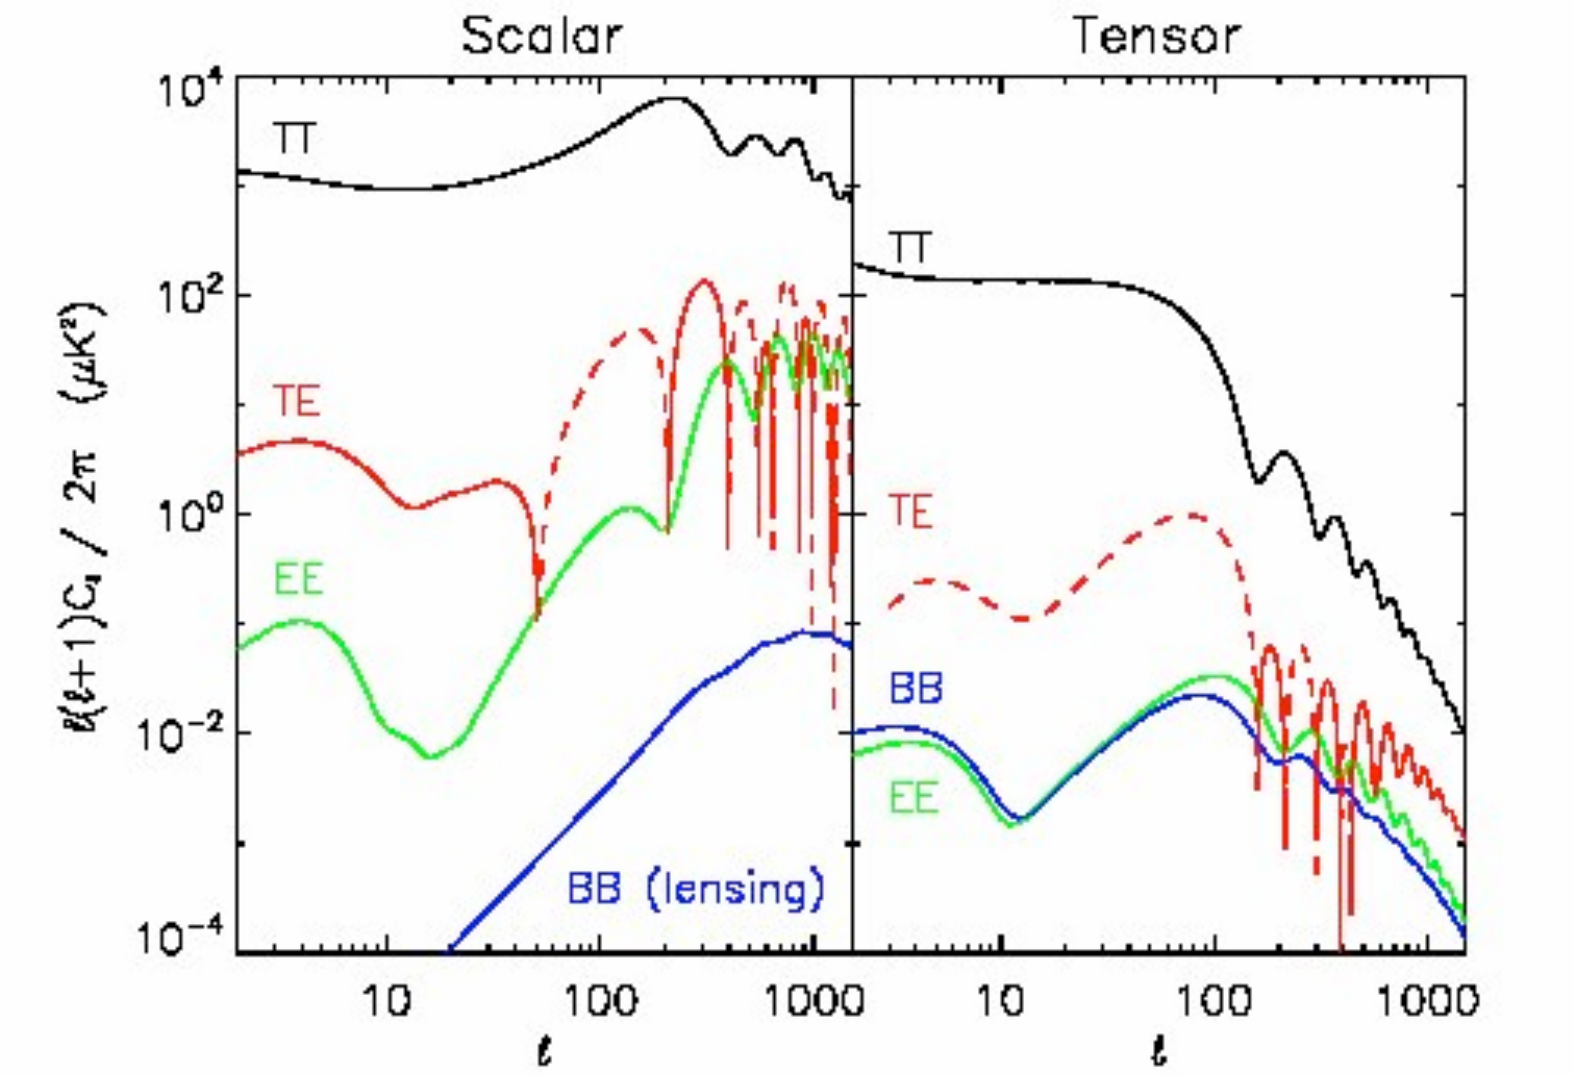
Remember A. Lasenby´s talk

Physics of the CMB anisotropies: the angular power spectrum



Power spectra - Theory



Stokes parameters

❖The polarization state of a electromagnetic wave propagating in a direction **n** can described by the intensity matrix

$$P_{ij} = \left\langle E_i(\hat{n}) E_j^*(\hat{n}) \right\rangle$$

where **E** is the electric field vector and the brackets denote time averaging.

❖ P is a hermitian 2x2 matrix and thus can be decomposed into the Pauli basis

$$P = I(\hat{n})\sigma_0 + Q(\hat{n})\sigma_3 + U(\hat{n})\sigma_1 + V(\hat{n})\sigma_2$$

$$\sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

❖ In terms of the electric field, the Stokes parameters are defined as:

$$I = |E_1|^2 + |E_2|^2 \qquad Q = |E_1|^2 - |E_2|^2$$

$$U = (E_1^* E_2 + E_2^* E_1) = 2\mathrm{Re}(E_1^* E_2) \qquad V = 2\mathrm{Im}(E_1^* E_2)$$

Stokes parameters

❖ Linear polarization is described by Stokes Q and U parameters.

❖ Q measures the different of intensities in the to axes x and y, while U measures the difference of intensities in a coordinate system at 45º.

❖ Not all Stokes parameters are rotationally invariant. Under a rotation of ψ degrees of the coordinate system, we have

$$I' = I \qquad V' = V$$

$$Q' = Q\cos(2\psi) - U\sin(2\psi) \qquad U' = U\cos(2\psi) + Q\sin(2\psi)$$

or in a more compact form

$$Q' \pm iU' = e^{\pm 2i\psi}(Q \pm iU)$$

❖Hence, (Q±iU) transforms like a spin-2 variable under rotations.

Spin weighted spherical harmonics

- Spin-s spherical harmonics.
- Under rotations, they transform as: $${}_sY_{\ell m} \rightarrow e^{\pm si\psi}\, {}_sY_{\ell m}(\hat{n})$$
- Orthogonality and completeness

$$\int d\hat{\mathbf{n}}\, {}_sY^*_{\ell m}(\hat{\mathbf{n}})\, {}_sY_{\ell m}(\hat{\mathbf{n}}) = \delta_{\ell\ell'}\delta_{mm'}$$

$$\sum_{\ell m} {}_sY^*_{\ell m}(\hat{\mathbf{n}})\, {}_sY_{\ell m}(\hat{\mathbf{n}}') = \delta(\phi-\phi')\delta(\cos\theta-\cos\theta')$$

- Relation to Wigner rotation matrices:

$${}_sY_{\ell m}(\theta,\phi) = (-1)^m \sqrt{\frac{2\ell+1}{4\pi}} e^{-is\psi} D^{\ell}_{-m,s}(\phi,\theta,-\psi)$$

Statistical representation

❖ All-sky decomposition:

$$(Q \pm iU)(\hat{n}) = \sum_{\ell=2}^{\infty} \sum_{m=-\ell}^{+\ell} a_{\ell m}^{\pm 2} \; {}_{\pm 2}Y_{\ell m}(\hat{n}) = \sum_{\ell=2}^{\infty} \sum_{m=-\ell}^{+\ell} (a_{E,\ell m} \pm i a_{B,\ell m}) \; {}_{\pm 2}Y_{\ell m}(\hat{n})$$

❖ Here, $a_{lm}^{\pm 2}$ is a decomposition into positive and negative helicity. The helicity basis

$$e^{\pm} = \frac{1}{\sqrt{2}}(e_\theta \pm i e_\phi)$$

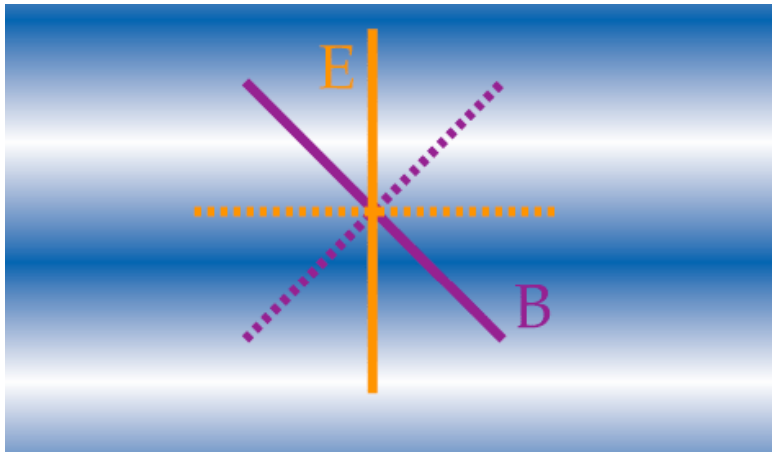
❖ In the last equality we have defined E- and B-modes:

$$a_{E,\ell m} = \frac{1}{2}(a_{\ell m}^{+2} + a_{\ell m}^{-2})$$

$$a_{B,\ell m} = \frac{-i}{2}(a_{\ell m}^{+2} - a_{\ell m}^{-2})$$

❖ Under parity transformations (**n→-n**), the E-modes remain invariant, while B-modes change sign.

E and B modes



A plane wave moving from top to bottom. The direction of the polarization vector defines if they are E or B modes.

- **Full-sky** polarization maps can be decomposed into two components usually called **E-modes** (analog of the gradient component) and **B-modes** (analog of the curl component) (see Kamionkowski et al. 1997; Seljak & Zaldarriaga 1997).
- These modes are independent on the coordinate system, and are related to the Q and U Stokes parameters by a non-local transformation.

(A pure E-mode turns into pure B-mode if we turn all polarization vectors by 45º).

Angular power spectra

$$C_{Tl}=\frac{1}{2l+1}\sum_m \langle a^*_{T,lm}a_{T,lm}\rangle,$$

$$C_{El}=\frac{1}{2l+1}\sum_m \langle a^*_{E,lm}a_{E,lm}\rangle,$$

$$C_{Bl}=\frac{1}{2l+1}\sum_m \langle a^*_{B,lm}a_{B,lm}\rangle,$$

$$C_{Cl}=\frac{1}{2l+1}\sum_m \langle a^*_{T,lm}a_{E,lm}\rangle,$$

in terms of which,

$$\langle a^*_{T,l'm'}a_{T,lm}\rangle = C_{Tl}\delta_{l'l}\delta_{m'm},$$

$$\langle a^*_{E,l'm'}a_{E,lm}\rangle = C_{El}\delta_{l'l}\delta_{m'm},$$

$$\langle a^*_{B,l'm'}a_{B,lm}\rangle = C_{Bl}\delta_{l'l}\delta_{m'm},$$

$$\langle a^*_{T,l'm'}a_{E,lm}\rangle = C_{Cl}\delta_{l'l}\delta_{m'm},$$

$$\langle a^*_{B,l'm'}a_{E,lm}\rangle = \langle a^*_{B,l'm'}a_{T,lm}\rangle = 0.$$

The polarization of the CMB anisotropies

- **Four parity-independent power spectra can be formed:**

$$C_{TT} = \frac{1}{2l+1} \sum_m \left\langle a^*_{T,lm} a_{T,lm} \right\rangle \qquad C_{BB} = \frac{1}{2l+1} \sum_m \left\langle a^*_{B,lm} a_{B,lm} \right\rangle$$

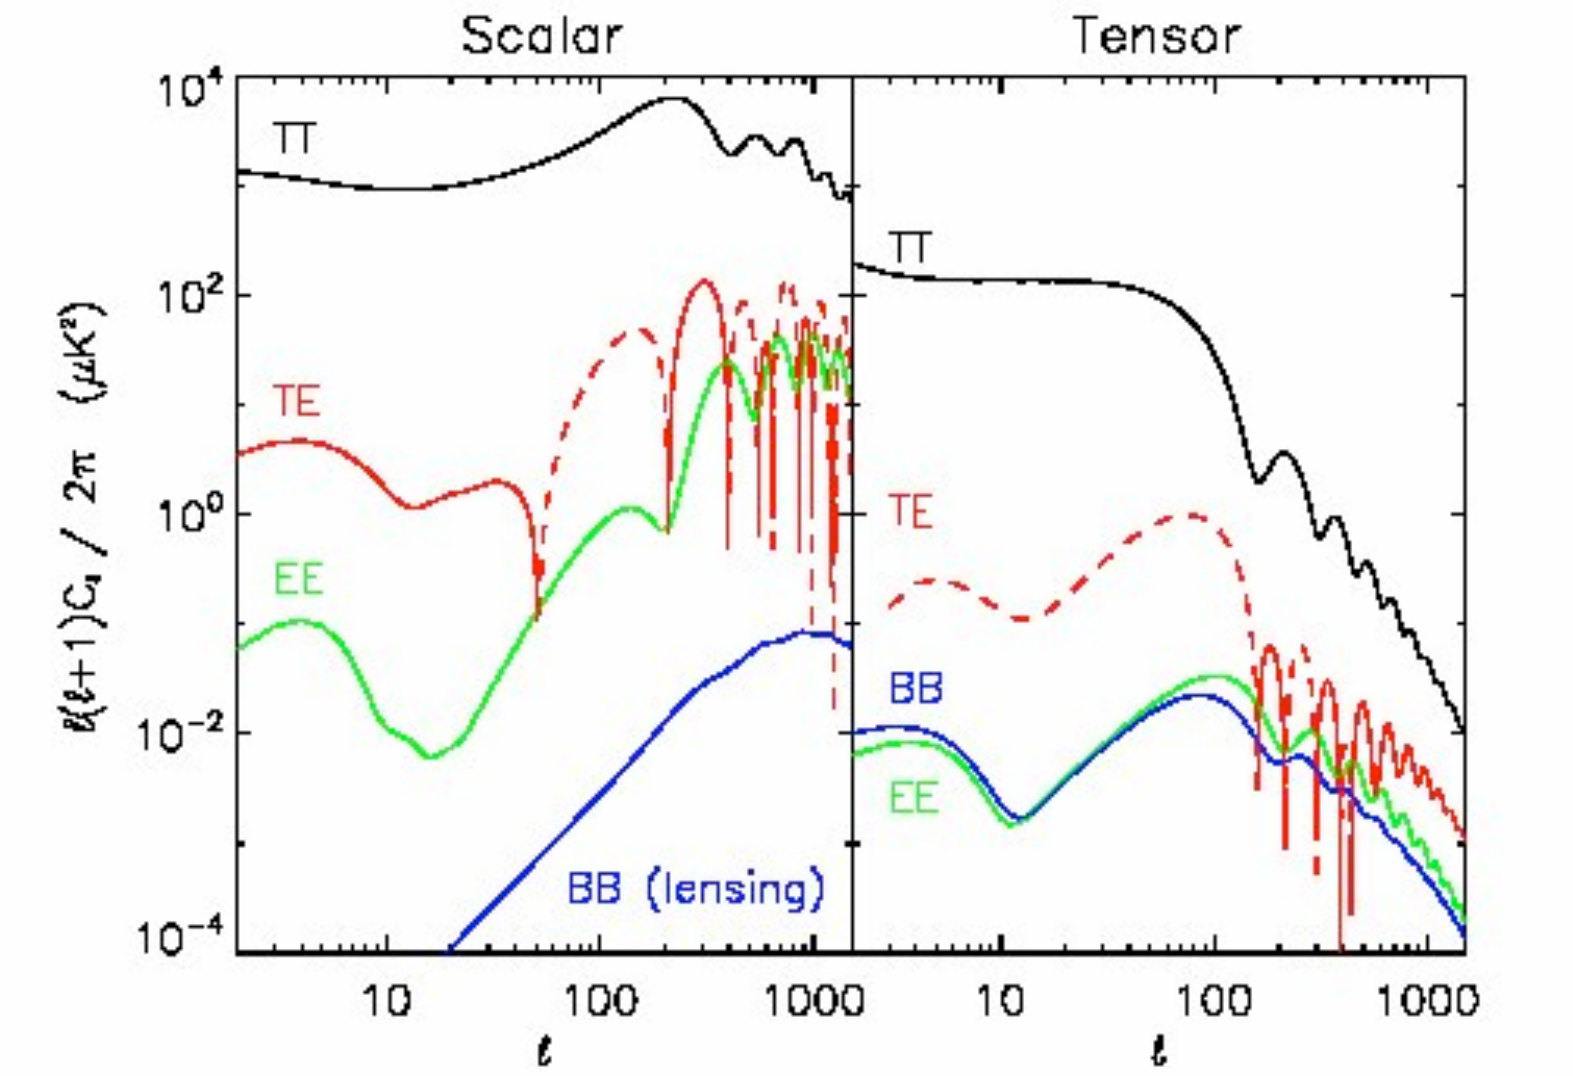
$$C_{EE} = \frac{1}{2l+1} \sum_m \left\langle a^*_{E,lm} a_{E,lm} \right\rangle \qquad C_{TE} = \frac{1}{2l+1} \sum_m \left\langle a^*_{T,lm} a_{E,lm} \right\rangle$$

- **Physics of generation of the Polarization.** Different sources of anisotropies generate different types of modes:

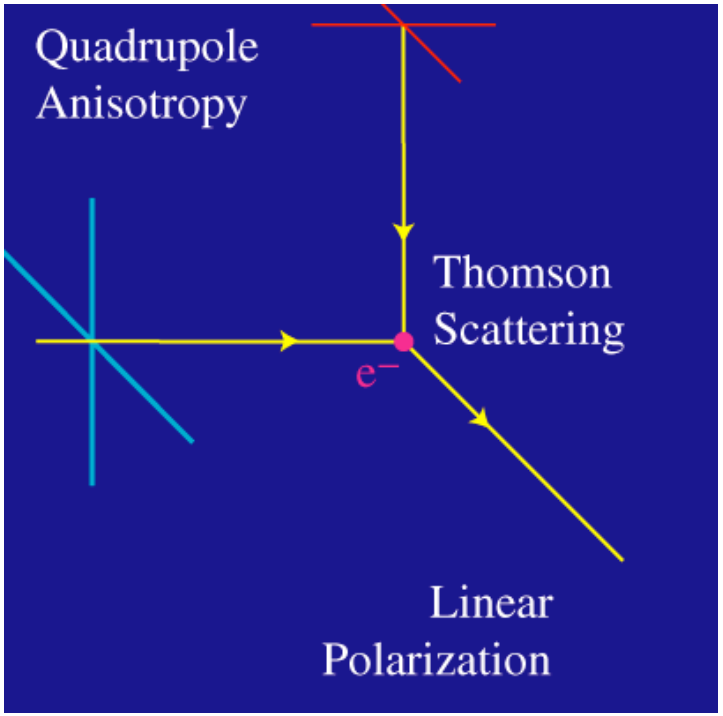
	Scalar (density perturbations)	Tensor (gravitational waves)
E-modes	Yes	Yes
B-modes	No	Yes

- **B-modes probe the existence of primordial gravitational waves.**

Power spectra - Theory



Thomson scattering



❖Differential cross-section

$$\frac{d\sigma}{d\Omega} = \frac{3}{8\pi}\left|\hat{\varepsilon}' \cdot \hat{\varepsilon}\right|^2 \sigma_T$$

❖A net polarization is generated during recombination if there is a quadrupole anisotropy in the radiation field.

❖ Defining the y-axes of the incoming and outgoing coordinate systems to be in the scattering plane, the Stokes parameters of the outgoing beam, defined with respect to the x-axis, we have:

$$I = \frac{3\sigma_T}{8\pi R^2} I'(1+\cos^2(\beta)) \qquad Q = \frac{3\sigma_T}{8\pi R^2} I' \sin^2(\beta) \qquad U = V = 0$$

❖ The net polarization produced by the scattering of an incoming, unpolarized ratiation field of intensity I′(θ,ϕ) is determined by integrating over all incoming directions.

$$I(\hat{z}) = \frac{3\sigma_T}{8\pi R^2} \int d\Omega\, I'(\theta,\phi)(1+\cos^2(\theta))$$

$$Q(\hat{z}) - iU(\hat{z}) = \frac{3\sigma_T}{8\pi R^2} \int d\Omega\, \sin^2(\theta) e^{i2\phi} I'(\theta,\phi)$$

Only a_{2m} components contribute.

Polarization: scalar perturbations

❖Breakdown of tight-coupling leads to a quadrupole anisotropy.

❖ For scalar perturbations, the polarization signal arises from the gradient of the peculiar velocity of the photon fluid (e.g. Zaldarriaga & Harari 1995).

❖ The basic argument is:

❖ Consider a scattering ocurring at x_0. The mean free path is λ_T. Photons coming from a direction **n** roughly come from

$$x = x_0 + \lambda_T \hat{n}$$

❖ The photon-baryon fluid at that point was moving with velocity

$$v(x) = v(x_0) + \lambda_T \hat{n}_i \partial_i v(x_0)$$

❖ Due to Doppler effect, the temperature by the scatterer at x_0 is

$$\delta T(x_0, \hat{n}) = \hat{n} \cdot [v(x) - v(x_0)] \approx \lambda_T \hat{n}_i \hat{n}_j \partial_i v_j(x_0)$$

Polarization: scalar perturbations

❖Breakdown of tight-coupling leads to a quadrupole anisotropy.

❖ For scalar perturbations, the polarization signal arises from the gradient of the peculiar velocity of the photon fluid (e.g. Zaldarriaga & Harari 1995).

❖ Gradient of the velocity is along the direction of the wavevector, so the polarization is purely E-mode:

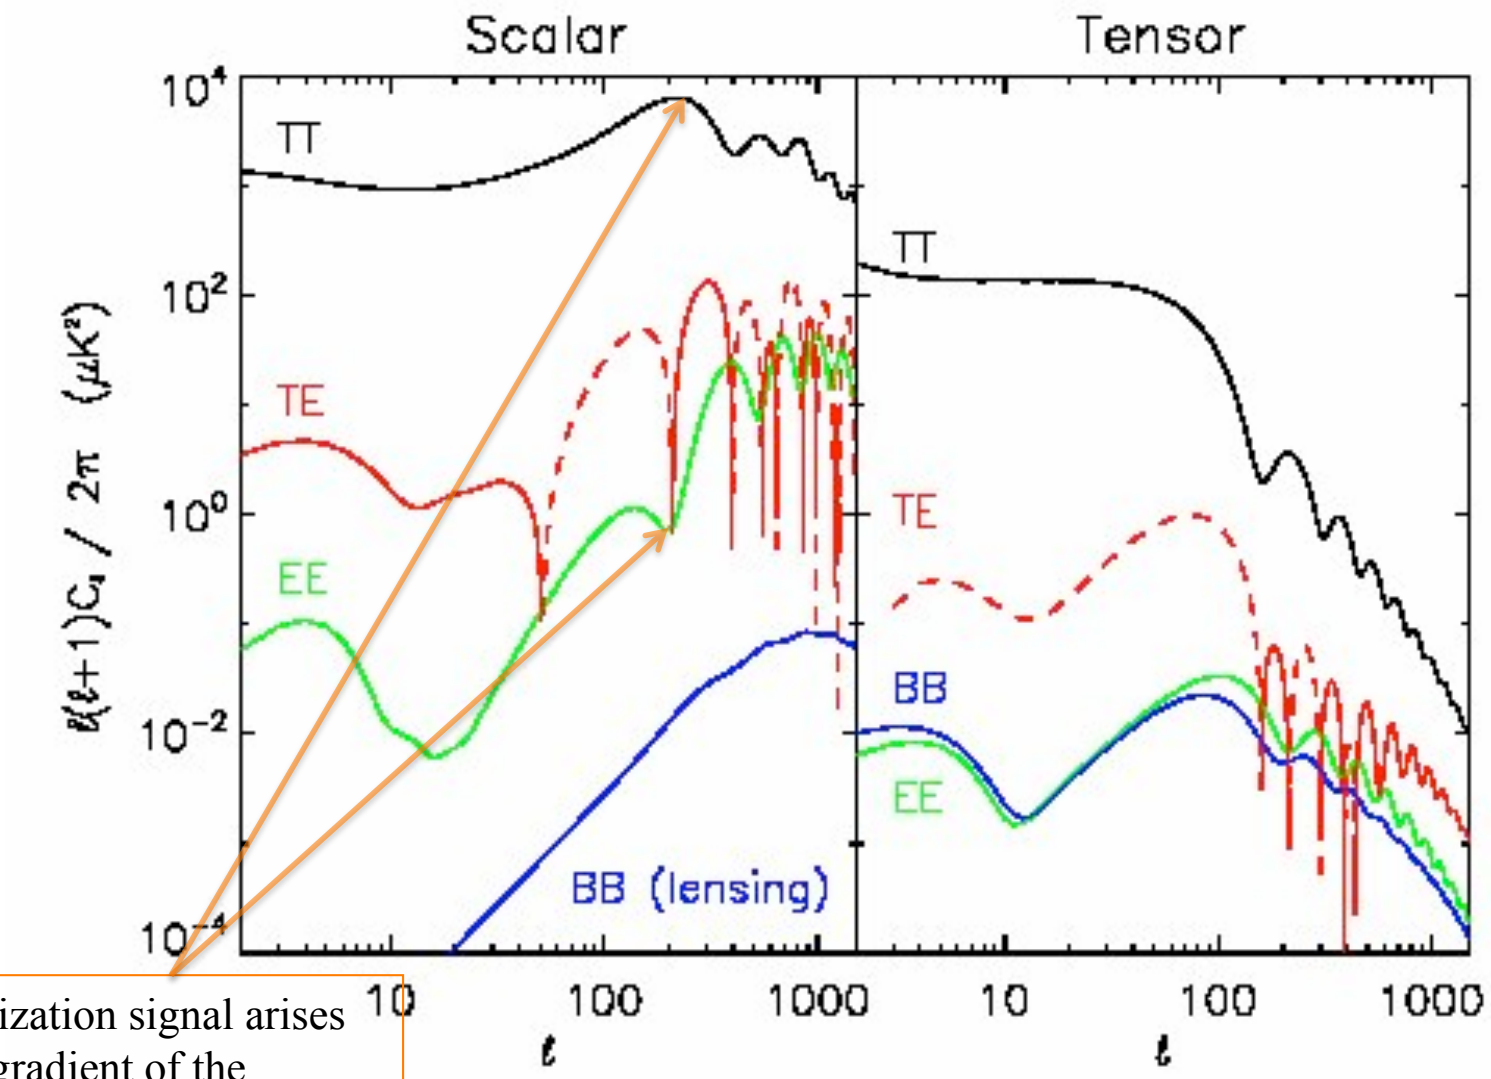
$$\Delta_E \approx -0.17(1-\mu^2)\Delta\eta_{dec} k\, v_\gamma(\eta_{dec})$$

❖ Velocity is 90º out of phase with respect to temperature – turning points of oscillator are zero points of velocity:

$$\Delta_T \propto \cos(kr_s) \qquad v_\gamma \propto \sin(kr_s)$$

❖ Polarization peaks are at troughs of temperature peaks.

Power spectra - Theory



The polarization signal arises from the gradient of the peculiar velocity of the photon fluid => TT and EE peaks are out of phase.

TE Polarization and acoustic peaks

❖Cross-correlation of temperature and polarization

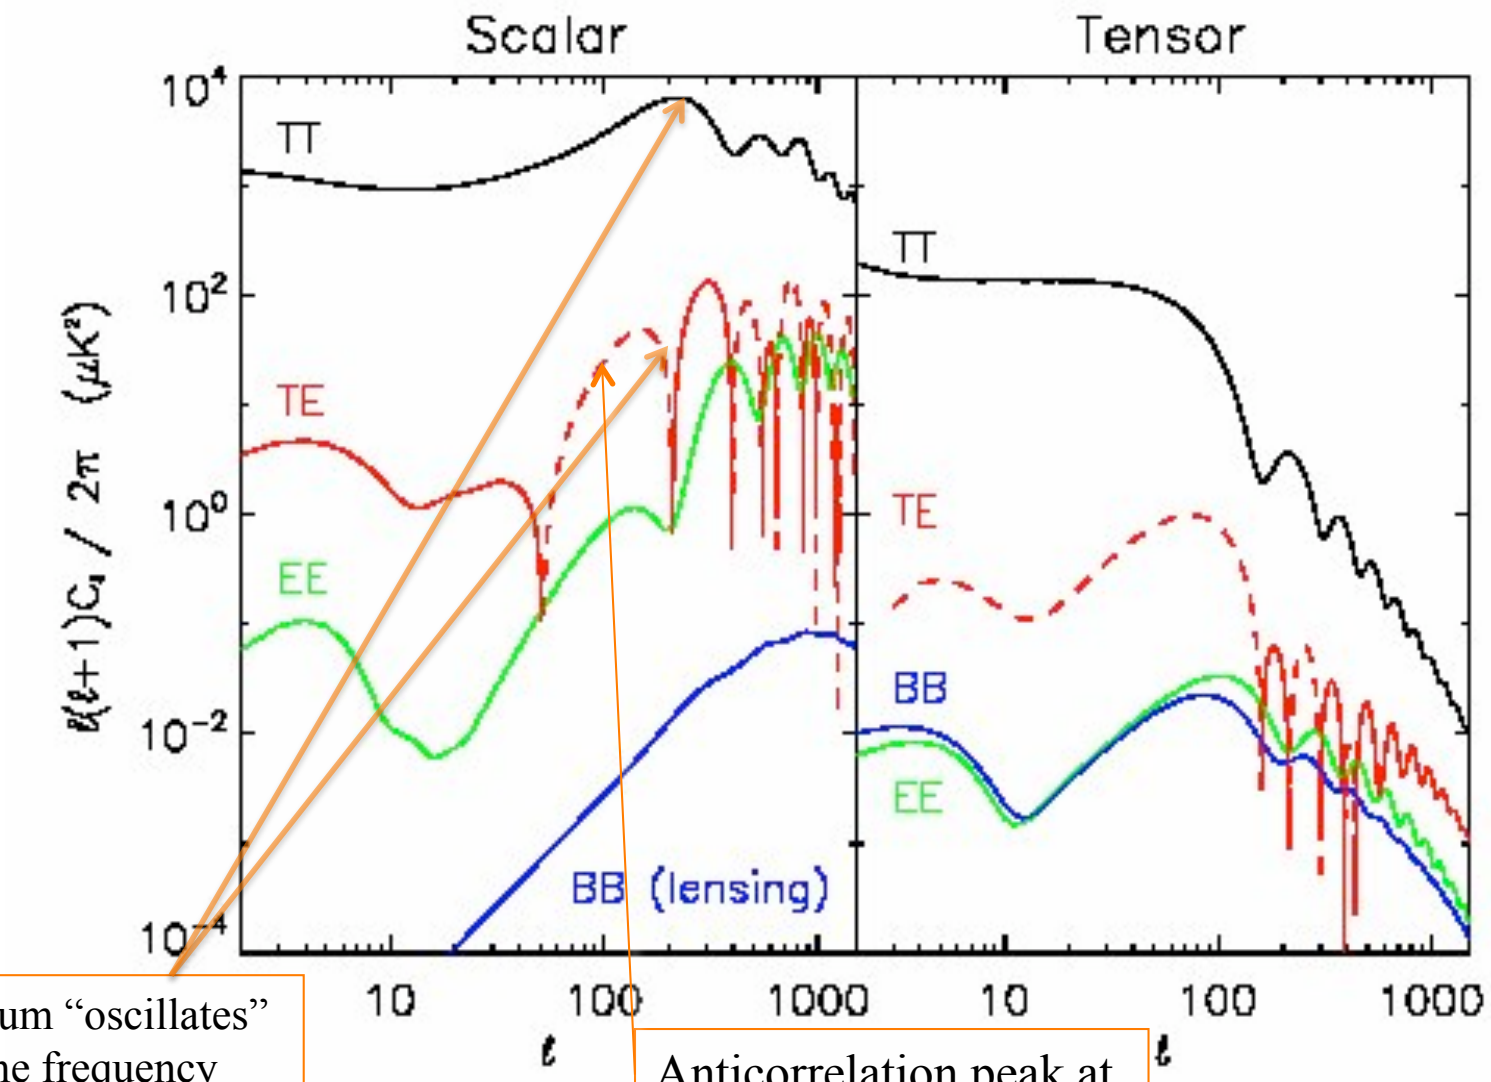
$$\Delta_T \Delta_E \propto \cos(kr_s)\sin(kr_s) \propto \sin(2kr_s)$$

❖ TE spectrum “oscillates” at twice the frequency

❖ TE correlation is radial or tangential around hot spots (see later, WMAP result).

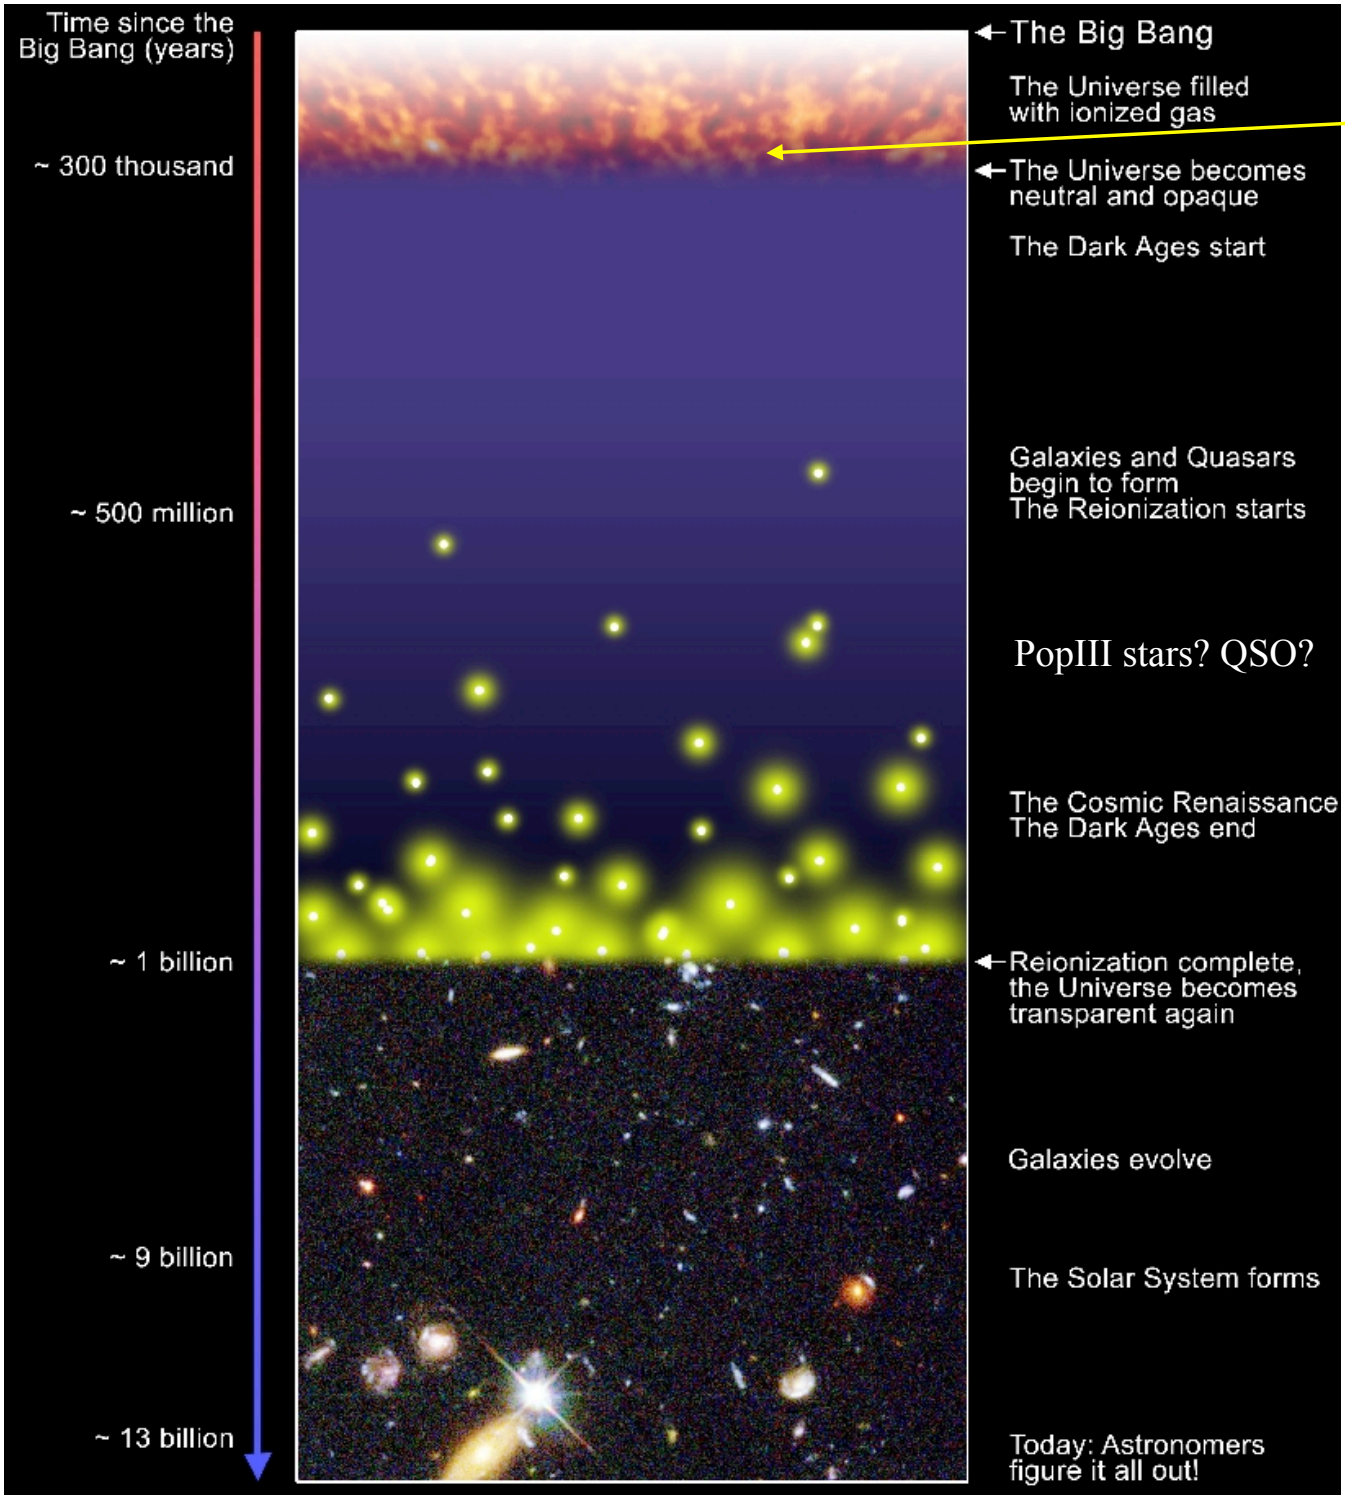
❖ Large scales: anticorrelation peak around l=150, a distinctive signature of primordial adiabatic fluctuations (Peiris et al. 2003).

Power spectra - Theory



TE spectrum "oscillates" at twice the frequency

Anticorrelation peak at l=150 is a signature of superhorizon adiabatic fluctuations



Recombination (z ~ 1000)

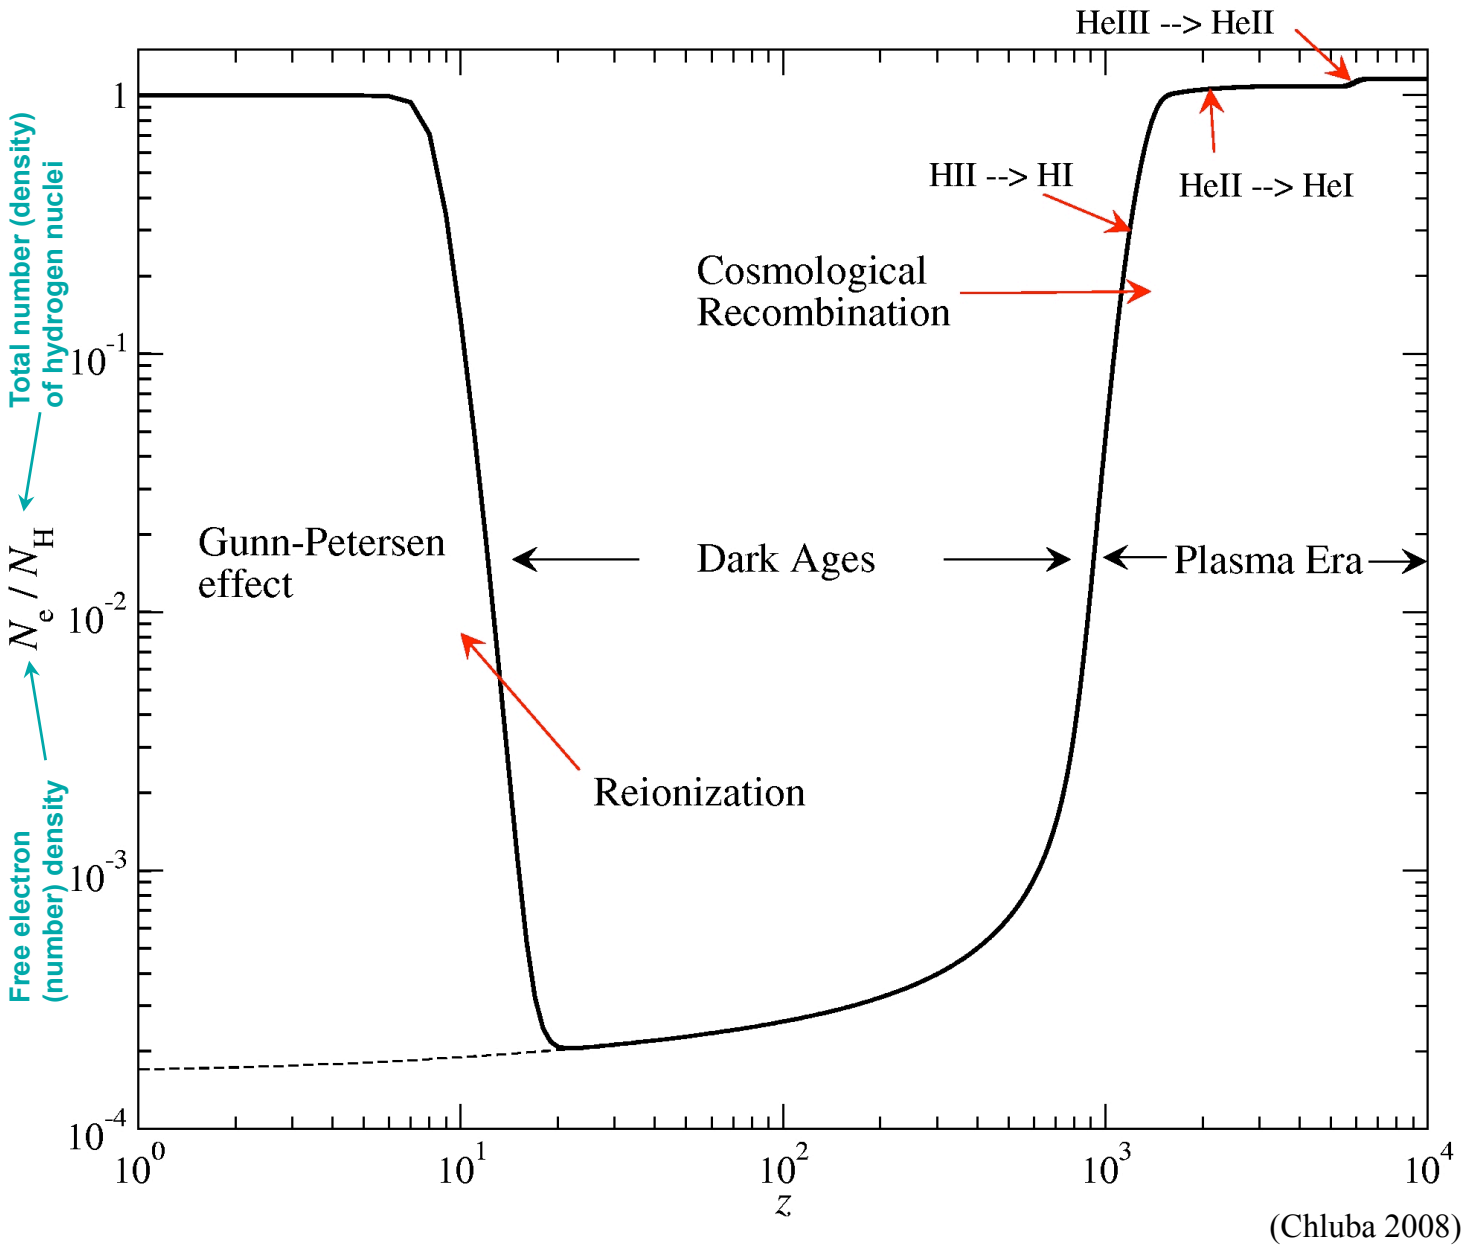
Galaxies form and evolve

(Universe accesible with optical/IR telescopes)

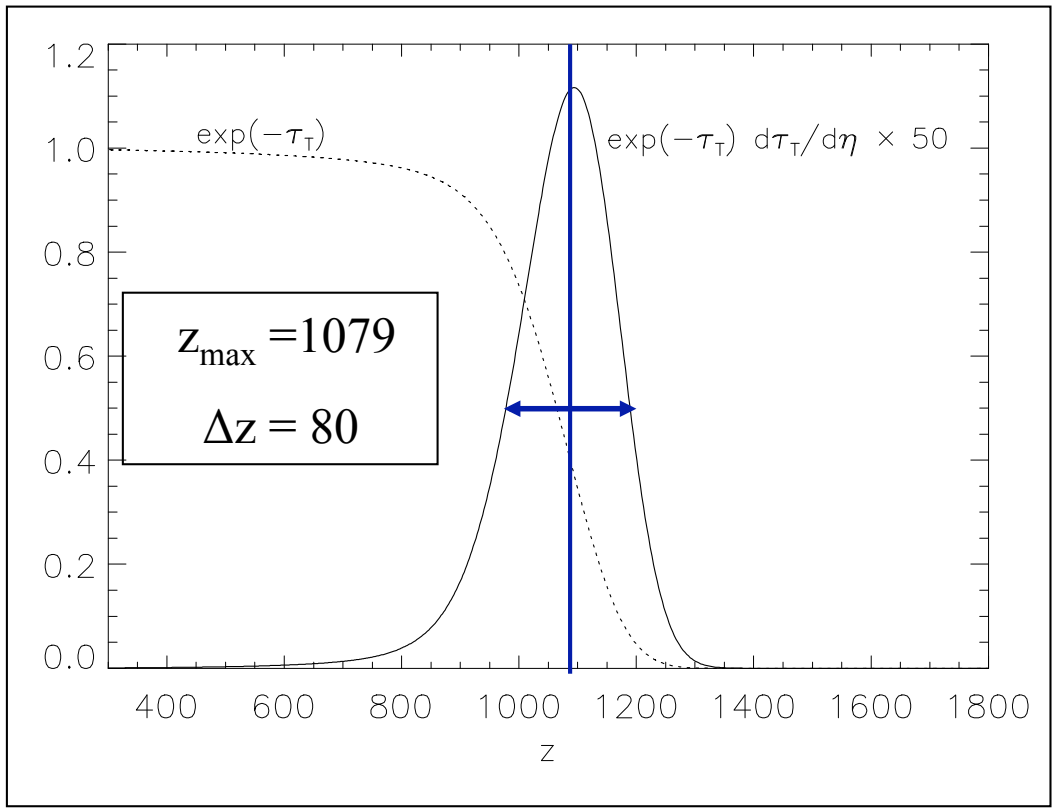
How did the Universe became neutral? Sketch of the Ionization History



(Chluba 2008)

The Thomsom visibility function

Prior to the recombination epoch, the photons and the electrons are tighly coupled due to Thomson scattering. When the number density of electrons decreases, the photons are released and the CMB is formed.



- The relevant quantity is the Thomson optical depth.

$$\tau = \int \sigma_T\, n_e\, dl$$

- The **visibility function** gives the probability that a photon observed now was last scattered at redshift z:

$$V = \exp(-\tau)\, d\tau/d\eta$$

Reionization

❖Optical depth to Thomson scattering to reionization

$$\tau(z) = \int d\eta n_e \sigma_T a = \int d\ln a \frac{n_e \sigma_T}{H(a)} \propto (\Omega_b h^2)(\Omega_m h^2)^{-1/2}(1+z)^{3/2}$$

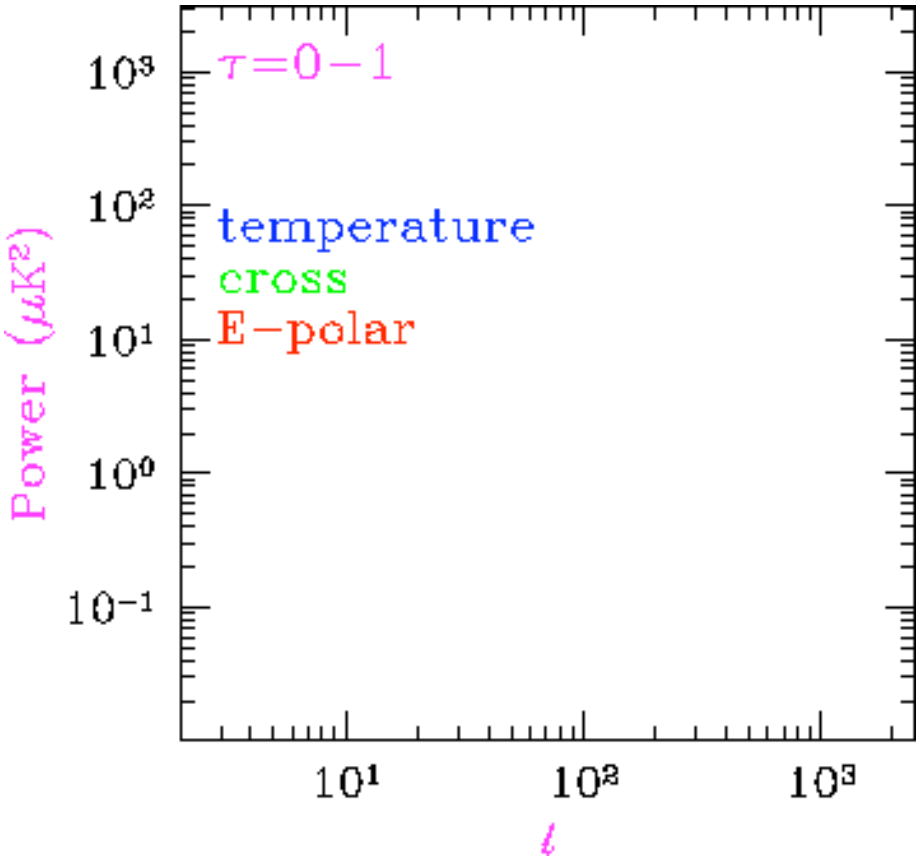
$$= \left(\frac{\Omega_b h^2}{0.02}\right)\left(\frac{\Omega_m h^2}{0.15}\right)^{-1/2}\left(\frac{1+z}{61}\right)^{3/2}$$

❖ CMB re-scatters off re-ionized gas. Generation of new anisotropies at large scales (Doppler) and absorption at small scales:

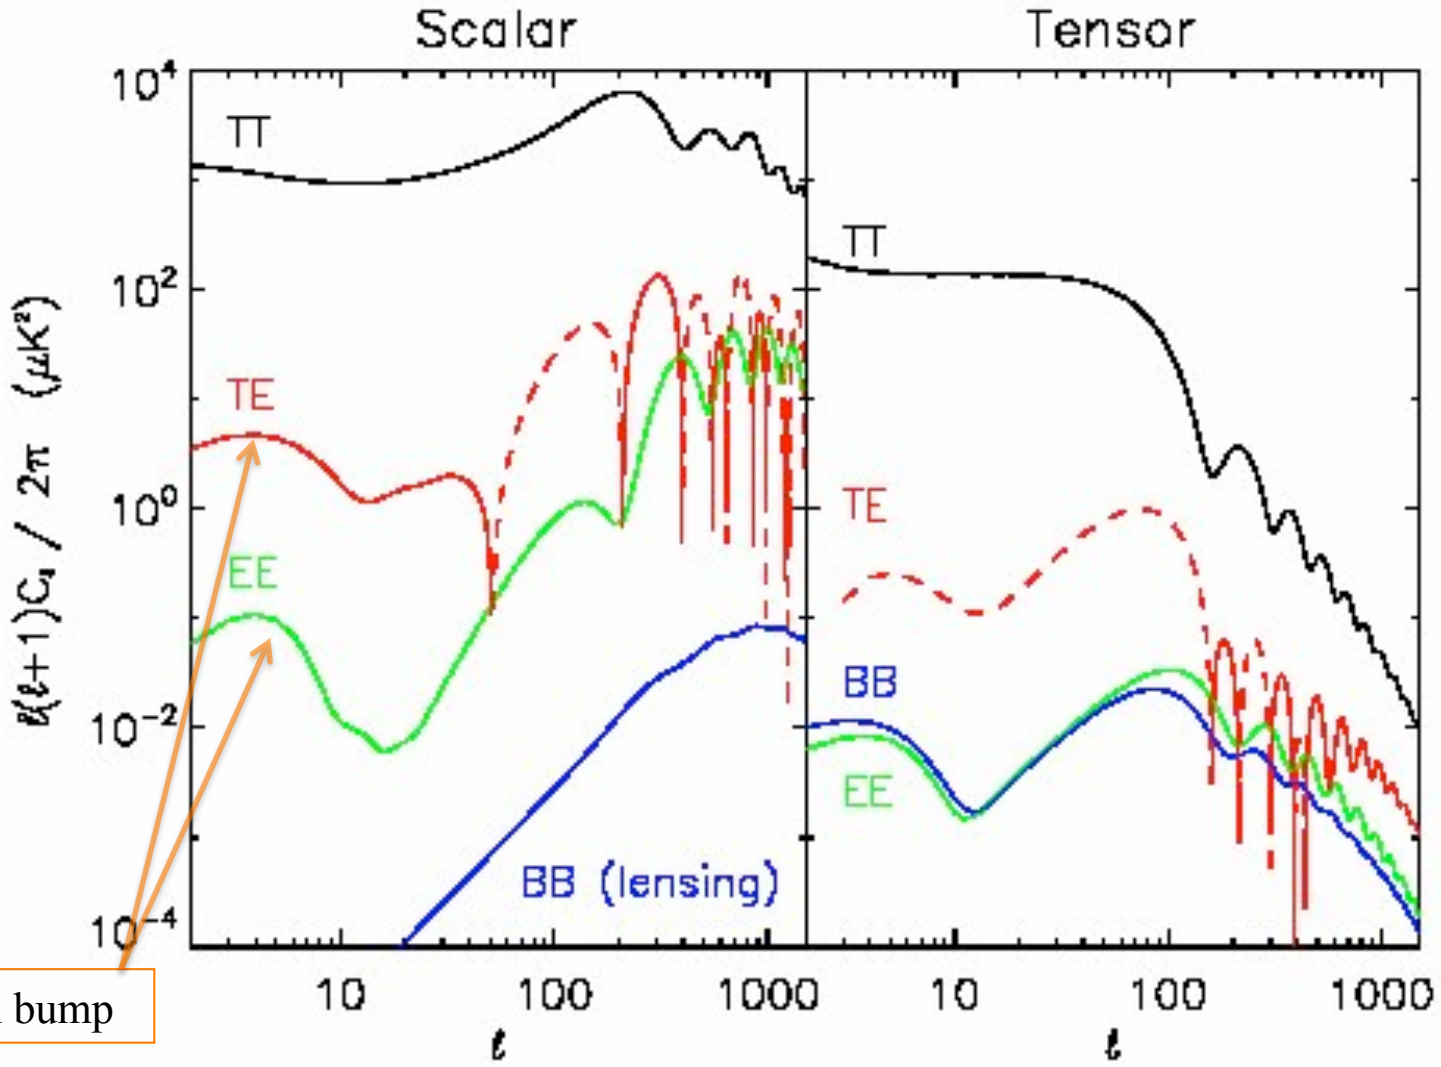
$$\Delta_T \to \Delta_T e^{-\tau} \qquad \Delta_E \to \Delta_E \tau$$

$$C_\ell^{TE} \propto \tau e^{-\tau} \qquad C_\ell^{EE} \propto \tau^2$$

❖ Effect peaks at horizon scale at recombination (l≈2-3). If the optical depth is very large, primordial anisotropies are erased.



Power spectra - Theory



Reionization bump

Gravitational lensing

❖ Large scale density fluctuations in the Universe induce random deflections in the direction of CMB photons as they propagate from last scattering surface to us. In the small scale limit, we have

$$Q(\boldsymbol{\theta}) = \tilde{Q}(\boldsymbol{\theta} + \delta\boldsymbol{\theta}) = (2\pi)^{-2} \int d^2\boldsymbol{l} e^{i\boldsymbol{l}\cdot(\boldsymbol{\theta}+\delta\boldsymbol{\theta})} \times [E(\boldsymbol{l})\cos(2\phi_l) - B(\boldsymbol{l})\sin(2\phi_l)],$$

$$U(\boldsymbol{\theta}) = \tilde{U}(\boldsymbol{\theta} + \delta\boldsymbol{\theta}) = (2\pi)^{-2} \int d^2\boldsymbol{l} e^{i\boldsymbol{l}\cdot(\boldsymbol{\theta}+\delta\boldsymbol{\theta})} \times [E(\boldsymbol{l})\sin(2\phi_l) + B(\boldsymbol{l})\cos(2\phi_l)].$$

(Zaldarriaga & Seljak 1998)

Gravitational lensing

❖ Zaldarriaga & Seljak (1998), PRD 58, 23003.

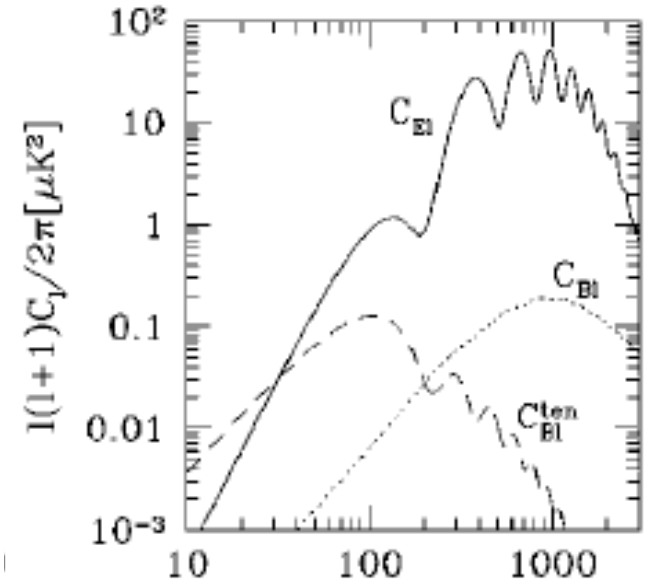
$$C_{Tl} = C_{\tilde{T}l} + \mathcal{W}^{l'}_{1l} C_{\tilde{T}l'} ,$$

$$C_{El} = C_{\tilde{E}l} + \frac{1}{2}[\mathcal{W}^{l'}_{1l} + \mathcal{W}^{l'}_{2l}] C_{\tilde{E}l'} + \frac{1}{2}[\mathcal{W}^{l'}_{1l} - \mathcal{W}^{l'}_{2l}] C_{\tilde{B}l'} ,$$

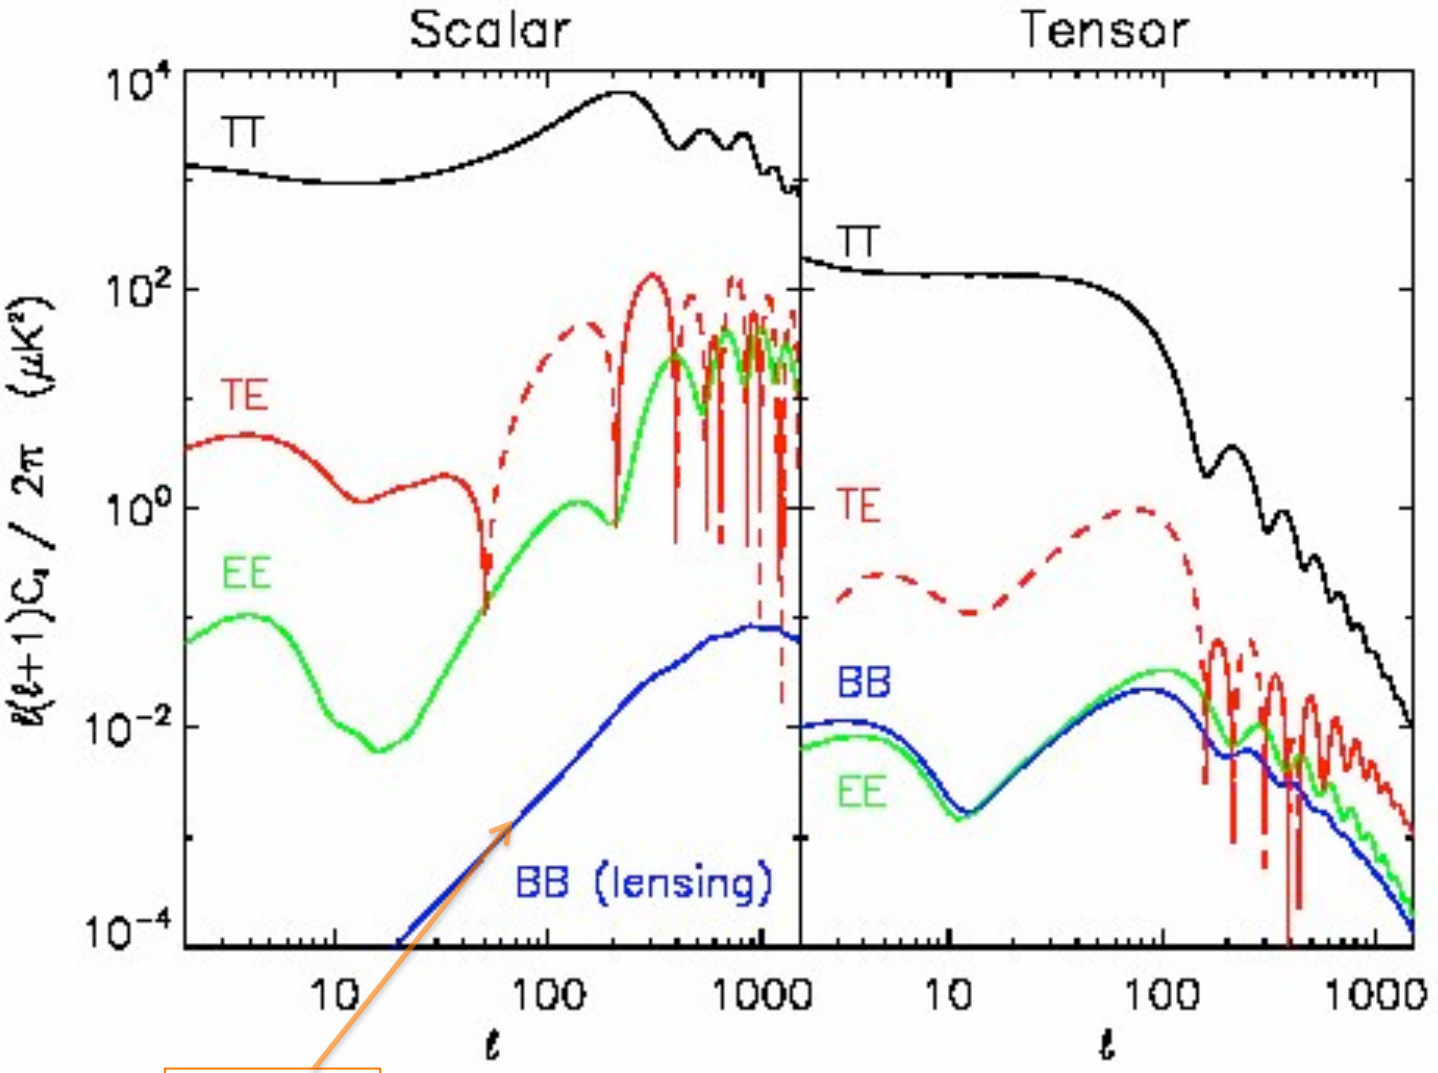
$$C_{Bl} = C_{\tilde{B}l} + \frac{1}{2}[\mathcal{W}^{l'}_{1l} - \mathcal{W}^{l'}_{2l}] C_{\tilde{E}l'} - \frac{1}{2}[\mathcal{W}^{l'}_{1l} + \mathcal{W}^{l'}_{2l}] C_{\tilde{B}l'} ,$$

$$C_{Cl} = C_{\tilde{C}l} + \mathcal{W}^{l'}_{3l} C_{\tilde{C}l'} ,$$

❖ Lensing mixes E and B polarization modes. Even for pure scalar fluctuations, B-modes are generated at small scales.



Power spectra - Theory



Polarization and tensor modes: Gravitational waves

❖ Gravitational waves are a natural consequence of inflationary models (Grishchuk 1974; Rubakov et al. 1982; Starobinsky 1982, 1983; Abbott & Wise 1984).

❖ GW created as vacuum fluctuations (exactly as density perturbations).

❖ GW correspond to spatial metric perturbations. From A. Lasenby´s talk:

- Tensor metric perturbations $ds^2 = a^2[d\eta^2 - (\delta_{ij} + 2h_{ij})dx^i dx^j]$ where h_{ij} is traceless and transverse
- If substitute this into Einstein equations, and use modes of the form $\exp(ik_i x^i)$, then find

$$\ddot{h}_{ij} + 2aH\dot{h}_{ij} + k^2 h_{ij} = 8\pi G\Sigma^T_{ij}$$

  where Σ^T_{ij} is the transverse and traceless part of the anisotropic stress
- Express h_{ij} in terms of the two independent gravitational wave polarization components, h_+ and $h_\times$

Polarization and tensor modes: Gravitational waves

❖From A. Lasenby´s lecture:

- Two independent solutions:

$$h \propto \frac{1}{\eta^3}(\cos(k\eta)k\eta - \sin(k\eta)) \quad \text{and} \quad h \propto \frac{1}{\eta^3}(\cos(k\eta)k\eta + \sin(k\eta))$$

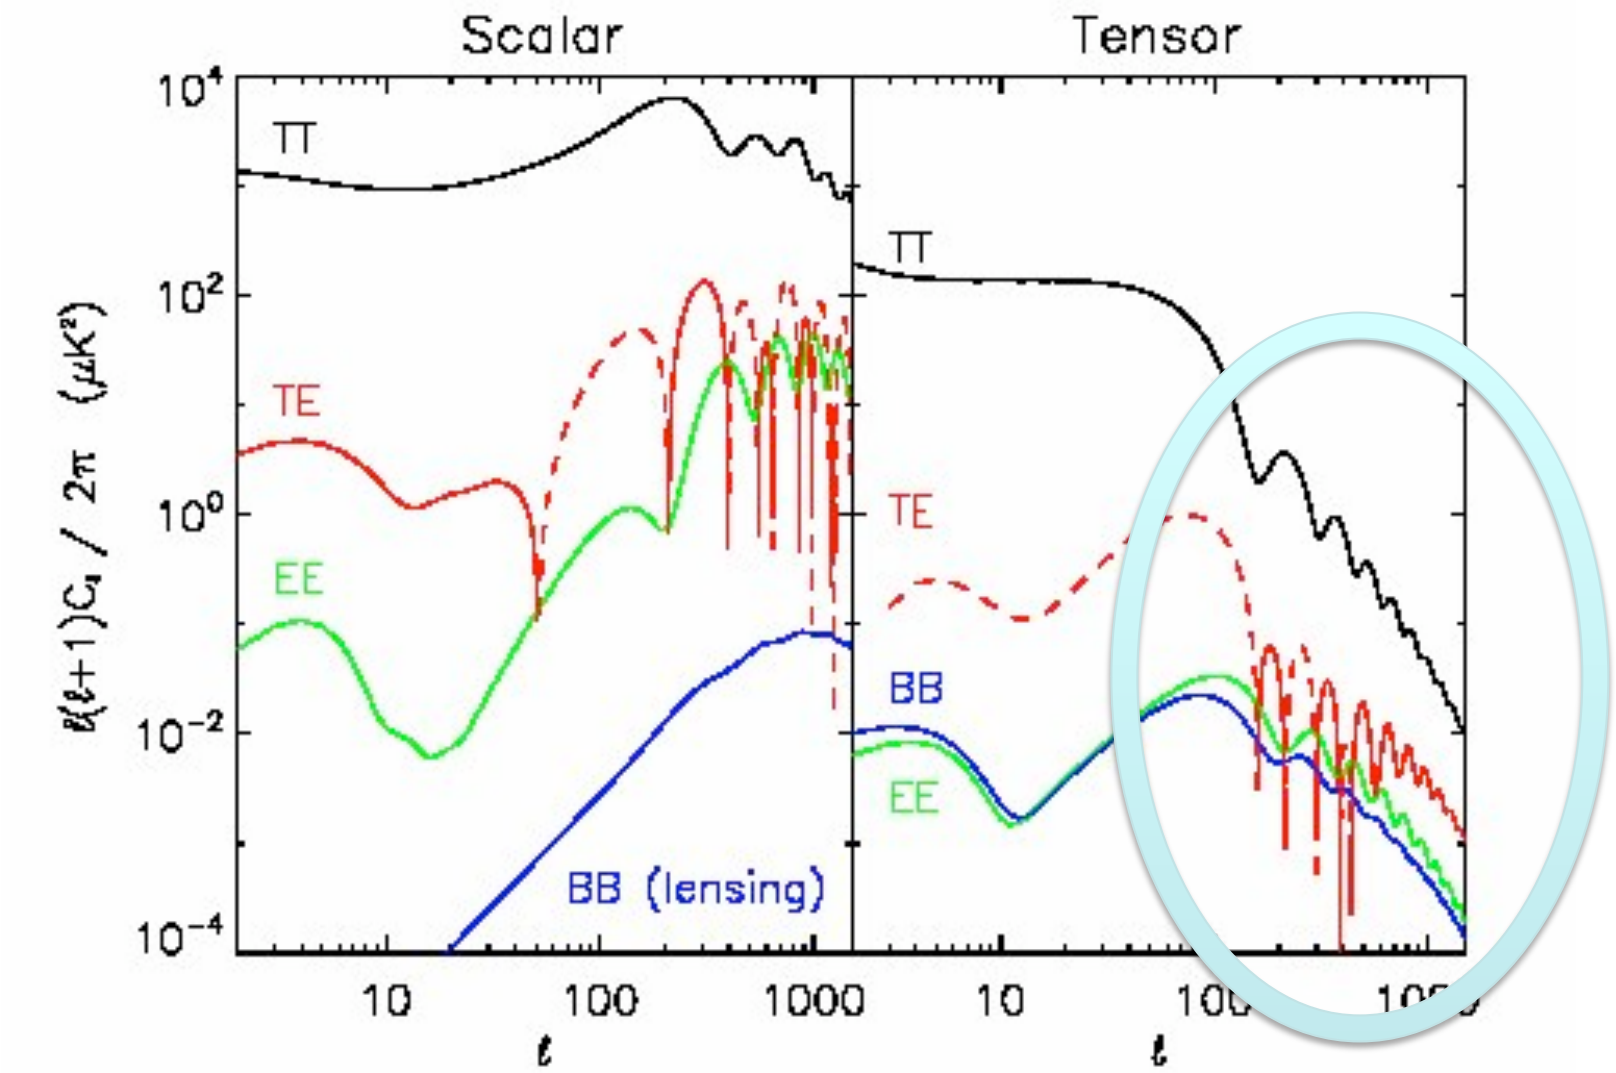
- Find following behavior as one goes back in time: only one of these is non-singular, and here can write

$$h_{+,\times}(\eta) = -\frac{3}{k^3\eta^3}(\cos(k\eta)k\eta - \sin(k\eta))h_{+,\times}(0) = 3\sqrt{\frac{\pi}{2}}\frac{J_{3/2}(k\eta)}{(k\eta)^{3/2}}h_{+,\times}(0)$$

- So this is solution for scales entering the horizon well after matter domination
- Note that overall η dependence for large η is $1/\eta^2 \propto 1/t^{2/3} \propto 1+z$, so the gravitational perturbations redshift away inside the horizon — quite unlike the scalar perturbations
- Therefore only important at degree scales and above

❖ GW oscillate and decay at horizon crossing.

Power spectra - Theory



Effects only on large scales because gravity waves damp inside horizon.

Polarization and tensor modes: Gravitational waves

❖Gravitational waves produce a quadrupolar distortion in the temperature of the CMB.

❖ B-mode polarization is produced, because the symmetry of a plane wave is broken by the transverse nature of gravity wave polarization.

$$C_{El}^{(T)} = (4\pi)^2 \int k^2\, dk\, P_h(k) \left| \int d\tau\, g(\tau)\Psi(k,\tau)\left[-j_l(x) + j_l''(x) + \frac{2j_l(x)}{x^2} + \frac{4j_l'(x)}{x} \right] \right|^2,$$

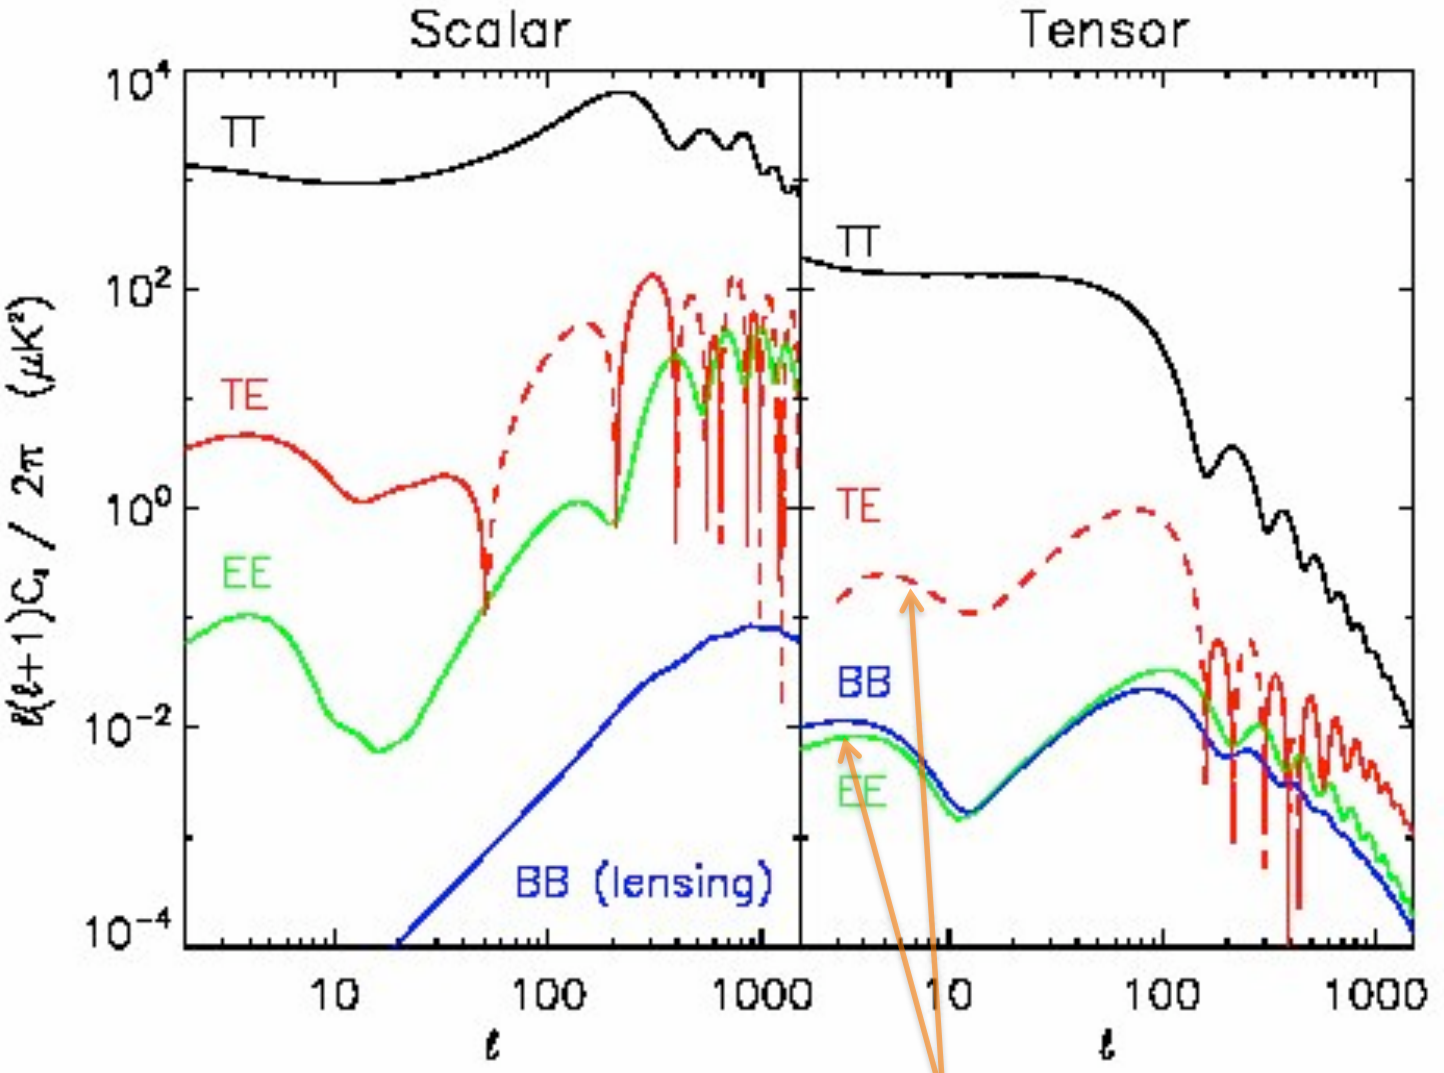
$$C_{Bl}^{(T)} = (4\pi)^2 \int k^2\, dk\, P_h(k) \left| \int d\tau\, g(\tau)\Psi(k,\tau)\left[2j_l'(x) + \frac{4j_l}{x} \right] \right|^2,$$

(Seljak & Zaldarriaga 1997)

❖ E and B modes have similar amplitude.

❖Again, polarization is only generated at last scattering surface (or reionization).

Power spectra - Theory



What would a detection of GW tell us?

- It would provide strong evidence that inflation happened!
- The amplitude of the power spectrum is a (model-independent) measurement of the energy scale of inflation.

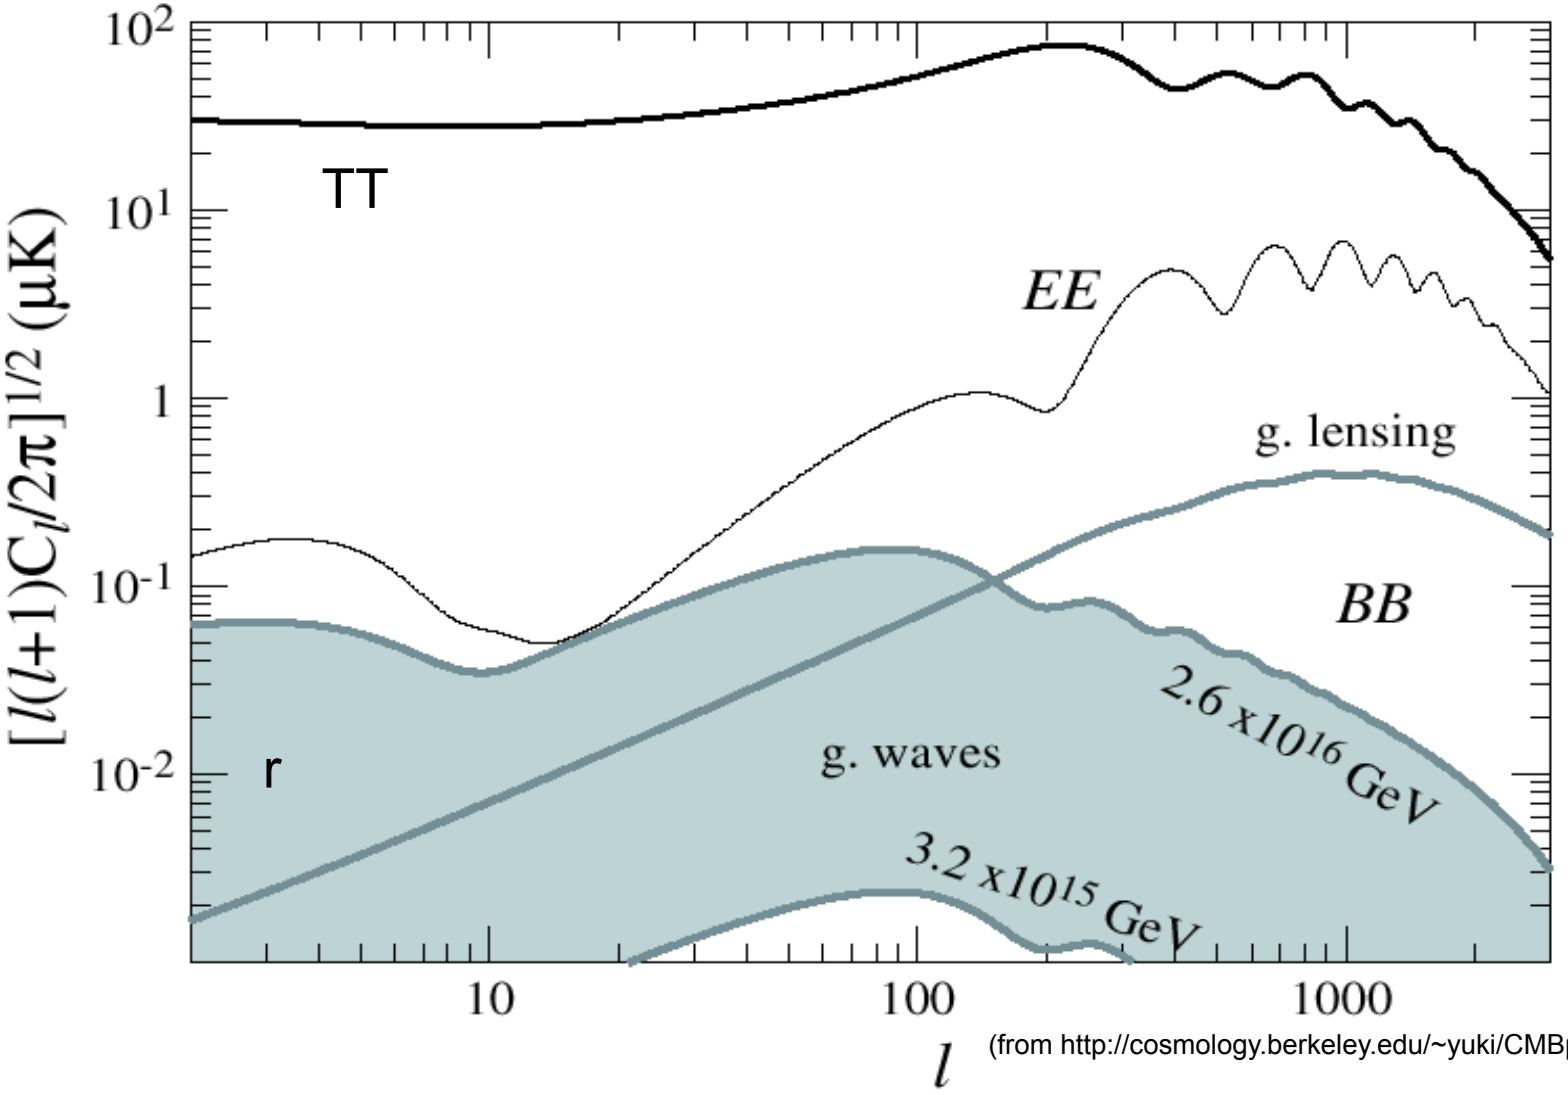
$$P_{tensor} = \frac{8}{m_{Pl}^2}\left(\frac{H}{2\pi}\right)^2 \propto E_{\inf}^4$$

- Defining the tensor-to-scalar ratio (r) at a certain scale k_0 (typically 0.001 Mpc^{-1}), we have

$$r \equiv \frac{P_{tensor}(k_0)}{P_{scalar}(k_0)} = 0.008\left(\frac{E_{\inf}}{10^{16}GeV}\right)^4$$

- Values of r of the order of 0.01 or larger would imply that inflation occurred at the GUT scale.
- These scales are 12 orders of magnitude larger than those achievable at LHC!

Primordial gravitational waves and B-modes



(from http://cosmology.berkeley.edu/~yuki/CMBpol/CMBpol.htm)

- r=0.1 corresponds to an energy scale of inflation around 2×10^{16} GeV.

Direct measurements of primordial Gravitational Waves

Raising/lowering operators

An important property of spin-s functions is that there exists a spin raising (lowering) operator $\eth$ ($\bar{\eth}$) with the property of raising (lowering) the spin weight of a function, $(\eth_s f)' = e^{-i(s+1)\psi}\eth_s f$, $(\bar{\eth}_s f)' = e^{-i(s-1)\psi}\bar{\eth}_s f$. Their explicit expression is given by

$$\eth_s f(\theta,\phi) = -\sin^s(\theta)\left[\frac{\partial}{\partial\theta} + i\csc(\theta)\frac{\partial}{\partial\phi}\right]\sin^{-s}(\theta)\,{}_s f(\theta,\phi),$$

$$\bar{\eth}_s f(\theta,\phi) = -\sin^{-s}(\theta)\left[\frac{\partial}{\partial\theta} - i\csc(\theta)\frac{\partial}{\partial\phi}\right]\sin^{s}(\theta)\,{}_s f(\theta,\phi). \tag{A2}$$

Raising/lowering operators

❖ They can be used to define spin zero quantities:

$$\bar{\eth}^{\,2}(Q+iU)(\hat{\boldsymbol{n}})=\sum_{lm}\left[\frac{(l+2)!}{(l-2)!}\right]^{1/2}a_{2,lm}Y_{lm}(\hat{\boldsymbol{n}}),$$

$$\eth^{2}(Q-iU)(\hat{\boldsymbol{n}})=\sum_{lm}\left[\frac{(l+2)!}{(l-2)!}\right]^{1/2}a_{-2,lm}Y_{lm}(\hat{\boldsymbol{n}}).$$

❖ For real-space computations, it is useful to define:

$$\begin{aligned}\chi_E &\equiv [\bar{\eth}\,\bar{\eth}(Q+iU)+\eth\eth(Q-iU)]/2\\ &=-\sum_{lm}[(l+2)!/(l-2)!]^{1/2}a_{E,lm}Y_{lm},\\ \chi_B &\equiv i[\bar{\eth}\,\bar{\eth}(Q+iU)-\eth\eth(Q-iU)]/2\\ &=\sum_{lm}[(l+2)!/(l-2)!]^{1/2}a_{B,lm}Y_{lm}.\end{aligned}$$

E/B mixing

❖In finite patches of sky, the separation between E and B modes can not be done perfectly.

❖ Aliasing effects from E modes into B modes are very important, as E-mode spectrum is much larger in amplitude.

❖Specific methods in Fourier space or real space to minimize this problem.

TB, EB and BB spectra: hints for new physics?

Testing CPT Symmetry

if terms like Chern-Simons have to be added to the standard electrodynamic Lagrangian, than Lorentz, P and CPT symmetries will be violated. This will induce a rotation of the polarization direction of each photon as it propagates from the LSS to us. This effect is called "Cosmic Birefringence"

$$C_\ell^{\mathrm{TE,obs}} = C_\ell^{\mathrm{TE}} \cos(2\Delta\alpha),$$

$$C_\ell^{\mathrm{TB,obs}} = C_\ell^{\mathrm{TE}} \sin(2\Delta\alpha),$$

$$C_\ell^{\mathrm{EE,obs}} = C_\ell^{\mathrm{EE}} \cos^2(2\Delta\alpha),$$

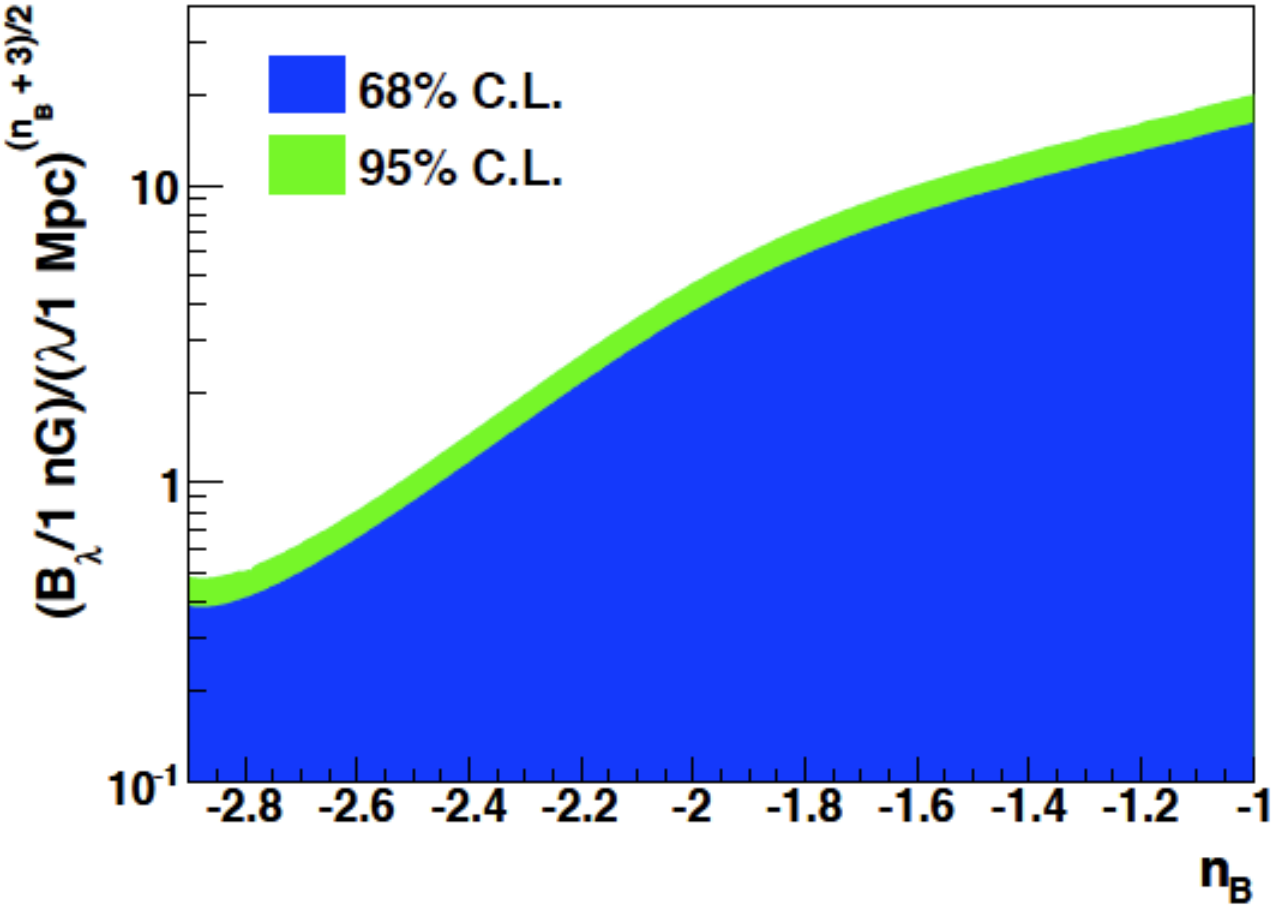
$$C_\ell^{\mathrm{BB,obs}} = C_\ell^{\mathrm{EE}} \sin^2(2\Delta\alpha),$$

$$C_\ell^{\mathrm{EB,obs}} = \tfrac{1}{2}(C_\ell^{\mathrm{EE}}) \sin(4\Delta\alpha).$$

alpha = Birefringence angle

From these equations it is possible to build estimators for alpha (as long as it is zero these violating terms are excluded)

Constraining Primordial magnetic fields



- Faraday rotation by a primordial magnetic field produce B-mode polarization.
- Kahniashvili et al. (2008). At scales of 1 Mpc and n_B=-2.9, constraints are better than 1nG (extrapolated to present).

Observability of B-modes

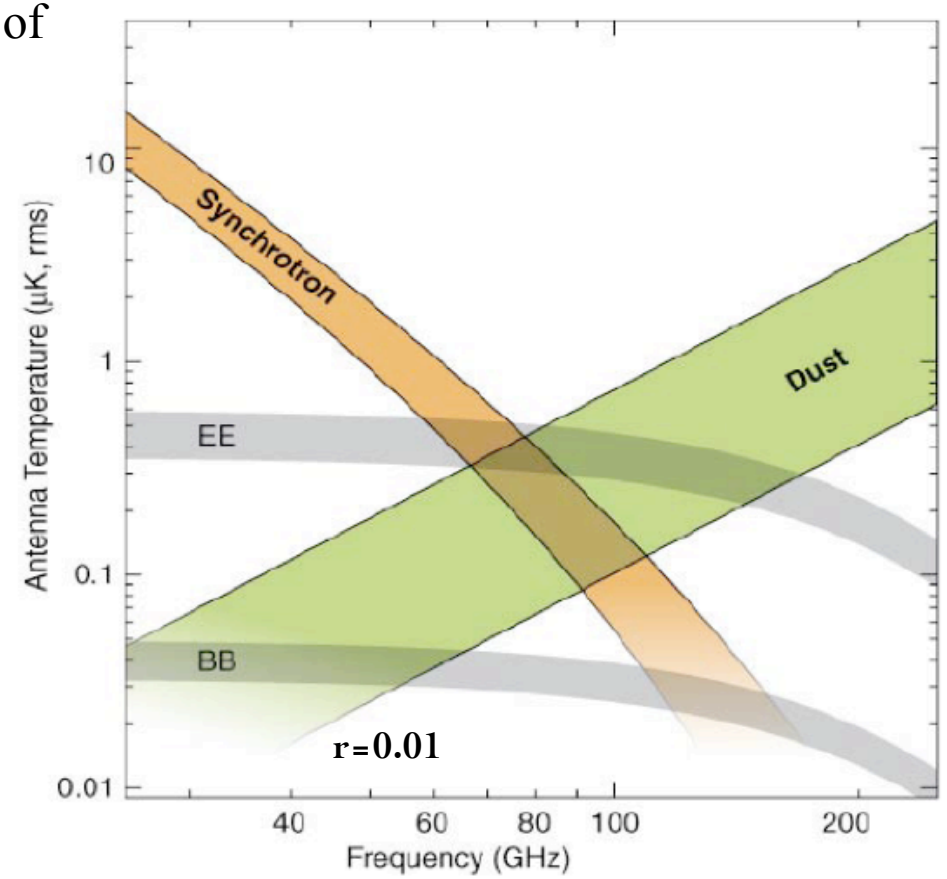
❖ Critical issues:

• **Signals are extremely small** ⇒ large number of receivers with large bandwidths are required.

• Accurate **control of systematics** (cross-pol, spillover,...) is mandatory.

• **Foregrounds**. B-mode signal is subdominant over Galactic foregrounds

- Free-free, low-freq, not polarized
- Synchrotron, low-freq, pol ~10%
- Thermal dust, high-freq, pol ~10%
- Anomalous emission, 20-60 GHz, pol ~3%?
- Point sources, low-freq, pol ~5%



GRAVITY WAVE GENERATION BY VORTICAL FLOWS IN A ROTATING FRAME

Preface

This thesis is the result of my own work, and includes nothing which is the outcome of work done in collaboration. Except where stated otherwise, the research reported in this thesis is original. No part of it has been submitted for a degree or any similar qualification at any other university.

This thesis would not have been possible without the enthusiasm, suggestions and encouragement of my supervisor, Professor Michael E. McIntyre. His enduring love of fluid dynamics will remain an inspiration to me for the rest of my life. All members of the atmospheric dynamics group have, at some time, made a valued contribution to my academic life in DAMTP. I would particularly like to thank Peter Haynes for discussions about instability theory, David Dritschel for discussions about vortex dynamics and conformal mappings, and Saravanan for suggestions about numerical modelling. Stephen Cowley generously allowed me use of his computational resources to enable me to complete the simulations in chapter 4 quickly. I would also like to thank the people who have given so generously of their time over the last few months in reading the manuscript and suggesting improvements to it. They are Ben Edgington, Stefan Llewellyn-Smith, Gudrun Magnusdottir, John Scinocca and David Tan — my deepest thanks to you all. I would also like to thank all other members of DAMTP, research staff, computer officers and secretaries, who have helped me in any way.

Throughout my thesis work I have profited from discussions with many scientists at other institutions. Particular thanks go to Glenn Flierl, Joe Keller, Bernard Legras, Lorenzo Polvani, Rich Rotunno, Ted Shepherd and Joe Tribbia. During the summer of 1992 I was a fellow at the Woods Hole Summer School in Geophysical Fluid Dynamics. I thank the organisers and participants for an enjoyable and rewarding summer.

For financial and travel support I thank the Natural Environment Research Council, and for travel support I thank additionally Churchill College and the European Geophysical Society. Finally, I would like to thank my parents for getting me this far, and for their unending love.

Chapter 1

Introduction

1.1 Balance and Imbalance

> *"The striking errors in the 'forecast', which has been obtained by computing forms, may be traced back to the large apparent convergence of wind. It may be asked whether this spurious convergence arises from the errors of observations with balloons, or from the finite horizontal differences being to large, or thirdly from the process by which winds at points, arranged in a rectangular pattern, are interpolated between the observing stations ..."*

Thus Richardson (1922) first gave prominence to the idea that inaccuracies in the data used to initialize his pioneering numerical forecast could have given rise to the failure of that forecast. The failure consisted of large spurious variations in the computed pressure field over a 6 hour forecast interval. In fact, Richardson had forecast a pressure variation in one location of 145mb in 6 hours, whereas the actual change in pressure over that period had been of the order of 1mb.

The phenomenon that Richardson had come upon is well known today both to theoreticians and to practitioners of numerical weather prediction - that large scale atmospheric flow away from the equator is, to a good first approximation, in a state of geostrophic balance, in which the Coriolis and pressure gradient terms constitute the principal balance in the horizontal momentum equation.

It now seems almost certain (Platzman 1967, 1968) that Richardson developed some appreciation of this fact in the following twenty years, and that the difficulty had even been foreseen by Margules (1904). Eventually, however, it was when Charney (1951) applied his recently-developed "quasi-geostrophic" theory (Charney 1947, 1948, 1949) to numerical forecasting that forecasts were able to predict an evolution of fields at least qualitatively in line with observations. Even more remarkable in Charney's (1948) paper is his far-sighted remark that the conservation of potential temperature and potential vorticity on fluid particles may alone be sufficient to determine the nature of large scale atmospheric motions. In his words

> *"The motion of large-scale atmospheric disturbances is governed by the laws of conservation of of potential temperature and potential vorticity, and by the conditions that the horizontal velocity be quasi-geostrophic and the pressure be quasi-*

hydrostatic."

In present day terminology, adopted in this thesis, the quasi-geostrophic and quasi-hydrostatic conditions are "balance" conditions, which enable one to determine the velocity and temperature fields knowing only the mass under each isentropic surface, and the distribution of potential vorticity on each isentropic surface. The resulting system of equations is referred to as a balanced model.

Some appreciation of the importance of potential vorticity had already been developed in the ten years preceeding Charney's work. Rossby (1936), Rossby *et al.* (1939) and Ertel (1942) had been independently developing some fundamental understanding of the dynamical implications of the conservation of potential vorticity on fluid particles, although they did not postulate that it could be "inverted" to give other dynamical information, as Charney (1948) had noted in his "quasi-geostrophic" approximation. The first explicit application of potential vorticity inversion was made by Kleinschmidt (1950a,b;1951,1955,1957), who used an exact form of potential vorticity inversion for axisymmetric structures in his studies of upper level cyclones.

The potential vorticity Q is defined by

$$Q = \rho^{-1}(2\boldsymbol{\Omega} + \nabla \times \boldsymbol{u}).\nabla\theta, \tag{1.1}$$

where ρ is the air density, Ω is the Earth's angular rotation vector, $\boldsymbol{u}$ is the fluid velocity in coordinate axes fixed on the Earth, and θ is the potential temperature (or any function of it). In the absence of friction or diabatic processes, Q is a materially conserved quantity:

$$\frac{DQ}{Dt} = 0. \tag{1.2}$$

Although the hydrostatic approximation is valid for large scale motion throughout the atmosphere, the quasi-geostrophic approximation is seldom sufficiently accurate to render it of practical use in numerical weather prediction. On the other hand, the absence of any balancing procedure is known to give rise to large errors of the type encountered by Richardson. Consequently, balanced equations have been developed for atmospheric modelling which are more accurate than the quasi-geostrophic equations, while still retaining the robustness of a balanced system of equations, being insensitive to errors in the initial data. Indeed, although the "quasi-

geostrophic" approximation remains the best known example of a balanced system, many others have been proposed, each with varying degrees of analytical tractibility and practical accuracy.

At this point, it is essential to be clear as to exactly what is required of a balanced model. Following Hoskins *et al.* (1985), we may define a balanced model by prescribing a method for determining the velocity field everywhere given only the mass under each isentrope (θ-surface), the potential vorticity distribution on each isentrope, and the θ distribution on the boundary of the domain. The proposed "inversion" procedure should not depend on knowledge of the PV distribution at any time other than the current time. The integration forward in time proceeds in principle by advecting the potential vorticity according to (1.2).

Before proceeding, in §1.2, to a discussion of how one might set about inverting the potential vorticity to obtain the other dynamical fields, it is instructive to consider the features of the flow which no balanced model, however accurate, can capture.

To fix ideas, let us consider the shallow water equations on an f-plane:

$$\frac{D\boldsymbol{u}}{Dt} + f\boldsymbol{k} \times \boldsymbol{u} + g\nabla h = 0 \tag{1.3}$$

$$\frac{Dh}{Dt} + h\nabla.\boldsymbol{u} = 0, \tag{1.4}$$

Firstly, we consider the dispersion relation for the linearized system corresponding to (1.3,1.4):

$$\omega(\omega^2 - f^2 - c_0^2(k^2 + l^2)) = 0, \tag{1.5}$$

where ω is the wave frequency and $c_0 = (gH)^{1/2}$ is the gravity wave phase speed. There are three roots. One root, $\omega = 0$, corresponds to "slow" waves, which are the analogue of Rossby waves in this system. Their frequency would be modified in the presence of a background planetary vorticity gradient. The other two roots correspond to propagating waves only if $\omega > f$. These correspond to "fast" surface inertio-gravity waves, which owe their existence to the restoring effect of gravity on the free surface, and whose frequency is modified by background rotation.

In a balanced model, however, there is only one time derivative, resulting from the advection of potential vorticity. The resulting dispersion relation will therefore have only one root, which must, by symmetry, correspond to some appropriate generalization of the slow Rossby wave. A balanced model is therefore a model which filters from the equations of motion gravity waves, which are generally of much greater phase speed than typical fluid velocities.

Moreover, since a balanced model contains two fewer time derivatives that the full system, the inversion procedures required by a balanced model to obtain the velocity and height fields from the potential vorticity can in general be defined by imposing two constraints on the full shallow water system. The selection of the two constraints must be made carefully, however, if the model is still to possess analogues of potential vorticity, which should be conserved on fluid particles, and analogues of total mass, energy, and enstrophy, which should be conserved globally. Indeed, several popular balanced models, such as the Balance Equations (Lorenz, 1960) in the form in which they are usually integrated, do not possess a full set of conservation laws. However, from a theoretical viewpoint, it nonetheless seems clear that the unifying concept in any discussion of balanced dynamics must be that of advection of potential vorticity on fluid particles, together with the specification of sufficient constraints that the potential vorticity can be inverted to give all the other dynamical information necessary to proceed with the integration.

A second thought experiment which one can conduct, and which also illustrates that there cannot be freely propagating gravity waves in a balanced model, is to consider the classical "Rossby adjustment" problem (see, e.g., Gill, 1982). In this thought experiment we consider a rotating shallow water fluid consisting of two semi-infinite regions of uniform potential vorticity of different values, which intersect along a straight line of infinite length. If we suppose that initially there is no motion then, by considering the potential vorticity, there must be a discontinuity in surface elevation along the line of intersection. Now suppose that ultimately the fluid evolves to remove the surface discontinuity. By symmetry, the final state must also be one of two semi-infinite regions of uniform potential vorticity intersecting along a straight line of infinite length, but the energy associated with this final state is always less than the energy associated with the initial state.

Now, since the potential vorticity is uniform everywhere in the fluid away from the interface, its conservation on fluid particles reduces the number of independent time derivatives away from the interface from three to two in the fluid away from the interface. The resulting waves in these regions are therefore gravity waves, which can propagate away from the interface to infinity, and account for the loss of energy. To a balanced model, however, which depends only upon knowledge of the potential vorticity field, both initial and final states look exactly the same, and would possess the same velocity and height fields. There is no Rossby adjustment, and no

gravity wave radiation.

1.2 Potential vorticity inversion

Over the years, many balanced models have been proposed for use in different circumstances. In this section, we start by deriving two very simple balanced models via scaling arguments, and proceed to discuss different ways in which balanced models can be constructed.

To begin, let us return briefly to the shallow water equations, this time on a β-plane:

$$\frac{D\boldsymbol{u}}{Dt} + f\boldsymbol{k} \times \boldsymbol{u} + g\nabla h = 0 \tag{1.6}$$

$$\frac{Dh}{Dt} + h\nabla.\boldsymbol{u} = 0, \tag{1.7}$$

in which the Coriolis parameter f represents $f_0 + \beta y$, where f_0 and β are constants. Let us further assume that $\beta y \ll f_0$ (in a sense to be defined), so that the Coriolis parameter does not change much over the range of latitudes which we are considering (these assumptions are made here to facilitate a pedagogical development of a "potential vorticity view" of quasi-geostrophy, and will be removed in subsequent discussions of balance). The potential vorticity is defined as

$$Q = \frac{f + \zeta}{H + h}, \tag{1.8}$$

where H is the mean layer depth and h represents departures of the total layer depth from the mean; and ζ is the relative vorticity. Let us now assume, as is implicit in the scalings of Charney (1948), that Q has only small departures from its background value f_0/H. This requires that the Rossby number $Ro = U/fL \ll 1$, so that

$$Q \sim \frac{f_0}{H} + \frac{\zeta + \beta y}{H} - \frac{f_0 h}{H^2}. \tag{1.9}$$

Then the advective timescales D/Dt must be long compared with the inertial timescale f_0^{-1}, so the shallow water momentum equation (1.6) gives

$$f_0\boldsymbol{k} \times \boldsymbol{u} + g\nabla h = 0 \tag{1.10}$$

at leading order. Taking the curl of this equation implies $\nabla.\boldsymbol{u} = 0$. Therefore we can introduce a streamfunction ψ such that $\boldsymbol{u} = \boldsymbol{k} \times \nabla\psi$, and from (1.10) we have $h = (f_0/g)\psi$. The

approximation (1.9) to the potential vorticity becomes

$$Q \sim \frac{1}{H}\left(f_0 + \beta y + \nabla^2\psi - \frac{f_0^2}{gH}\psi\right). \tag{1.11}$$

Scaling arguments show that f_0 is an order of Ro^{-1} larger than either of the terms involving ψ in (1.11), which are themselves of the same order of magnitude, and hence the effects of local potential vorticity anomalies and the background planetary vorticity gradient enter at the same order in the quasi-geostrophic scaling if $\beta y/f_0 = O(Ro)$.

It follows that, knowing Q, one can in principle invert (1.11) with evanescence or no normal flow boundary conditions to give ψ, and hence $\boldsymbol{u}$ and h.

An alternative, but equally valid, balance condition is to relax the assumption that potential vorticity perturbations are small compared with the background value f_0/H, but to continue to assume, as is implicit in the quasi-geostrophic scaling, that the Froude number $F = U/(gH)^{1/2} \ll 1$. The implication of this assumption (see chapter 2 for details of the scaling analysis) is that $h/H = O(F^2)$. This means that height perturbations are small, the flow is approximately non-divergent, and the potential vorticity perturbations are dominated by the relative vorticity ζ and variations in the planetary vorticity βy, which is not now required to be small compared with f_0. Once again we may introduce a streamfunction ψ, but now the potential vorticity becomes

$$Q \sim \frac{1}{H}\left(f_0 + \beta y + \nabla^2\psi\right). \tag{1.12}$$

The result is the Euler equations for a two-dimensional incompressible perfect fluid. Again, decay of velocity to infinity or no normal flow boundary conditions can be used to invert (1.12) to give velocity and height fields.

The quasi-geostrophic and Euler equations have been widely used for both analytical and numerical work. Analytically, and from the perspective of the "contour dynamics" algorithm (Dritschel, 1989, 1993; Pullin 1992; Dritschel & Saravanan 1993) they are attractive because a linear operator (Laplacian or Helmholtzian) must be inverted to obtain the other dynamical fields from the potential vorticity. Along with the Planetary Geostrophic or "thermocline" equations (Robinson & Stommel, 1959), in which the effects of inertia are neglected entirely, they are the only balanced models to have been proposed in which only linear operators need be inverted. From the perspective of numerical methods other than contour dynamics, their

advantage also derives from their simplicity. Indeed, few other balanced models can be integrated as quickly as the full shallow water equations, provided the latter are integrated using a large implicit time-step (Allen, personal communication).

The disadvantage of these simple balanced models lies in that they are only leading order approximations, and it is quite possible that one could proceed to higher order in Rossby or Froude number before nonlinear coupling between vortical motions and gravity waves led inevitably to the appearance of freely propagating gravity waves in the solution, and made any further improvements fundamentally impossible.

Indeed, the quasi-geostrophic approximation places two additional constraints upon the flow: the Coriolis parameter can vary only by an amount of order Rossby number throughout the entire domain of interest, and the surface elevation must have a gradient of the order of the Rossby number. These restrictions can be lifted by using the semi-geostrophic approximation (Salmon, 1985), which is also a low Rossby number approximations, formally valid to the same order in Rossby number as the quasi-geostrophic approximation. An interesting derivation of the semi-geostrophic system with variable Coriolis parameter and order-one surface gradients was given by Salmon (1988a), in which he showed that the semi-geostrophic equations can be derived from the shallow water system by making an approximation to the symplectic tensor in a constrained Hamiltonian, whereas an equivalent derivation of the quasi-geostrophic equations required the arbitrary introduction of a reference state and a metric tensor. The Euler equations were also derived via the constrained Hamiltonian approach, making approximations in the symplectic tensor. This method ensures that any balanced equations which are derived possess a full set of conserved quantities.

The essential point is that, although in principle the quasi-geostrophic system had solved the basic problem of unbalanced fields which Richardson had encountered, by the mid-1950s it was becoming clear that something more accurate was needed for practical purposes. A significant development in balanced models occurred when Charney (1955) proposed a balanced system with a higher order of approximation than the quasi-geostrophic system.

For his new system, he assumed that the flow was non-divergent ($\nabla.\boldsymbol{u} = 0$). Taking the divergence of the momentum equation (1.6), and applying $\nabla.\boldsymbol{u} = 0$, one obtains a second

constraint:

$$\nabla.(f\nabla\psi) + 2\left(\frac{\partial^2\psi}{\partial x^2}\frac{\partial^2\psi}{\partial y^2} - \left(\frac{\partial^2\psi}{\partial x\partial y}\right)^2\right) = \nabla^2 h. \tag{1.13}$$

The two constraints, (1.13) and $\nabla.\boldsymbol{u} = 0$, thus constitute a balanced model.

Condition (1.13) was also one of the balance constraints used by Lorenz (1960) in his derivation of what have now become known as the Balance Equations. However, although he used only the rotational component of the velocity in his balance constraint (1.13), some divergence remains in his system. The divergence is obtained via a diagnostic relation, and is used in the prognostic equation for the vorticity. The system constitutes a balanced model, since there is one prognostic equation and two constraints, although vorticity, rather than potential vorticity, has typically been used as the prognostic variable of integration in numerical work (Norton *et al.*, 1986).

McWilliams (1992) presents a scaling analysis to show that (1.13) is formally valid when $F^2 \ll 1$ and $F^2/Ro \ll 1$. At high Rossby number, the condition is simply one of small divergence, and at leading order (1.13) reduces to the barotropic vorticity equation. At small Rossby number one recovers the quasigeostrophic scaling, and (1.13) reduces to quasigeostrophic balance.

The Balance Equations have been the focus of several numerical studies over the last decade. Norton *et al.* (1986) show how the balance equations may be implemented in a numerical scheme, and McWilliams *et al.* (1986) present a numerical study of oceanic vortices on a β plane, in which there is practically no discernable difference between the potential vorticity fields of the Balance Equation integrations and the shallow water integrations. In their cases, Rossby numbers are of order one, but they consider vortices which are either barotropic or have at most two baroclinic modes. The structures are thus rather deep, and their Froude numbers are consequently rather small, so explaining the good agreement between Balance Equation and shallow water integrations.

An extensive numerical and analytical investigation of the properties of a large number of different balanced models has been presented by Allen *et al.* (1990a,b) and Barth *et. al* (1990). In addition to considering existing balanced models, they also present some models of their own. In interpreting their results, however, it should be noted that their models impose only one, not two, constraints, on the dynamics, and two fields must be integrated in the subsequent

evolution (albeit that one is integrated using an implicit time step). Their models should not therefore be regarded as balanced models in the sense described above, although their dynamics are certainly constrained in some way. For the purposes of this discussion, I shall refer to these as "semi-balanced" models.

The first paper (Allen *et al.*, 1990a), presents the models they considered, and investigates properties of their stationary solutions and coastal Kelvin waves. Following Gent & McWilliams (1983a), they use boundary conditions in such a form that coastally trapped Kelvin waves are retained in all balanced models except the quasi-geostrophic model. In the subsequent analysis of the performance of the different models, presented in the second and third papers, they take as a measure of model accuracy the root mean square departure of the surface height from that of the corresponding shallow water integration.

The second paper (Barth *et al.*, 1990) investigates the evolution when the models are initialized with sinusoidal flow over a Gaussian topography in a doubly periodic geometry. The main conclusion is that the classical Balance Equations perform best - almost as well as the shallow water equations. One of the "semi-balanced" models constructed by Allen *et al.* (1990a) performs about equally well though, for reasons described above, should probably not be regarded as a balanced model. The quasigeostrophic model invariably performs the worst, all the more so when the topography is of order one height.

The third paper (Allen *et al.*, 1990b) is similar in spirit to the second, but the geometry is now a confined channel, which makes desirable the inclusion of coastal waves in as many balanced models as will support them. To satisfy the channel wall boundary conditions, the initial flow is uniform, rather than sinusoidal. Similar results on the relative accuracy of the various balanced models are found here when compared with those presented in the second paper, although in this case one of the "semi-balanced" systems performs better than the Balance Equations, and even better than the shallow water equations with a large implicit time step.

Spall & McWilliams (1992) addressed the question of whether there might be significantly more accurate balance schemes than the Balance Equations by comparing integrations of the Balance Equations and of a higher order balance scheme with integrations of the shallow water equations initialized with the same (balanced) fields in a doubly-periodic domain. They define the "unbalanced" amplitude for any field as the difference between the balanced model inte-

gration and the shallow water integration with the same balanced initial fields. In their study, they find that, at very low Rossby numbers, the higher order balance scheme initially gives rise to less energy in the unbalanced motions than the Balance Equations, but in time both orders of balance lead to the same (very small) degree of energy in the unbalanced flow. At higher Rossby number, agreement between the two different orders of balance is even closer for earlier times, and remains good for the whole integration, but both model integrations depart significantly further from the corresponding shallow water integrations than was the case at low Rossby number.

They present two different scaling analysis to investigate the nature of the "unbalanced" flow, which predict how its amplitude should scale with Froude and Rossby numbers. At low Rossby numbers, the unbalanced flow is consistent with a single scale analysis, which assumes that it has length and time scales of the same order as the balanced flow. The so-called unbalanced flow therefore has characteristics very similar to the balanced flow, and it seems plausible that it might be possible to obtain it as a higher order correction to balance in a more accurate balanced model. At high Rossby numbers, however, the amplitude of the unbalanced flow is consistent with a multiple scale analysis. The multiple scale analysis assumes that the unbalanced flow is dominated by free gravity waves, which appear to inherit the length scale of the balanced motions, but possess significantly higher frequencies. They conclude that at low Rossby numbers further corrections may be possible to their balance schemes, since the dynamics which is not captured by the balanced models seems nonetheless similar in character to the balanced dynamics. On the other hand, at high Rossby numbers the principal component of the unbalanced flow is similar for both balanced models, but is essentially different from the balanced dynamics. The principal unbalanced flow in this case corresponds to freely propagating gravity waves. Such motions are, for reasons described in §1.1, essentially unbalanced, and can almost certainly not be slaved to the potential vorticity evolution, as is required for a balanced model.

Charney balance (condition (1.13) with $\nabla.\boldsymbol{u} = 0$) was the basis for a study of a series of balanced models by Norton (1988), and McIntyre & Norton (1993). Their hierarchy of balanced models was constructed by successively eliminating higher order Eulerian or Lagrangian time derivatives of the divergence field. Their "first order" balance sets the divergence field and its first Eulerian time derivative to zero, and is therefore equivalent to Charney's (1955) balance

scheme. Their "second order" balance sets the first and second time derivatives of the divergence field to zero, their "third order" the second and third time derivatives to zero, and so on. With two constraints now supplied, they use the advection of potential vorticity as their temporal evolution equation, and at every time-step the velocity fields required to advect the potential vorticity are obtained through instantaneous nonlinear elliptic inversion operators acting on the potential vorticity field.

They present integrations of a forced polar vortex in a single layer of shallow water on a hemisphere, with balanced initial conditions. They compare their integrations using successive order of balanced models with integrations of the full shallow water equations, and find that successive models up to the third order of their balanced models achieve improvements over lower orders in the hierarchy, but that their fourth order model seldom achieved noticeable improvements over their third order one. Boundary conditions imposed at the equator are equivalent to imposing antisymmetry. The simulations do not therefore have physical boundaries at the equator, and any equatorial Kelvin waves which develop must be regarded as part of the unbalanced flow (for a discussion of equatorial Kelvin waves in balanced models, see Gent & McWilliams, 1983b).

Comparing the divergence field from the shallow water and balanced integrations, they find that, aside from small differences in the magnitude of features which are common to both integrations, the most significant difference between balanced and shallow water simulations is a long equatorial Kelvin wave, trapped at the hemispherical "boundary", but apparently propagating freely around the equator, with a group velocity consistent with the dispersion relation for equatorial Kelvin waves, and not apparently slaved to the vortical motions. This Kelvin wave is not present in any of their balanced integrations, but is present in almost all the corresponding shallow water integrations. This fact should not be surprising in view of the discussion of the inadmissibility of inertio-gravity waves in balanced models at the end of §1.1. What might be regarded as surprising, however, is that the wave has exceptionally low amplitude (at most about 10% of the maximum divergence in the flow), even when the Rossby numbers are of order one throughout a large region of the domain, and the Froude number reaches a maximum value of 0.7. It seems that the coupling between vortical motions and free gravity waves tends to be rather weak, even when there are no obvious small parameters in the flow, and hence, for systems without a large initial amount of free gravity wave activity, free

gravity waves develop in the flow only to very low amplitude. On the other hand, the fact that the fourth order inversion scheme does not perform significantly better than the third, and the ubiquitous emergence of a well-defined Kelvin wave in the shallow water simulations, suggest, but do not prove, that there is some ultimate limitation to potential vorticity inversion and balanced dynamics. We shall return to this point in §1.3, and again in chapter 3.

A somewhat different framework of balance was also considered by Norton (1988), following on the ideas of Non Linear Normal Mode Initialization, developed independently by Machenhauer (1977) and Baer & Tribbia (1977). The technique consists of first decomposing the equations into linear normal modes. The full equations are then cast in the framework of the normal mode decomposition, and a slaving relation derived to bound the gravity modes to the Rossby modes, on the assumption that the natural frequencies of the gravity modes are large compared with typical inverse time scales for the flow. A succession of balance inversion operators can be derived by this procedure. The zeroth order normal mode inversion consists in setting the amplitudes of the gravity wave mode amplitudes to zero. The first order inversion sets the time derivative of the gravity modes to zero. The second order inversion, obtained by Tribbia (1984), effectively sets the second time derivative of the gravity modes to zero. Like McIntyre & Norton's (1993) primitive equation inversions, this procedure can proceed indefinitely although, also like McIntyre & Norton's procedure, it will quickly become impractical as its complexity increases.

It has occasionally been suggested that the generation of gravity waves by vortical motions could be thought of as a generalization of the Rossby adjustment process discussed in §1.1, and that construction of an accurate balanced model might require the adjustment to be parametrized in some way. Although there are some difficulties with the idea, which will become clear as the thesis develops, two interesting proposals have developed from it.

In a recent paper, Vallis (1992) suggested that the production of gravity waves by vortical motions might be parametrized as a form of generalized Rossby adjustment. Following this idea, he proposed a balanced model in which the total energy of the system is minimized, subject to the condition that the potential vorticity field remain unchanged. Two constraints can be derived from the associated Euler-Lagrange equations, which can be used to define a balance system. Curiously, however, the method does not reconstruct steady axisymmetric solutions of the shallow water equations, which is perhaps related to the fact that it does not respect the

Casimir invariants of the shallow water system.

Another proposal (T. G. Shepherd, personal communication), is to divide the system into fast and slow components, very much like the normal mode decomposition. In the case of a canonical Hamiltonian system, in which fast variables have only fast conjugate variables, and slow variables have only slow conjugate variables, it is clear that, regarding the slow variables as fixed, the fast variables on their own constitute a reduced Hamiltonian system. To parametrize the adjustment process one might think of extremizing the "fast" Hamiltonian with respect to the fast variables, holding the slow variables fixed, since they are not supposed to change appreciably while the adjustment process is taking place. This procedure provides a slaving relation for the fast variables to the slow variables.

In truncated models of the atmosphere, there are typically twice as many gravity modes as Rossby modes. The reason for this is the presence of a Casimir density - the potential vorticity - which makes the full system non-canonical and, in the case of the shallow water system, reduces its order from 4 to 3. The canonical description involves either particle positions and momenta (two of each), or three Clebsh potentials and height (Salmon, 1988b). Truncated models of the atmosphere tend to inherit the non-canonical structure of their infinite dimensional counterpart (Bokhove, personal communication), and it is no longer clear whether the fast variables constitute a Hamiltonian system by themselves, since the existence of a Hamiltonian for the fast variables, which could be extremized to parametrize an adjustment process, is not assured if the full system is non-canonical. If Darboux' theorem is invoked to make the system canonical, it is not clear that the canonical variables will separate into canonically conjugate fast variables and canonically conjugate slow variables.

1.3 Slow manifold hypothesis

In assessing different schemes for potential vorticity inversion, with different properties with respect to accuracy, analytical tractibility and attempts to parametrize gravity wave generation in a physically motivated way, one is constantly left to wonder whether there might not be some more fundamental property of the shallow water equations involved – whether they might not possess a true "slow manifold", on which the entire flow is determined exactly by the potential vorticity field, and which, once on, the solution will remain on for all time.

The origination of the "slow manifold" hypothesis originated in a paper of Leith (1980), in which he postulates the existence of a manifold $\mathcal{M}$ with a phase space one third the dimension of the phase space of a full normal mode decomposition of the shallow water equations, for which, in his words

> *"any state vector in $\mathcal{M}$ would continue to move slowly in it, while any state vector not in $\mathcal{M}$ would oscillate about it".*

The implication of the existence of a slow manifold for any finite dimensional system is that the gravity wave modes can be slaved exactly to the Rossby wave modes. Similarly, for an infinite dimensional system, there would exist elliptic inversion operators acting on the instantaneous potential vorticity field such that, if the velocity and height fields associated with a given potential vorticity field were consistent with the inversion operators at an initial instant in time, then they would remain consistent with the given inversion operators for all subsequent times under evolution of the full (shallow water) system. A slow manifold can then be regarded as an exact balance, to which all known balanced models are approximations.

Questions regarding the existence or non-existence of a slow manifold have almost always been posed within the context of low order models. There are obvious conceptual simplifications in doing so. In particular, the fields are typically broken down into $3 \times N$ normal modes of the system. One third of the modes are "Rossby" modes ($\mathcal{R}_i$), and two thirds are gravity modes ($\mathcal{G}_i$). The evolution of the $\mathcal{R}_i$ and the $\mathcal{G}_i$ is given by

$$\frac{d\mathcal{R}_i}{dt} + \Omega_i \mathcal{R}_i = \mathcal{N}_{\mathcal{R}_i}(\mathcal{R}, \mathcal{G}) \tag{1.14}$$

$$\frac{d\mathcal{G}_i}{dt} + \omega_i \mathcal{G}_i = \mathcal{N}_{\mathcal{G}_i}(\mathcal{R}, \mathcal{G}) \tag{1.15}$$

where the $\mathcal{N}_{\mathcal{R}_i}$ and $\mathcal{N}_{\mathcal{G}_i}$ are nonlinear functions required to account for the nonlinear interaction of Rossby modes $\mathcal{R}_i$ and gravity modes $\mathcal{G}_i$, and no summation over repeated indices is intended.

The existence of a slow manifold for this system is equivalent to the existence of functions $\mathcal{F}_i$ for $i = 1, \ldots 2N$, such that, given suitable initial conditions, the gravity wave modes can be slaved exactly to the Rossby wave modes by the functional relationship

$$\mathcal{G}_i = \mathcal{F}_i(\mathcal{R}_1, \ldots, \mathcal{R}_N). \tag{1.16}$$

On the slow manifold, we would have

$$\frac{d\mathcal{G}_i}{dt} \equiv \frac{d\mathcal{F}_i}{d\mathcal{R}_j}\frac{d\mathcal{R}_j}{dt}, \tag{1.17}$$

where summation is understood for $j = 1, \ldots, N$, and hence for a slow manifold to exist there would equivalently have to be exist a solution to the nonlinear slaving relation

$$\sum_{j=1}^{N} \frac{d\mathcal{F}_i}{d\mathcal{R}_j}\left(\mathcal{N}^{\mathcal{R}}{}_j(\mathcal{R},\mathcal{F}) - \Omega_j\mathcal{R}_j\right) + \omega_i\mathcal{F}_i = \mathcal{N}^{\mathcal{G}}{}_i(\mathcal{R},\mathcal{F}) \tag{1.18}$$

for $i = 1, \ldots, 2N$.

The suitable boundary conditions are that the amplitudes of the gravity wave modes $\mathcal{G}_i$ should tend to zero as the amplitudes of the Rossby wave modes $\mathcal{R}_j$ tend to zero. The leading order of the solution should then be equivalent to a quasi-geostrophic normal mode expansion. If this is not assured, then any invariant manifold found could not really be thought of as a slow manifold, since it would be dominated by gravity wave activity in the low Rossby number limit.

A further subtlety is that the the slow manifold, if it exists, might not exist over the whole range of $\mathcal{R}$–space, but rather might only exist in some region $\mathbf{M}$ of Rossby mode phase space. The important point is that, if this is so, any trajectory initially in $\mathbf{M}$ must remain in $\mathbf{M}$. It is not sufficient, for example, to be able to define a slow manifold in the neighbourhood of the origin if trajectories can then depart from that neighbourhood, perhaps to re-enter it not on the slow manifold.

Lorenz (1980) considered a 9 component model based on the shallow water equations on the f-plane. He found that for sufficiently small Rossby numbers the system appeared evolve towards a three-dimensional attractor, which corresponded approximately to quasi-geostrophic balance. Subsequently, he showed (Lorenz, 1986) that an unforced 5-component system, with three Rossby wave components and two gravity wave components, possessed a slow manifold. The proof, however, relied on an additional symmetry of the equations, in part an artifact of the small number of gravity wave components in the system, and it was not clear that the nine-component model used in Lorenz (1980), or a continuous fluid model, would possess sufficient symmetries to allow similar construction of a slow manifold..

Experiments with 9 component systems by Errico (1982), Warn & Ménard (1986), and Vautard & Legras (1986) have suggested that gravity wave generation is an almost universal

property of models with the appropriate ratio of gravity wave modes to Rossby wave modes, and the result of Lorenz (1986) should be regarded as somewhat atypical of low order models.

There are various other ways in which simple models can be made to have slow manifolds. Tribbia (personal communication) has investigated a model in which the Rossby wave modes force the gravity wave modes, but the gravity wave modes do not react back upon the Rossby wave modes. It follows at once that the Rossby modes can be integrated on their own, and the gravity modes can then be integrated *a posteriori*. Imposing the condition that the gravity mode amplitudes tend to zero as the Rossby mode amplitudes tend to zero determines the gravity modes uniquely, and the model thus possesses a slow manifold, on which the gravity modes can be diagnosed from the Rossby modes, and are not required for the temporal integration of the model. One might in some sense regard the model of a description of how gravity waves are generated by vortical motions, but not including the effect describing how the vortical motions are affected by gravity wave generation. This philosophy has strong parallels with the Lighthill theory of aerodynamic sound generation (Lighthill, 1952), which we shall discuss in chapter 2 but is almost certainly fundamentally different from a realistic model of Rossby wave – gravity wave interaction.

When forcing and dissipation are introduced into simple models, additional difficulties may arise. Lorenz & Krishnamurthy (1987) demonstrated numerically that the 5 component model of Lorenz (1986) did not possess a slow manifold when forcing was introduced and was sufficiently strong. Some doubt has recently been cast on their result by Jacobs (1991), who shows for the same model how to obtain the slow manifold in the neighbourhood of fixed points of the system. His proof, however, relies on constructing analytic solutions by Taylor series, whose radius of convergence vanishes when the forcing and dissipation are turned off, and may be quite small otherwise. The Rossby numbers required for the slow manifold to exist thus depend on the amplitudes of forcing and dissipation. Moreover, phase space trajectories are guaranteed to remain in the region where the slow manifold exists only when the dissipation dominates over forcing and nonlinear evolution, in which case the entire system evolves towards a fixed point. The problem in all other cases is exactly that which was discussed earlier – the trajectories are not assured to remain in the region in which the slow manifold is defined, and may leave the region, perhaps to subsequently re-enter it not on the slow manifold. The study of Lorenz & Krishnamurthy (*op. cit.*) was not confined to the limited regime where all trajectories approach

the fixed point, so explaining the apparent discrepancy between the two papers. This has been discussed in the literature by Lorenz (1992).

1.4 Approach of this thesis

The aims of this thesis are three-fold:

- To investigate the generation of gravity waves in the shallow water system, and the dependence of their amplitudes and character on the Froude and Rossby numbers of the basic flow:
- To quantify the effect of the generation of gravity waves in the shallow water system on the potential vorticity distributions which generate them;
- To establish whether, without additional regard to flow geometry, there can or cannot exist a slow manifold for the shallow water equations in any region of Froude and Rossby number space.

The approach adopted to these questions in this thesis is as follows:

In chapter 2, we analyse the nature of interaction between vortical motions and gravity waves in the limit of low Froude number F and order-one Rossby number Ro. We begin by developing a theory of gravity wave generation by vortical motions. It is straightforward to show that there is a formal equivalence between two-dimensional compressible gas dynamics and the non-rotating shallow water system, in the case where the adiabatic gas exponent γ in the former is taken equal to two. The theory is thus an extension of the existing theory of aerodynamic sound generation, first proposed by Lighthill (1952), in which a compact vortical source generates acoustic waves having the same frequency as the vortical motions, but a wavelength which is greater than the vortical length scale by the order of F^{-1}.

The analysis proceeds via a singular perturbation expansion in F, generalizing the analysis of Crow (1970) to include the effect of background rotation upon both the high order Froude number corrections to the vortical source motion and gravity waves it generates. Within this framework we can also investigate the effect which the radiated waves have on the vortical motions, which is inaccessible via Lighthill's (1952) analysis. The chapter ends with a specific

example of the effect of gravity wave radiation on a rotating ellipse of uniform potential vorticity, which is a consistent leading order solution to the low Froude number dynamics (Kida, 1981; Lamb; 1932), generalizing a study by Zeitlin (1988, 1991).

Chapter 3 is motivated by the observation that when a small disturbance is made to the boundary of an axisymmetric vortex of uniform potential vorticity in the shallow water equations, the low Froude number analysis of chapter 2 predicts that, provided the frequency of the disturbance exceeds the inertial frequency in magnitude, the disturbance at a rate of order F^{2m}, where m is the mode number of the disturbance (Broadbent & Moore 1979; Kop'ev & Leont'ev, 1983, 1985, 1986).

We note that the instability may be regarded as a mixed Rossby-gravity instability in the sense of Sakai (1989), and investigate its growth rates over a range of F—Ro space. In the spirit of Knessel & Keller (1992), we develop a WKBJ analysis to show that the instability persists for all Froude and Rossby numbers of the basic vortex, and can be generalized in a limited fashion to vortices with a continuous and monotonic potential vorticity profile. The implications for the existence of a slow manifold for the shallow water system are discussed.

The analysis for the axisymmetric vortex is compared with a similar analysis for parallel flow, with a single discontinuity of potential vorticity. Ripa's (1983) theorem states that the parallel flow will be stable of the ratio of the potential vorticities in the two layers is less than 4:1. In the final part of chapter 3, I show that the stability boundary provided by Ripa's theorem is indeed the stability boundary of the flow, and that at potential vorticity ratios exceeding 4:1 the flow is unstable to short wave disturbances.

In chapter 4 we return to the Lighthill theory of gravity wave generation, to assess its predictive power in cases where the Froude number is not small. Webster (1970) has investigated the validity of the F^7 power scaling law experimentally for a non-rotating jet in shallow water, and found that it applied for Froude number up to approximately $F = 1$. In this thesis I present a numerical investigation of barotropically unstable jets which generate gravity waves as a result of coupling between vortex motions and gravity waves as the instability saturates and the potential vorticity rolls up.4:1

It is found that, when background rotation is included, the vortical dynamics will tend to become less unsteady as the Froude number is increased. This effect, combined with the fact

that gravity waves can not propagate with frequencies below the inertial frequency, acts to reduce the amplitude of gravity wave radiation at larger Froude numbers, unless the potential vorticity in the strip is zero or of opposite sign to the background potential vorticity.

In the final chapter, I summarise the results obtained in the thesis, discuss possible connections between this work and observed phenomena in atmospheres and oceans, and make some suggestions for further research.

Chapter 2

Asymptotic analysis at low Froude number

2.1 Introduction

It is now more than forty years since Lighthill (1952) proposed his successful theory for predicting the intensity acoustic emissions from turbulent jets. The starting point for any theory of aerodynamic sound generation must be the compressible fluid equations:

$$\frac{\partial}{\partial t}\rho u_i + \frac{\partial}{\partial x_j}\rho u_i u_j + \frac{\partial p}{\partial x_i} = 0 \tag{2.1}$$

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_i}\rho u_i = 0 \tag{2.2}$$

$$\left(\frac{p}{p_0}\right) = \left(\frac{\rho}{\rho_0}\right)^{\gamma}, \tag{2.3}$$

where γ is the adiabatic gas exponent. For a diatomic gas, one takes $\gamma = 1.4$, but for our purposes it is important to note that if the fluid is assumed to be two-dimensional, the choice $\gamma = 2$ yields the (non-rotating) shallow water equations, with density ρ in place of the shallow water height. Gravity waves in the shallow water system are the counterpart of acoustic waves in the compressible gas equations, and it follows that any analysis of sound wave generation by vortical motions in two-dimensional compressible fluids should be equally valid in analysing gravity wave generation by vortical motions in the shallow water equations.

The crucial step of Lighthill's (*op. cit.*) so-called "acoustic analogy" theory is to combine (2.1) – (2.3) to yield

$$\left(\frac{\partial^2}{\partial t^2} - c_0^2\nabla^2\right)\rho' = \frac{\partial^2}{\partial x_i \partial x_j}T_{ij}, \tag{2.4}$$

where $c_0^2 = \gamma p_0/\rho_0$, $\rho = \rho_0 + \rho'$, ρ_0 is constant, and

$$T_{ij} = \rho u_i u_j + (p - c_0^2\rho)\delta_{ij}. \tag{2.5}$$

The left hand side of (2.4) is then simply the acoustic wave operator acting on the density field, and the right hand side is to be regarded as the effective acoustic source.

So far we have proceeded by formal manipulation of (2.1 - 2.3). The predictive power of (2.4), however, comes only as a result of making certain assumptions about the nature of the source tensor T_{ij}.

Lighthill (*op. cit.*) proceeded by assuming that the eddy Mach number is small, so that each eddy is acoustically compact. Scaling arguments for small Mach numbers imply that $T_{ij} \approx \rho_0 u_i u_j$. In deriving scaling laws for the wave field due to a low Mach number eddy, it is

convenient to follow Crighton (1975) and work in the frequency domain $(\boldsymbol{x},\omega)$, rather than the time domain $(\boldsymbol{x},t)$.

The solution to (2.4) may then be written down as

$$\rho'(\boldsymbol{x},\omega) = -\frac{1}{4\pi c_0^2}\int \frac{\partial^2}{\partial x_i' \partial x_j'} T_{ij}(\boldsymbol{x}',\omega)\frac{\exp(i\omega|\boldsymbol{x}-\boldsymbol{x}'|/c_0)}{|\boldsymbol{x}-\boldsymbol{x}'|}d^3\boldsymbol{x}' \tag{2.6}$$

in three space dimensions, and

$$\rho'(\boldsymbol{x},\omega) = \frac{1}{16\pi i c_0^2}\int \frac{\partial^2}{\partial x_i' \partial x_j'} T_{ij}(\boldsymbol{x}',\omega)\mathrm{H}_0(\omega|\boldsymbol{x}-\boldsymbol{x}'|/c_0)d^2\boldsymbol{x}' \tag{2.7}$$

in two space dimensions, where H_0 is the Hankel function of the first kind of order zero. If the source T_{ij} is assumed acoustically compact, we may expand the integrals (2.6) and (2.7) to obtain far field expressions for the radiated waves as

$$\rho' \sim \frac{1}{4\pi c_0^2}\frac{\omega^2}{c_0^2}\frac{x_i x_j}{|\boldsymbol{x}|^2}\frac{1}{|\boldsymbol{x}|}\exp(i\omega|\boldsymbol{x}|/c_0)\int T_{ij}(\boldsymbol{x}',\omega)d^3\boldsymbol{x}' \tag{2.8}$$

in three space dimensions, and

$$\rho' \sim \frac{i}{16\pi c_0^2}\frac{\omega^2}{c_0^2}\frac{x_i x_j}{|\boldsymbol{x}|^2}\frac{1}{(\omega|\boldsymbol{x}|/c_0)^{1/2}}\int T_{ij}(\boldsymbol{x}',\omega)d^2\boldsymbol{x}' \tag{2.9}$$

in two. The asymptotic expressions (2.8) and (2.9) enable us to obtain the dependence of the radiated far wave field upon the parameters of the source flow. In three dimensions, we have

$$\rho' \sim \frac{1}{c_0^2}\frac{\omega^2}{c_0^2}\frac{1}{|\boldsymbol{x}|}\rho_0 u^2 l^3 = \rho_0 \frac{l}{|\boldsymbol{x}|}\left(\frac{u}{c_0}\right)^2\left(\frac{\omega l}{c_0}\right)^2 \tag{2.10}$$

and in two dimensions

$$\rho' \sim \frac{1}{c_0^2}\frac{\omega^{3/2}}{c_0^{3/2}}\frac{1}{|\boldsymbol{x}|^{1/2}}\rho_0 u^2 l^2 = \rho_0\left(\frac{l}{|\boldsymbol{x}|}\right)^{1/2}\left(\frac{u}{c_0}\right)^2\left(\frac{\omega l}{c_0}\right)^{3/2}. \tag{2.11}$$

Typically, one assumes that the frequency ω is set by the velocity and length scales of the eddies, so that $\omega \sim u/l$. These expressions then lead directly to the most startling results of the theory – that at low Mach number the acoustic intensity $I \equiv (c_0^3/\rho_0)\rho'^2$ of the radiated waves at fixed $l/|\boldsymbol{x}|$ obeys the scaling laws

$$I \sim \begin{cases} M^8 & 3 \text{ dimensions} \\ M^7 & 2 \text{ dimensions} \end{cases}, \tag{2.12}$$

where M is Mach number of the turbulence in the eddy, holding c_0 and ρ_0 constant. The high exponent in the power scaling law derives from three facts: power is a quadratic quantity in

wave amplitude; the power radiated will depend on the intensity of the turbulence generating it; and the effective source term for the acoustic radiation corresponds to a quadrupole source distribution in the compact limit, cancelling out the potentially stronger effects of monopoles or dipoles. The implication is that acoustic disturbances generated by vortical motions will be exceptionally weak, at least in the limit of low Mach number, and can be expected to have a negligible impact on the flows which generate them.

One shortcoming of the Lighthill theory is that there is no way to quantify the effect of acoustic wave radiation on the vortical flows which generate the acoustic waves. A significant advance in the general theory of aerodynamic sound generation was made when several workers (Obermeier, 1967; Lauvstad, 1968; Crow, 1970) independently developed analyses of the phenomenon using the method of matched asymptotic expansions, taking the Mach number M as the small asymptotic parameter. Two asymptotic regions are established: a source region of length scale l, in which the flow is nearly incompressible, and a wave region of length scale lM^{-1}, in which acoustic waves are linear at the leading two orders in Mach number at which they appear.

One generally assumes that the vorticity in the eddy is zero outside a region of finite extent on the l length scale. In the vortical flow region, the flow is incompressible at leading order in Mach number. Therefore, if the vorticity field is specified, the velocity and pressure fields at leading order in Mach number can be obtained directly from it. If the vorticity is zero except in some bounded domain, the velocity fields will decay as r^{-3} in three dimensions, or r^{-1} in two dimensions. Higher order Mach number corrections to the velocity and pressure in the vortical region are obtained by perturbation expansion. The expansion is singular, with acoustic waves on a length scale of order lM^{-1}, which is long compared with the scale of the vortical region. At high order in Mach number, details of the matching conditions are required to uniquely determine the velocity and height fields in the vortical regions.

The principal acoustic waves obtained by the matched asymptotic analysis correspond exactly to those predicted by the original Lighthill theory as described above, provided T_{ij} is formed from the incompressible velocity field associated with the vorticity distribution for the eddy. The analysis of Crow is distinguished among these studies in that he carries out the Mach number expansion in the source region to a sufficiently high order in M to establish that corrections due to the compressibility of the vortical region do not introduce monopoles or

dipoles, which could in principle give rise to waves of the same amplitude as the leading order quadrupole.

In addition to a general analysis of the radiated sound field, the method of matched asymptotic expansions has also been used to obtain expressions for the sound radiated from flows whose leading order incompressible solution may be expressed analytically. Two-dimensional flows analysed in this way include point vortex flows (Klyatskin 1966; Stuber 1970; Rahman 1971; Crighton 1972a; Gryanik 1983), vortex sheets (Crighton 1972b; Crighton & Leppington, 1974) and a limited class of flows with distributed vorticity (Zeitlin 1988, 1991).

Application of the theory to simple three-dimensional flows is less common since, unlike a large class of two-dimensional point vortex solutions, there are comparatively few three dimensional flows with confined vorticity whose solution can be expressed in closed analytical form. The only reported calculations of sound generation by three dimensional ideal flows in free space are for interacting vortex rings (Klyatskin 1966; Kambe & Minota 1981), and for the Hasimoto soliton (Kimura 1989). Kambe and Minota have subsequently obtained good agreement between experimental measurements of the acoustic sound field generated by low Mach number colliding vortex rings in the laboratory and the corresponding theoretical predictions (Kambe & Minota 1983; Minota & Kambe 1986; Kambe, 1986).

Despite considerable interest in the sound field generated by two and three dimensional vortical motions, comparatively little attention has been paid to the effect of sound radiation upon the flow which generates it. Exceptions are the papers of Klyatskin (1966) and Gryanik (1983) for simple point vortex flows, and Zeitlin (1988, 1991) for two dimensional flows with distributed vorticity.

In the point vortex paper of Gryanik (1983), the flows consist of rotating configurations of point vortices. The point vortices are of equal strength, and placed at the vertices of a regular polygon. The acoustic wave field is calculated using the leading order of matched asymptotic expansions, and the radiated power computed from it. The interaction energy of the point vortex configurations depends on a single parameter: the distance from the centre of the polygon to the vortices, which is assumed to adjust slowly to account for the energy lost due to the acoustic wave radiation. However, a difficulty with point vortex calculations for essentially compressible fluid dynamics problems is that the point vortex model collapses at order M in the expansion as an evacuated region forms at a finite $O(M)$ distance from the

vortex core (see Barsony-Nagy *et al.*, 1987; Moore & Pullin, 1987). The resulting complexity of the asymptotic expansions makes it practically impossible to continue the analysis to sufficiently high order in M to account for the effect of acoustic radiation within a matched asymptotic framework, and we feel it is therefore desirable to investigate the effect of radiation on some distributed vortex flows, such as those analysed by Zeitlin (1988, 1991).

However, one can raise concerns about the analysis of Zeitlin (*op. cit.*). In his study, he took the initial vorticity distribution to be a member of the class of steadily rotating two dimensional vortical flows with vorticity of finite extent investigated by Abrashkin & Yakubovich (1984). The flows belong to distinct one-parameter families, each family being characterised by its circulation and degree of rotational symmetry. Again, using the leading order of matched asymptotics, Zeitlin obtains the wave field, and hence rate of energy radiation. He then assumes that the flows evolve to take account of this energy loss by adjusting the available free parameter, conserving circulation but reducing the energy of the vortical flow.

The important point is that, although distributed vorticity makes it quite possible to construct a singular perturbation expansion in M which remains regular over the vortical scale, and requires rescaling only to account for acoustic wave radiation, there seems to be no reason to assume, as Zeitlin does, that the effect of the acoustic radiation is to cause the vortex to evolve slowly between different states of the one parameter family. Williams (1992) has undertaken a weakly nonlinear analysis of the case with 180° rotational symmetry, in which the steadily rotating states are ellipses with small aspect ratio. His analysis showed that the vortex could split at a time of $O(F^{-4})$, which seems inconsistent with the supposition of Zeitlin that the ellipses would simply elongate, conserving their area, but remaining elliptical.

It is therefore of interest to perform a full analysis of this flow using matched asymptotic expansions, expanding the vortical and acoustic scale flows in the small parameter M until the matching condition between them requires a term to be introduced to the vortical scale flow which accounts for the loss of energy to the acoustic waves at some (high) order in M. The behaviour would then be described entirely in terms of advection of potential vorticity in the vortical region. The flow evolution should be consistent with energy arguments in cases where the latter apply, but would also be able to show when energy arguments would not apply.

Norton (personal communication) has shown how to recast the f-plane shallow water equa-

tions

$$\frac{D\boldsymbol{u}}{Dt} + f\boldsymbol{k} \times \boldsymbol{u} + g\nabla h = 0 \tag{2.13}$$

$$\frac{Dh}{Dt} + h\nabla.\boldsymbol{u} = 0 \tag{2.14}$$

into a similar form to (2.4), viz:

$$\left(\frac{\partial^2}{\partial t^2} + f^2 - c_0^2\nabla^2\right)\frac{\partial h}{\partial t} = \frac{\partial^2}{\partial x_i \partial x_j}T_{ij}, \tag{2.15}$$

where now

$$T_{ij} = \frac{\partial}{\partial t}(hu_iu_j) + f\varepsilon_{ik}hu_ju_k + \frac{1}{2}g\frac{\partial}{\partial t}(h-h_0)^2\delta_{ij}. \tag{2.16}$$

Now, (2.15) will have propagating wave solutions if and only if their frequency exceeds the magnitude of the inertial frequency $|f|$. If T_{ij} is formed as the result of some fully nonlinear evolution, it would seem unlikely that all frequencies in all of its components will fall below the inertial frequency f, however small the Rossby number of the flow may be in some averaged sense. Therefore, it seems highly likely that gravity wave radiation is the inevitable consequence of fully nonlinear flow evolution.

Since balanced models do not admit freely propagating gravity waves, one might suppose that the present analysis shows that it is unlikely that one could construct a balanced model of the vortical flow at all orders in the Froude number expansion. This conclusion, however, should not be drawn too quickly, and we are certainly in no position to draw it as a result of the analysis presented so far.

To summarize, the essential feature of the matched asymptotic approach when used in aeroacoustics is that the Mach number is low, so that the source scale flow is nearly incompressible, and can be described by its vorticity alone. The sound field is obtained by an asymptotic matching process, which does not affect the source flow at leading order.

In the shallow water equations, if a low Froude number approximation is made, and T_{ij}, given by (2.16), is constructed using the incompressible velocity field, a similar matched asymptotic analysis may be used to predict the leading order gravity wave radiation due to a localized vortical flow knowing only the evolution of the potential vorticity field. With the gravity wave field now obtained, we might tentatively suggest that the vortical flow could be corrected at subsequent orders in Froude number to take account of the both the effects of divergence in

the vortical region and of gravity wave radiation. If so, then the entire perturbation expansion in Froude number for all fields could be constructed knowing only the potential vorticity. This would therefore constitute a balanced model which actually takes into account all the gravity wave radiation that is necessarily generated by the Lighthill mechanism, and would remain valid as the vortical flow is adjusted to take account of the gravity wave radiation. This would seem contrary to the intuitive notion that balanced models should not be able to take propagating gravity waves into account.

It is clear that the only way to address the possibility of a balanced model incorporating gravity wave radiation is to perform a matched asymptotic analysis of the entire problem. That analysis forms the basis for the rest of this chapter, which is organised as follows:

In §2.2 I present a matched asymptotic analysis of a compact vortical source in the f-plane shallow water equations at low Froude number. I assume throughout that the potential vorticity is confined to a finite compact region for all time. The applicability of the method of matched asymptotic expansions to gravity wave generation in the two-dimensional shallow water equations in a rotating frame is established. The analysis is carried sufficiently far to obtain the principal effect of the wave radiation on the source region.

In §2.3 the effect of the radiation on the source region is discussed within the context of balance and potential vorticity inversion.

In §2.4 the effect of gravity wave radiation on an ellipse of uniform potential vorticity is examined. The degree to which the solution agrees with, and differs from, the analysis of Zeitlin (1988, 1991) is clarified.

In §2.5, I offer some concluding remarks about the nature of the effect of gravity wave radiation on vortical sources, with particular reference to the "generalized adjustment" ideas of Vallis (1992) and Shepherd (personal communication), which were discussed briefly in chapter 1.

2.2 Gravity wave generation as a singular perturbation problem

To establish the nature of gravity wave generation by vortical motions at low Froude number, we are considering single layer shallow water dynamics on an f-plane. In the absence of motion,

we assume the layer has uniform depth H_0, and hence uniform potential vorticity $Q_0 = f/H_0$.

Suppose now that the potential vorticity Q differs from Q_0 only in some vortical region of finite extent, which is of dimension L. We must now turn to deriving a scaling of the shallow water equations valid in the limit of order–one Rossby number and small Froude number. From the definition of potential vorticity, it follows that the relative vorticity ζ scales as $\zeta \sim Q'H_0$, where $Q' \sim Q - Q_0$, and hence that the typical velocities U in the region of non-uniform potential vorticity scale according to $U \sim Q'H_0L$. The Rossby number Ro and Froude number F are defined by $F \sim U/(gH_0)^{1/2}$, $Ro = U/fL \sim Q'/Q$. We shall assume for the remainder of this chapter that $Q'/Q_0 = O(1)$, so that $Ro = O(1)$, and we shall also assume that $F \ll 1$.

Now we let the total layer depth be H. By considering the balance of terms in the momentum equation, it follows from the assumption of order-one Rossby number that the advective and Coriolis terms are of the same order. Consistency requires that all terms in the momentum equation are of the same order. This implies that $H - H_0 = O(F^2)$, and hence that the continuity equation reduces to the incompressibility constraint at leading order.

With velocity $\boldsymbol{u}$ scaled on U, length scaled on L, time t scaled on U/L, and writing $H - H_0 = F^2H_0h$, the shallow water equations take the nondimensional form:

$$\frac{D\boldsymbol{u}}{Dt} + f\boldsymbol{k} \times \boldsymbol{u} + \nabla h = 0 \tag{2.17}$$

$$F^2\left(\frac{Dh}{Dt} + h\nabla.\boldsymbol{u}\right) + \nabla.\boldsymbol{u} = 0. \tag{2.18}$$

The nondimensionalised potential vorticity takes the form

$$Q = \frac{f + \zeta}{1 + F^2h}. \tag{2.19}$$

The leading order dynamics are thus simply two-dimensional incompressible vortex dynamics. The presence of background rotation plays no part in the leading order evolution of the potential vorticity field, although the associated height field h will be modified due to background rotation.

With the nondimensional form of the equations now established for the vortical region which "drives" the flow, we may proceed to develop the singular perturbation expansion for the entire

flow which will enable us to determine the radiated wave field and the nature of its effect on the vortical flow.

2.2.1 Perturbation expansion for the vortical flow

We begin by developing the perturbation expansion for the vortical flow region. We write $\boldsymbol{u} = \nabla\phi + \boldsymbol{k} \times \nabla\psi$, and expand ϕ, ψ and h in perturbation expansions as

$$\psi = \psi_0 + F^2\psi_2 + \cdots; \quad \phi = F^2\phi_2 + \cdots; \quad h = h_0 + F^2 h_2 + \cdots. \tag{2.20}$$

The expansion for ϕ starts at $O(F^2)$ because from (2.18) we see that at leading order the flow is non-divergent.

We consider a flow in which initially the potential vorticity Q is specified as a function of position.

As the flow evolves, the potential vorticity is advected by all orders of the velocity field $\boldsymbol{u}$:

$$\frac{\partial Q}{\partial t} + (\boldsymbol{u}_0 + F^2\boldsymbol{u}_2 + \cdots).\nabla Q = 0. \tag{2.21}$$

As it stands, this equation cannot be correct, since there are advective terms at all orders in F, but the time derivative term $\partial Q/\partial t$ occurs only at the leading order in F.

For times of order unity, the difficulty may be easily resolved by expanding Q as an asymptotic series in F:

$$Q = Q_0 + F^2 Q_2 + \cdots. \tag{2.22}$$

However, over longer times, it is possible that this formulation might give rise to secular growth in Q_2 – for example, if there is a component of $\boldsymbol{u}_2$ which acts to slow down the rotation of vortices, or to move two vortices apart. To resolve these difficulties, we must introduce a long time scale $T = F^2 t$, and the potential vorticity evolution equation at $O(F^2)$ becomes

$$\frac{\partial Q_2}{\partial t} + \frac{\partial Q_0}{\partial T} + \boldsymbol{u}_0.\nabla Q_2 + \boldsymbol{u}_2.\nabla Q_0 = 0. \tag{2.23}$$

In general, there is no straightforward way to distinguish between the advective terms in (2.23) which give rise to slow secular behaviour in the order-unity potential vorticity field from those which give rise to $O(F^2)$ fluctuations of the potential vorticity on the fast ($O(1)$) timescale. Fortunately, this distinction is not important in analysing gravity wave generation and its effect

on the vortical flow, although it is important when specific flows are to be described, as in §2.4 below.

We shall now assume that $Q = f$ everywhere except in some finite domain, which we refer to as the vortex. Then, since $\nabla.\boldsymbol{u}_0 = 0$, we may write $\boldsymbol{u}_0 = \boldsymbol{k} \times \nabla\psi_0$, and obtain

$$\nabla^2\psi_0 = Q_0 - f. \tag{2.24}$$

$Q_0 - f$ represents the leading order relative vorticity $\boldsymbol{k}.(\nabla \times \boldsymbol{u})$, which for convenience we shall refer to as ζ_0, so that ζ_0 is zero outside some finite region on the vortical length scale. In general, the Laplacian can only be inverted up to non-singular harmonic terms. By Liouville's theorem, any nonsingular harmonic terms must be unbounded at infinity. Assuming, that ψ_0 does not contain any non-singular growing terms, we can obtain ψ_0 from (2.24) in terms of a Green function integral

$$\psi_0 = \frac{1}{2\pi}\int \zeta_0(\boldsymbol{x}')\ln|\boldsymbol{x}-\boldsymbol{x}'|d^2\boldsymbol{x}'. \tag{2.25}$$

For the present analysis, we are primarily concerned with obtaining expressions for the vortical flow fields $\psi_0, h_0, \psi_2, \phi_2, \ldots$ in sufficient generality that we may evaluate them in the limit as $|\boldsymbol{x}| \to \infty$, in preparation for matching onto the wave region. First, we expand $\ln|\boldsymbol{x}-\boldsymbol{x}'|$ for $|\boldsymbol{x}| > |\boldsymbol{x}'|$, using the Taylor expansion for the logarithm:

$$\ln|\boldsymbol{x}-\boldsymbol{x}'| = \ln|\boldsymbol{x}| + x_i'\frac{\partial}{\partial x_i}\ln|\boldsymbol{x}| + \frac{1}{2}x_i'x_j'\frac{\partial^2}{\partial x_i\partial x_j}\ln|\boldsymbol{x}| + \cdots, \tag{2.26}$$

and substitute this for $\ln|\boldsymbol{x}-\boldsymbol{x}'|$ in (2.25). Since $Q - f$ is of compact support, all the resulting moment integrals converge, and it is simple to show that the remainder is of smaller order than the last moment integral taken. Taking terms to $O(r^{-2})$, we have

$$\begin{aligned}
\psi_0 &= \frac{1}{2\pi}\ln|\boldsymbol{x}|\int\zeta_0(\boldsymbol{x}')d^2\boldsymbol{x}' && (2.27)\\
&+ \frac{1}{2\pi}\frac{x_i}{|\boldsymbol{x}|^2}\int x_i'\zeta_0(\boldsymbol{x}')d^2\boldsymbol{x}' && (2.28)\\
&+ \frac{1}{2\pi}\left(\frac{\delta_{ij}}{|\boldsymbol{x}|^2} - \frac{2x_ix_j}{|\boldsymbol{x}|^4}\right)\int\frac{1}{2}x_i'x_j'\zeta_0(\boldsymbol{x}')d^2\boldsymbol{x}' && (2.29)\\
&+ O(r^{-3}).
\end{aligned}$$

Now, we may note that the integral in (2.27) is an $O(1)$ approximation to the circulation $\int\zeta d^2\boldsymbol{x}'$, and that in (2.28) is an $O(1)$ approximation to the Kelvin impulse $\int\zeta\boldsymbol{x}'d^2\boldsymbol{x}'$. These

are both constant on the $O(1)$ timescale t, and so the fluctuating part of the leading order streamfunction ψ_0 is $O(r^{-2})$ as $r \to \infty$. Since $\int(x^2+y^2)\zeta$ is also independent of time on the $O(1)$ timescale, the time-dependent part of (2.29) may be represented as

$$\frac{A(t)}{r^2}\cos 2\theta + \frac{B(t)}{r^2}\sin 2\theta. \tag{2.30}$$

This represents a quadrupolar far field for ψ_0, and will clearly match to a radiating wave field of quadrupole form.

It is straightforward to see from dimensional grounds, and it will be verified in §2.2.2 below, that if the vortical source has a length scale of order unity, then the gravity waves generated will have a long wavelength of order F^{-1}. It follows that the leading order temporally fluctuating quadrupole in ψ_0, given by (2.30), will be of order F^2 in the wave region, where the radial variable is $R \equiv Fr$.

On the other hand, it is clear that $O(F^2)$ fields will arise in the vortical region as a direct result of the local effects of divergence. If any of these fields should have a temporally fluctuating monopolar far field, they would give rise to monopolar gravity wave radiation at $O(F^2)$, which would be formally of the same order as the quadrupolar radiation obtained from the incompressible source scale dynamics. We shall therefore proceed to obtain the far field expressions for ψ_2 and ϕ_2, to determine whether the leading order quadrupole is the only $O(F^2)$ wave field.

To obtain expressions for ψ_2 and ϕ_2, we must first obtain an expression for h_0. If we attempt to use the divergence of the momentum equation (2.17):

$$\nabla.(\boldsymbol{u}_0.\nabla\boldsymbol{u}_0) + f\nabla.(\boldsymbol{k}\times\boldsymbol{u}_0) + \nabla^2 h_0 = 0 \tag{2.31}$$

directly to obtain h_0, we obtain the integral expression

$$h_0 = f\psi_0 - \frac{1}{2\pi}\int \frac{\partial^2}{\partial x_i' \partial x_j'}\left(u_{0i}(\boldsymbol{x}')u_{0j}(\boldsymbol{x}')\right)\ln|\boldsymbol{x}-\boldsymbol{x}'|d^2\boldsymbol{x}'. \tag{2.32}$$

Although $\partial^2(u_{0i}u_{0j})/\partial x_i \partial x_j = O(r^{-4})$ as $r \to \infty$, and therefore the integral in (2.32) converges, it is not straightforward to extract the asymptotic form of h_0 for large $|\boldsymbol{x}|$ from (2.32). To see this, substitute the expansion for $\ln|\boldsymbol{x}-\boldsymbol{x}'|$ into (2.32). The $\ln r$ and r^{-1} terms vanish after integration by parts, and we are left with a divergent integral:

$$h_0 \sim f\psi_0 - \frac{1}{2\pi}\left(\frac{\partial^2}{\partial x_i \partial x_j}\ln|\boldsymbol{x}|\right)\int (u_{0i}(\boldsymbol{x}')u_{0j}(\boldsymbol{x}'))\, d^2\boldsymbol{x}'. \tag{2.33}$$

The integrand is now of order r^{-2} for large r, and therefore the moment integrals for the far field of h_0 fail to converge at the first order at which they are non-zero. We are therefore unable to predict the far-field behaviour of h_0 directly from (2.31), and some other method must be found to obtain the far-field expression for h_0.

The resolution to the difficulty is to introduce the Bernoulli variable $B = h + \frac{1}{2}\boldsymbol{u}^2$ in (2.17), which was used extensively by Howe (1975) for his study of the aerodynamic sound generation problem, to obtain Crocco's equation:

$$\frac{\partial \boldsymbol{u}}{\partial t} + (f+\zeta)(\boldsymbol{k}\times\boldsymbol{u}) + \nabla B = 0. \tag{2.34}$$

As with ψ, ϕ and h, we expand B in an asymptotic series in F:

$$B = B_0 + F^2 B_2 + \cdots. \tag{2.35}$$

From (2.34) one then obtains at order unity

$$\nabla^2 B_0 = -\nabla.(\zeta_0 \boldsymbol{k}\times\boldsymbol{u}) + f\nabla^2\psi_0. \tag{2.36}$$

Inverting the Laplacian, we obtain[1]

$$B_0 = f\psi_0 + \frac{1}{2\pi}\int \nabla.(\zeta_0\nabla\psi_0)\ln|\boldsymbol{x}-\boldsymbol{x}'|d^2\boldsymbol{x}'. \tag{2.37}$$

The important point is that ζ_0 is zero outside some finite domain. Therefore we may obtain the far field expansion for B_0 by expanding the logarithm in the form (2.26) and substituting it into the integral in (2.37). Moreover, since the leading order term in the far field expansion of (2.37) has the coefficient

$$\int \zeta_0 \nabla\psi_0 d^2\boldsymbol{x}' = 0, \tag{2.38}$$

[1] In (2.37) and, expect where otherwise stated, in all subsequent integrals in §2.2.1, all terms in integrands are functions of $\boldsymbol{x}'$, and all gradients, represented by ∇, when acting on integrands, are gradients with respect to $\boldsymbol{x}'$.

it follows from conservation of Kelvin's impulse on timescale t (see, e.g. Batchelor, 1967) that the far field expansion of B_0 to $O(r^{-2})$ takes the form

$$B_0 \sim f\psi_0 - \frac{1}{2\pi}\left(\frac{\delta_{ij}}{|\boldsymbol{x}|^2} - \frac{2x_i x_j}{|\boldsymbol{x}|^4}\right)\int \zeta_0(\boldsymbol{x}')x_i'\frac{\partial\psi_0}{\partial x_j'}d^2\boldsymbol{x}' + O(r^{-3}) \tag{2.39}$$

in the limit of large r. Consequently, the leading order Bernoulli function B_0 has a quadrupolar far field. To obtain the far field for h_0, we then use $h_0 = B_0 - \frac{1}{2}\boldsymbol{u}_0^2$. From the far field expression for ψ_0 (2.27-2.29),we can see that $u_0 = O(r^{-1})$ in the far field, and the only r^{-1}-like term in $\boldsymbol{u}_0$ is the circulation, which is independent of time. Therefore, at $O(r^{-2})$, B_0 and h_0 differ in the far field by a time-independent term only, and the principal time fluctuating part of h_0 is therefore also quadrupolar in the far field.

This resolves our first difficulty, which arose due to the nonconvergence of the integral in (2.33). We must now proceed to resolve whether there are competing monopoles introduced by compressibility at $O(F^2)$. If the time fluctuating parts of the far fields of ψ_2 and ϕ_2 at $O(1)$ have only $e^{2i\theta}$ dependence, then they will correspond to higher order matching for the quadrupole in the wave region. If, on the other hand, they contain components which are independent of θ, these would correspond to an $O(F^2)$ monopole. The principal wave field could not then be deduced directly from the incompressible velocity field, and we could not truly refer to the radiation as "quadrupole".

To resolve this, we carry out the perturbation expansion to the next order in F in the source region. Writing $\boldsymbol{u}_2 = \nabla\varphi_2 + \boldsymbol{k}\times\nabla\psi_2$, we have

$$\nabla^2\phi_2 = -\frac{\partial h_0}{\partial t} - \nabla.(\boldsymbol{u}_0 h_0) \tag{2.40}$$

$$\nabla^2\psi_2 = (f+\zeta_0)h_0 + Q_2. \tag{2.41}$$

From (2.37), and using the identity

$$\boldsymbol{u}_0^2 \equiv |\nabla\psi|^2 = \frac{1}{2}\nabla^2\psi_0^2 - \psi_0\nabla^2\psi_0, \tag{2.42}$$

we may write h_0 as

$$h_0 = \left(f + \frac{1}{2}\zeta_0\right)\psi_0 - \frac{1}{4}\nabla^2\psi_0^2 + \frac{1}{2\pi}\int \nabla.(\zeta_0\nabla\psi_0)\ln|\boldsymbol{x}-\boldsymbol{x}'|d^2\boldsymbol{x}'. \tag{2.43}$$

In addition, it is helpful to note the identity:

$$\nabla.(\psi_0 \boldsymbol{u}_0) = 0, \tag{2.44}$$

and hence to use the expression

$$\nabla.(h_0 \boldsymbol{u}_0) = \nabla.((h - f\psi_0)\boldsymbol{u}_0) \tag{2.45}$$

in (2.40). The point here is that $h_0 = O(\ln r)$ as $r \to \infty$, whereas, from (2.39), it is straightforward to show that $h_0 - f\psi_0 = O(r^{-2})$. This turns out to be essential in determining the far field expression for ϕ_2.

With h_0 now in a suitable form for integration, the solution to (2.40) may be written as

$$\begin{aligned}
\phi_2 = \quad & - \frac{f}{8\pi}\frac{\partial}{\partial t}\int \zeta_0 |\boldsymbol{x} - \boldsymbol{x}'|^2 (\ln|\boldsymbol{x} - \boldsymbol{x}'| - 1) d^2\boldsymbol{x}' && (2.46)\\
& - \frac{1}{4\pi}\frac{\partial}{\partial t}\int \psi_0 \zeta_0 \ln|\boldsymbol{x} - \boldsymbol{x}'| d^2\boldsymbol{x}' && (2.47)\\
& + \frac{1}{2}\psi_0 \frac{\partial \psi_0}{\partial t} && (2.48)\\
& - \frac{1}{8\pi}\frac{\partial}{\partial t}\int \nabla.(\zeta_0 \nabla\psi_0)|\boldsymbol{x} - \boldsymbol{x}'|^2 (\ln|\boldsymbol{x} - \boldsymbol{x}'| - 1) d^2\boldsymbol{x}' && (2.49)\\
& - \frac{1}{2\pi}\int \nabla.((h_0 - f\psi_0)\boldsymbol{u}_0) \ln|\boldsymbol{x} - \boldsymbol{x}'| d^2\boldsymbol{x}'. && (2.50)
\end{aligned}$$

The first four terms (2.46 - 2.49) all come from inversion of the Laplacian on $-\partial h_0/\partial t$, using (2.43) to first obtain an expression for $-\partial h_0/\partial t$. The last term (2.50) comes from inversion of the Laplacian on $-\nabla.(h_0\boldsymbol{u}_0)$. However, $h_0\boldsymbol{u}_0 = O((\ln r)/r)$, and it is not immediately clear that the Laplacian can be inverted via an integral expression such as (2.50). Using expression (2.45) makes it clear that the integrand in (2.50) is of order $O(r^{-4})$ as $r \to \infty$, and hence the integral converges.

The solution to (2.41) for ψ_2 can also be written down as an integral expression:

$$\begin{aligned}
\psi_2 = \quad & - \frac{1}{4} f \psi_0^2 && (2.51)\\
& + \frac{1}{2\pi}\int Q_2 + \zeta_0 \left(h_0 + \frac{1}{2} f\psi_0\right) \ln|\boldsymbol{x} - \boldsymbol{x}'| d^2\boldsymbol{x}' && (2.52)\\
& + \frac{1}{8\pi} f^2 \int \zeta_0 |\boldsymbol{x} - \boldsymbol{x}'|^2 (\ln|\boldsymbol{x} - \boldsymbol{x}'| - 1) d^2\boldsymbol{x}' && (2.53)\\
& + \frac{1}{8\pi} f \int \nabla.(\zeta_0 \nabla\psi_0)|\boldsymbol{x} - \boldsymbol{x}'|^2 (\ln|\boldsymbol{x} - \boldsymbol{x}'| - 1) d^2\boldsymbol{x}'. && (2.54)
\end{aligned}$$

We must now obtain the far field expansions of these expressions for ϕ_2 and ψ_2.

Consider first the far field form of ϕ_2 (2.46-2.50). We shall consider the far field form of each of expressions (2.46-2.50) in turn.

Starting with (2.46), we have

$$\begin{aligned}\frac{\partial}{\partial t}\int \zeta_0|\boldsymbol{x}-\boldsymbol{x}'|^2(\ln|\boldsymbol{x}-\boldsymbol{x}'|-1)d^2\boldsymbol{x}' &= |\boldsymbol{x}|^2(\ln|\boldsymbol{x}|-1)\frac{d}{dt}\int \zeta_0 d^2\boldsymbol{x}' && (2.55)\\ &+ \frac{\partial}{\partial x_i}(|\boldsymbol{x}|^2(\ln|\boldsymbol{x}|-1))\frac{d}{dt}\int x_i'\zeta_0 d^2\boldsymbol{x}' && (2.56)\\ &+ \frac{1}{2}\frac{\partial^2}{\partial x_i\partial x_j}(|\boldsymbol{x}|^2(\ln|\boldsymbol{x}|-1))\frac{d}{dt}\int x_i'x_j'\zeta_0 d^2\boldsymbol{x}' && (2.57)\\ &+ O(r^{-1}\ln r). && (2.58)\end{aligned}$$

Now, since

$$\frac{d}{dt}\int \zeta_0 d^2\boldsymbol{x}' = 0 \tag{2.59}$$

by conservation of circulation, and

$$\frac{d}{dt}\int x_i'\zeta_0 d^2\boldsymbol{x}' = 0 \tag{2.60}$$

by conservation of Kelvin's impulse, it follows that

$$\begin{aligned}\frac{\partial}{\partial t}\int \zeta_0|\boldsymbol{x}-\boldsymbol{x}'|^2(\ln|\boldsymbol{x}-\boldsymbol{x}'|-1)d^2\boldsymbol{x}' &= \frac{1}{2}\frac{\partial^2}{\partial x_i\partial x_j}(|\boldsymbol{x}|^2(\ln|\boldsymbol{x}|-1))\frac{\partial}{\partial t}\int x_i'x_j'\zeta_0 d^2\boldsymbol{x}' && (2.61)\\ &+ O(r^{-1}\ln r). && (2.62)\end{aligned}$$

We can now show that (2.46) does not contribute a monopolar source term. We start by noting that

$$\frac{d}{dt}\int (x'^2+y'^2)\zeta_0 d^2\boldsymbol{x}' = 0. \tag{2.63}$$

It then follows that the tensor integral in (2.61) is traceless The $O(1)$ far field component of (2.61) therefore corresponds to the higher order in Froude number matching conditions for the quadrupolar wave field, but contributes no further monopolar wave field of its own.

Continuing to analyse (2.47), it follows from conservation of energy in the source region on the timescale of the vortex dynamics that

$$\frac{d}{dt}\int \zeta_0\psi_0 d^2\boldsymbol{x}' = 0. \tag{2.64}$$

Expanding the logarithm and substituting, it follows that the far field of (2.47) is $O(r^{-1})$.

Since $\psi_0 \sim \ln r$, and $\partial\psi_0/\partial t \sim r^{-2}$, it follows that (2.48) is $O(r^{-2}\ln r)$ in the far field, so we need not consider it further.

For (2.49), it follows again from conservation of Kelvin's impulse that

$$\begin{aligned}\frac{\partial}{\partial t}\int \nabla.(\zeta_0\nabla\psi_0)|\boldsymbol{x}-\boldsymbol{x}'|^2(\ln|\boldsymbol{x}-\boldsymbol{x}'|-1)d^2\boldsymbol{x}' = \\ \frac{1}{2}\frac{\partial^2}{\partial x_i\partial x_j}(|\boldsymbol{x}|^2(\ln|\boldsymbol{x}|-1))\frac{\partial}{\partial t}\int x_i'\zeta_0\frac{\partial\psi_0}{\partial x_j'}d^2\boldsymbol{x}' \\ + \quad O(r^{-1}\ln r)\end{aligned} \tag{2.65}$$

Like (2.46), this also has a fluctuating far field at $O(1)$, but also like (2.46), we can show that the trace of the tensor integral is zero, and therefore this too corresponds only to higher order matching for the quadrupolar waves, and does not introduce a monopole either.

To see this, note that the trace of (2.65) is proportional to $\int(xv_0 - yu_0)$. One can see that this is zero from conservation of $\int(x^2+y^2)\zeta_0$, and therefore we can conclude that (2.49) has only $e^{2i\theta}$ behaviour at $O(1)$ in the far field. Consequently, (2.49) does not contribute a monopole in the far field.

Finally we consider (2.50). If we proceed by expanding the logarithm and integrating by parts, as before, the first term we obtain is

$$\int \nabla.((h_0 - f\psi_0)\boldsymbol{u}_0)\ln|\boldsymbol{x}-\boldsymbol{x}'|d^2\boldsymbol{x}' = \frac{\boldsymbol{x}}{|\boldsymbol{x}|^2}.\int(h_0 - f\psi_0)\boldsymbol{u}_0 d^2\boldsymbol{x}'. \tag{2.66}$$

However, we should note that, unlike the other integrals for which far field expressions have been obtained, the integrand here is not of compact support, and is of order $O(r^{-3})$ as $r \to \infty$. At the next order in the expansion of the logarithm, a factor x' is introduced into the integrand, making the integral non-convergent. It follows that the order of the remainder in this case cannot be determined from subsequent terms in the asymptotic expansion of the logarithm, and extensive analysis is required to show that the order of the remainder is $(r^{-2}\ln r)$, thus confirming that (2.50) is of order $O(r^{-1})$ for large r, and therefore does not contribute a monopole to the wave field. The analysis to show that the order of the remainder in (2.66) is $r^{-2}\ln r$ is presented in Appendix A.

We turn now to examining the far field of ψ_2.

Two of the four integrals in the representation of ψ_2 have counterparts in the representation of ϕ_2. They are (2.53), which is the counterpart of (2.46), and (2.54), which is the counterpart of (2.49). The only difference between (2.46) and (2.53) is a factor of $f^{-1}\partial/\partial t$. This is also the difference between (2.49) and (2.54). It follows from the analyses presented for (2.46) and (2.49) that neither (2.53) nor (2.54) can have time dependent monopoles in their far fields, although both terms do contain components of the time dependent quadrupole.

To show that (2.51) does not have a time dependent monopolar far field, we recall that although $\psi_0 = O(\ln r)$ for large r, $\psi_{0t} = O(r^{-2})$. Therefore, the time dependent part far field of (2.51) is of order $O(r^{-2}\ln r)$, and hence does not constitute a time dependent monopole.

To show that (2.52) does not have a time dependent monopolar far field, we first recall that $\int \zeta_0\psi_0$ is independent of time, and therefore we need only consider the term

$$\frac{1}{2\pi}\ln r \int Q_2 + \zeta_0 h_0. \tag{2.67}$$

However, it is simply the $O(F^2)$ contribution to the circulation. Since conservation of circulation is true of a general shallow water system, and does not rely on any small Froude number limit, it should be independent of time at all orders. To show that (2.67) is independent of time, we note that

$$\frac{\partial \zeta_0}{\partial t} = -\nabla.(\boldsymbol{u}_0\zeta_0); \quad \frac{\partial h_0}{\partial t} = -\nabla.(\boldsymbol{u}_0 h_0 + \boldsymbol{u}_2). \tag{2.68}$$

Hence

$$\frac{\partial}{\partial t}(\zeta_0 h_0) = -\nabla.(\zeta_0 h_0 \boldsymbol{u}_0) - \zeta_0 \nabla.\boldsymbol{u}_2. \tag{2.69}$$

Moreover, if we also recall that

$$\frac{\partial Q_2}{\partial t} + \frac{\partial \zeta_0}{\partial T} = -\boldsymbol{u}_0.\nabla Q_2 - \boldsymbol{u}_2.\nabla Q_0, \tag{2.70}$$

we obtain

$$\frac{d}{dt}(Q_2 + \zeta_0 h_0) = -\nabla.(\boldsymbol{u}_0 Q_2 + h_0\zeta_0\boldsymbol{u}_0 + \zeta_0\boldsymbol{u}_2) - \frac{\partial \zeta_0}{\partial T}. \tag{2.71}$$

It follows that

$$\frac{d}{dt}\int Q_2 + \zeta_0 h_0 = -\frac{d}{dT}\int \zeta_0 - \int (\boldsymbol{u}_0 Q_2 + \zeta_0\boldsymbol{u}_2 + \zeta_0 h_0\boldsymbol{u}_0).d\boldsymbol{s}. \tag{2.72}$$

Now since ζ_0 vanishes ouside some finite region, the boundary integral on the right hand side of (2.72) vanishes. Then, since $\int \zeta_0$ is independent of t, it follows that (2.52) does not have a time dependent far field at $O(1)$ in r for large r.

To obtain an integral representation for h_2, we expand (2.34) at order F^2 to obtain

$$\nabla^2\left(B_2 + \frac{\partial \phi_2}{\partial t} - f\psi_2 - \frac{1}{2}f^2\psi_0^2\right) = \nabla.(h_0\zeta_0\nabla\psi_0 + (h_0 - f\psi_0)\nabla\psi_0 - \zeta_0(\boldsymbol{k}\times\boldsymbol{u}_2)). \qquad (2.73)$$

Now ϕ_2 and ψ_2 have already been shown to contribute only quadrupoles. It is straightforward to show that the right hand side contributes a dipole only (in an analysis similar to that given for (2.50) in appendix A). Therefore B_2, and hence h_2, are also quadrupole at leading order in the far field. This is reassuring, since gravity waves involve perturbations in both velocity and height fields, and it should not have been possible to have a monopole in h_2 without a corresponding monopole in at least one of ψ_2 or ϕ_2.

2.2.2 Dynamics of the wave zone resulting from the vortical flow

Considering the orders of the unsteady terms in the limit $r \to \infty$ in the vortical flow, we have terms of orders $1 \times r^{-2}$ and $F^2 \times 1$, reminding us that the expansion becomes disordered when $r \sim F^{-1}$. To obtain the dynamics of the wave zone, we must rescale the equations using the long length scale F^{-1} corresponding to the wavelength of gravity waves. We therefore introduce the wave region spatial variable $\boldsymbol{X}$, defined such that $\boldsymbol{X} = F\boldsymbol{x}$. Rescaling the equations, we obtain

$$\frac{\partial}{\partial t}(\nabla\phi + \boldsymbol{k}\times\nabla\psi) + (f+\zeta)\boldsymbol{k}\times(\nabla\phi + \boldsymbol{k}\times\nabla\psi) + \nabla h + \frac{1}{2}F^2\nabla(\nabla\phi + \boldsymbol{k}\times\nabla\psi)^2 = 0 \qquad (2.74)$$

$$\frac{\partial h}{\partial t} + \nabla^2\phi + F^2\nabla.((\nabla\phi + \boldsymbol{k}\times\nabla\psi)h) = 0, \qquad (2.75)$$

where now ∇ represents $\partial/\partial\boldsymbol{X}$. These equations admit propagating gravity waves as solutions. In the wave region it is the nonlinear terms, rather than the divergence terms, which are of small order in the limit of small Froude number.

We now proceed to the details of matching the asymptotic expansions in the source region and the wave zone together. We start by expanding ψ, ϕ and h in asymptotic series in F:

$$\psi = \psi_0 + F\psi_1 + F^2\psi_2 + \cdots \tag{2.76}$$

$$\phi = \phi_0 + F\phi_1 + F^2\phi_2 + \cdots \tag{2.77}$$

$$h = h_0 + Fh_1 + F^2h_2 + \cdots. \tag{2.78}$$

Firstly, since, for the vortical region, ψ_0 and h_0 are independent of t at orders 1 and r^{-1} in their far field limits, it is sufficient in the expansion in the wave zone to take ψ_0, ψ_1, h_0 and h_1 to be independent of t, and to take $\phi_0 = \phi_1 = 0$. Thus, in the wave zone,

$$\{h_0, h_1\} = f\{\psi_0, \psi_1\} \tag{2.79}$$

$$(\nabla^2 - f^2)\{\psi_0, \psi_1\} = 0, \tag{2.80}$$

and it follows from applying decaying boundary conditions at infinity that

$$\psi_0 = C_0 \mathrm{K}_0(|f|R) \tag{2.81}$$

$$\psi_1 = C_1 \mathrm{K}_1(|f|R). \tag{2.82}$$

The values of the constants C_0 and C_1 are determined by matching conditions onto the source scale flow in the limit $R \to 0$.

The expansion of $\mathrm{K}_0(|f|R)$ for small R implies that constant corrections to h will be required at $O(1)$ and $O(\ln F)$, which will in turn affect the velocity field at $O(F^2)$ and $O(F^2 \ln F)$. Since these are time-independent terms, will shall not discuss them further here. We shall return to them in §2.4, where the complete solution to $O(F^2)$ is obtained for the model problem of the Kirchoff ellipse (Lamb, 1932).

At the next two orders ($O(F^2)$ and $O(F^3)$) in the wave zone, it is convenient to separate the fields into two parts: one part which is independent of t, and one part which is oscillatory in t. Taking, for example, ψ_2, we use $\hat{\psi}_2$ to represent the part which is independent of t, and $\tilde{\psi}_2$ to represent the oscillatory part. For the t-independent parts, we obtain from (2.74) at $O(F^2)$:

$$(\nabla^2 - f^2)\hat{\psi}_2 = -\frac{1}{2} f |\nabla \psi_0|^2 + \frac{1}{2} f^3 \psi_0^2. \tag{2.83}$$

A similar equation can be obtained for $\hat{\psi}_3$. Again, the boundary conditions on these equations are decaying at infinity, and matching conditions onto the source flow as $|\boldsymbol{X}| \to 0$.

For the oscillatory parts, we then have

$$\left(\frac{\partial^2}{\partial t^2} + f^2 - \nabla^2\right)\left\{\tilde{\phi}_2, \tilde{\psi}_2, \tilde{h}_2, \tilde{\phi}_3, \tilde{\psi}_3, \tilde{h}_3\right\} = 0, \tag{2.84}$$

with

$$\frac{\partial}{\partial t}\{\tilde{\psi}_2, \tilde{\psi}_3\} + f\{\tilde{\phi}_2, \tilde{\phi}_3\} = 0. \tag{2.85}$$

Here, the boundary conditions which we shall impose are a radiation condition at infinity, and matching onto the source flow as $|\boldsymbol{X}| \to 0$. When matching $\tilde{\phi}_2$ and $\tilde{\phi}_2$ onto the vortical region, we do not match ϕ and ψ individually, because the decomposition of the velocity field into streamfunction ψ and velocity potential ϕ is non-unique. In the vortical region, the leading order far field quadrupole comes about directly as a result of incompressible flow, and in the previous section we chose to represent that flow using only a streamfunction. Therefore, its far field does not satisfy the condition (2.85). However, since the vorticity is confined to a finite area of the vortical region, the flow is both incompressible and irrotational in the limit $r \to \infty$, and hence we are free to represent it far from the vortex using either a streamfunction or a velocity potential, or any combination of the two, including a combination which satisfies the constraint (2.85).

It is convenient to work in frequency space for the details of wave matching, in which the general solutions of (2.84) are the Hankel functions

$$\mathrm{H}_m^{(\cdot)}\left(\sqrt{\omega^2 - f^2}R\right)e^{im\theta}, \tag{2.86}$$

where m is the order, determined by the required θ dependence of the match on to the source flow; $(\cdot) = 1, 2$ is the type, determined by the radiation condition; and $R = |\boldsymbol{X}|$ as before. The order $m = 0$ corresponds to a monopole wave, $m = 1$ a dipole, $m = 2$ a quadrupole, and so on. Normally the Hankel functions $H_m^{(1,2)}$ are defined to be $J_m \pm iY_m$, where J and Y are Bessel and associated Bessel functions respectively (Abramowitz & Stegun, 1965). For convenience in the present analysis, we shall multiply H by $\pm i$, so that in our case $H_m^{(1,2)} = -Y_m \pm iJ_m$. Throughout, we shall represent the Fourier transform of a function $f(t)$ by $\tilde{f}(\omega)$, where

$$\tilde{f}(\omega) = \int_{-\infty}^{\infty} f(t)e^{i\omega t}dt. \tag{2.87}$$

Now, the time-dependent far field form of ψ_0 in the vortical region, given in (2.30), may be taken as

$$\psi_0 \sim \frac{4\alpha(t)}{\pi r^2}e^{2i\theta}. \tag{2.88}$$

Therefore, the outer limit of the inner expansion for ψ takes the form $r^{-2}e^{2i\theta}$. To satisfy the matching conditions for the wave fields at $O(F^2)$, we will require them to have 2θ angular dependence. Hence we choose mode $m = 2$ and write the general solution for the $O(F^2)$ wave fields in frequency space:

$$\tilde{\phi_2} = A(\omega)(\omega^2 - f^2)\mathrm{H}_2^{(\cdot)}\left(\sqrt{\omega^2 - f^2}R\right)e^{2i\theta} \tag{2.89}$$

$$\tilde{\psi_2} = B(\omega)(\omega^2 - f^2)\mathrm{H}_2^{(\cdot)}\left(\sqrt{\omega^2 - f^2}R\right)e^{2i\theta} \tag{2.90}$$

$$\tilde{h_2} = C(\omega)(\omega^2 - f^2)\mathrm{H}_2^{(\cdot)}\left(\sqrt{\omega^2 - f^2}R\right)e^{2i\theta}. \tag{2.91}$$

One matches the velocity $\nabla\phi + \boldsymbol{k} \times \nabla\psi$ and the height field h to get

$$A = \frac{f\tilde{\alpha}}{\omega + f}; \quad B = \frac{i\omega\tilde{\alpha}}{\omega + f}; \quad C = (\omega - f)\tilde{\alpha}, \tag{2.92}$$

where $\tilde{\alpha}(\omega)$ is the Fourier transform of $\alpha(t)$, defined by (2.87).

Since we have shown that there are no $O(F^2)$ monopoles in the source region, this is the complete representation of the leading order (i.e. $O(F^2)$) wave field. Thus we have confirmed that the principal radiation is quadrupole. In general, the $O(F^3)$ wave field will be composed of a dipole and an octupole.

2.2.3 The effect of wave radiation on the vortical flow

We have now determined the principal wave radiation in terms of integrals over the vortex. These integrals can be regarded as known functions of time. At any time, they can be determined by knowing only the potential vorticity distribution at that time.

We turn now to considering the "back-reaction" problem. That is, we calculate the effect of the radiation on the flow which is generating it. This consists in matching the wave solution back onto the source flow. To do this, we must consider the expansion of the Hankel function in the limit $R \to 0$:

$$\pi(\omega^2 - f^2)\mathrm{H}_2^{(\cdot)}(\sqrt{\omega^2 - f^2}R) =$$

$$\frac{4}{R^2} \tag{2.93}$$

$$+ \quad (\omega^2 - f^2) \tag{2.94}$$

$$- \quad \frac{1}{4}(\omega^2 - f^2)^2 R^2 \ln\left(\frac{1}{2}\sqrt{\omega^2 - f^2}R\right) \tag{2.95}$$

$$+ \quad \frac{1}{8}(\omega^2 - f^2)^2(\psi(1) + \psi(3))R^2 \tag{2.96}$$

$$\pm \quad i\pi\frac{1}{8}(\omega^2 - f^2)^2 R^2 \tag{2.97}$$

$$+ \quad O(R^4 \ln R),$$

where $\psi(\cdot)$ is the logarithmic derivative of the Γ function (Abramowitz & Stegun, 1965. p.258).

Expanding this in the source scale variables we get

$$F^2\pi(\omega^2 - f^2)\mathrm{H}_2^{(\cdot)}(\sqrt{\omega^2 - f^2}R) \quad =$$

$$\frac{4}{r^2} \tag{2.98}$$

$$+ \quad F^2(\omega^2 - f^2) \tag{2.99}$$

$$- \quad F^4 \ln F \frac{1}{4}(\omega^2 - f^2)^2 r^2 \tag{2.100}$$

$$+ \quad F^4\frac{1}{4}(\omega^2 - f^2)^2 r^2\left(\ln 2 - \ln(\sqrt{(\omega^2 - f^2)}r)\right) \tag{2.101}$$

$$+ \quad F^4\frac{1}{8}(\omega^2 - f^2)^2\left(\frac{3}{2} - 2\gamma\right)r^2 \tag{2.102}$$

$$\pm \quad i\pi\frac{F^4}{8}(\omega^2 - f^2)^2 r^2 \tag{2.103}$$

$$+ \quad O(F^4 \ln F),$$

where $\gamma \approx 0.5772$ is Euler's constant.

At this point, any attempt to separate the matching procedure into terms which are "due to the radiation" and "other terms" might seem somewhat arbitrary. For a start, there is the term (2.100) of order $F^4 \ln F$, which could certainly not have been predicted from considering the expansion for the source flow alone. However, it has none of the features that we would expect of a term due to the radiation. In particular, it is independent of the sign of $\pm$ in (2.103) taken to satisfy the radiation condition! The only term which actually depends on application of the radiation condition is (2.103). However, one can see that, when we take the convolution with $\tilde{\alpha}(\omega)$ to invert the Fourier transform, we recover an integral which depends on both past and future values of $\alpha(t)$, which appears to violate the radiation condition. Thus it seems misleading to regard term (2.103) alone as representing the effect of radiation on the source. Instead, we

amalgamate the $\ln(\omega^2 - f^2)$ term in (2.101) with (2.103) and the γ term from (2.102) to give

$$- F^4(\omega^2 - f^2)^2 r^2 \left(\frac{1}{8} \left(\ln(\omega^2 - f^2) r + 2\gamma \right) \mp \frac{i\pi}{8} \right) \tilde{\sigma}(\omega), \tag{2.104}$$

where $\tilde{\sigma}$ is the Fourier transform of a source function. For the present analysis, $\tilde{\sigma}$ is $A(\omega)$, $B(\omega)$ or $C(\omega)$, where A, B and C are given by (2.92), depending on whether we are considering the matching conditions for ϕ, ψ or h, respectively. When (2.104) is converted back into the time domain, we recover an integral in the matching condition which depends only on the past history of the dynamics:

$$r^2 \int_0^\infty \ln \tau \left[\cos(f\tau) g(t - \tau) \right]_\tau d\tau, \tag{2.105}$$

where $g(t)$ is the inverse Fourier transform of $\tilde{g}(\omega) \equiv (\omega^2 - f^2)^2 \tilde{\sigma}(\omega)/16$ (the details are given in appendix B). A term (2.105) $\times e^{2i\theta}$ is thus required in ϕ, ψ and h, in the vortical region, at order $O(F^4)$. The exact form of g depends, of course, on whether we are performing the match for ϕ, ψ or h. The important point is that, since $\tilde{\sigma}$ is related to $\tilde{\alpha}$ through (2.92), with $\sigma = A, B$, or C, $g(t)$ may be expressed as a sum of instantaneous time derivatives of $\alpha(t)$ defined by (2.88), and is therefore a known function of the dynamics of the vortex region. The choice of $\mp$ in (2.104), required to obtain an integral (2.105) over the past history only, and not involving the future evolution, can be shown to be equivalent to requiring an outgoing wave form for $H_2^{(\cdot)}$ as $R \to \infty$.

We further remark that $O(F^3)$ dipoles in the wave zone also give rise to non-local time integrals at $O(F^4)$ in the source region. In this case the flow induced in the source region is a uniform velocity which has no effect on the energy of the source at leading order, although it must be retained if the $O(F^6)$ and $O(F^6 \ln F)$ flows in the source are to be computed.

2.3 Implications for balance and potential vorticity inversion

The foregoing study was motivated by a desire to understand the fundamental limitations of the concept of balanced dynamics. We shall now discuss this concept in the context of the isolated low Froude number vortex which we have studied here.

At $O(1)$, the dynamics are just two-dimensional incompressible vortex dynamics. This clearly does not depend on any knowledge of the past history of the flow in the vortex region, or of the gravity wave field, and so the dynamics are balanced in the sense that the instantaneous

potential vorticity field is sufficient to determine the velocity and height fields, and hence to integrate the equations of motion by advecting the potential vorticity field.

At $O(F^2 \ln F)$, there is a non-uniform correction to the vorticity of the vortical region as a result of the matching conditions. Although it arises as a result of the matching conditions between the vortical region and the wave region, it is independent of time. It can therefore be obtained from instantaneous fields, and should be regarded as a balanced correction to the vortical dynamics.

At $O(F^2)$, the corrections to the dynamics are expressible entirely in terms of inversions of the Laplacian on the $O(1)$ fields and further time-independent terms introduced by the asymptotic matching conditions. At this order, still no knowledge of the gravity wave field or of the past history of the vortex dynamics is required. This means that we can think of corrections at this order as balanced corrections to the dynamics, which represent the effects of local divergence, but not of gravity wave generation.

However, at $O(F^4)$, terms arise which come about as a result of matching to the wave zone, which are non-local in time, and which depend on the gravity wave radiation condition. We should note, however, that the integral (2.105) is not strictly an integral over the past history of an actual flow. The source term $g(t-\tau)$ in the integral is to be regarded as a term $g(t-\tau, T_2, T_4, \ldots)$ in which only the shortest time variable t is allowed to vary, and all other time variables are kept fixed. Formally we regard the integral as bounded because, implicit in our scaling analysis, we have assumed that terms associated with two-dimensional vortex dynamics remain bounded as the integration proceeds for arbitrarily long times. In reality this may be true only for a very small number of vorticity distributions, such as the solutions presented by Abrashkin and Yakubovich (1984).

Interestingly, then, this integral can be computed, in principle, by knowing only the instantaneous potential vorticity, and then integrating the two-dimensional incompressible vortex dynamics equations backwards in time. One might be tempted to think that we could therefore regard this correction as known in terms of the potential vorticity evolution, and therefore part of the balanced dynamics. However, it is then not clear how far back into the past they should be integrated. If we assume that the disturbance is turned on at some time t_0 then, for consistency, we would have to integrate back to time t_0. We would then expect (2.105) to be sensitive to the value of t_0 chosen. In the standard situation we are given *no* information about

the past history of the flow: we are given a potential vorticity distribution and nothing else. The choice of t_0 then becomes entirely arbitrary, and we cannot satisfactorily say that we have evaluated (2.105).

If we were to try to integrate (2.105) back to $\tau = -\infty$, then there is no reason to expect the integral to converge, even if it remains bounded. One might be slightly worried by this, since it is the result of inverting an apparently well-behaved Fourier transform. Formally one should say that the integral (2.105) is defined by its Cauchy Principal Value, so that $\int_0^\infty \ln\tau \cos\Omega\tau d\tau$ is given by the corresponding Fourier Transform (2.104), with $\omega \equiv \Omega$ and $\tilde{\sigma} \equiv 1$.

Another interesting feature is the logarithmic kernel, which means that contributions to (2.105) are significant for times arbitrarily far into the past. This may seem surprising because one would expect activity in the source region not to continue to affect the source region at the same strength long after the waves have propagated away. If g is truly of compact support, then we can integrate (2.105) once by parts to obtain

$$\int_{t-a}^{t-b} \tau^{-1} \cos(f\tau) g(t-\tau) d\tau, \tag{2.106}$$

where a and b are the limits of the range over which g is non-zero. It follows that if g is bounded then the importance of its contribution to the back reaction decays as t^{-1} for large t. However, we cannot dispense with past history in this manner unless we know that g is zero for all times before some initial time t_0. This is because although the individual impact of finite time sources decays as t^{-1}, there are in principle an infinite number of such sources.

Finally, we should note that the "radiation term" (2.104) is non-vanishing even when all the frequencies in $\tilde{\sigma}(\omega)$ lie below the inertial frequency f in magnitude. This corresponds to the case where all the gravity waves are evanescent. Therefore, they do not transport energy to infinity, and we would not wish to refer to this term as the effect of radiation in this context. However, we can see that in the case where $|\omega| < |f|$, we can obtain an expression for (2.104) which requires only instantaneous time derivates of $a(t)$ at the current time to be known. If $|\omega| < f$ we may write

$$-F^4\pi(\omega^2 - f^2)^2 r^2 \left(\frac{1}{8\pi}\left(\ln(f^2-\omega^2)r + i\arg(\omega^2 - f^2) + 2\gamma\right) \mp i\frac{1}{8}\right)\tilde{\sigma}(\omega). \tag{2.107}$$

Then, selecting the sign $\mp$ appropriately, according to whether we take $\arg(-1)$ as $\pm\pi$, we

are left with the so-called radiation term expressed as

$$\frac{1}{8}F^4(f^2-\omega^2)^2r^2\left(\ln(f^2-\omega^2)r+2\gamma\right)\tilde{\sigma}(\omega). \tag{2.108}$$

The selection of the $\mp$ here is equivalent to an evanescence boundary condition in the wave far field.

The logarithmic term $\ln(f^2-\omega^2)$ can now be expanded as

$$\ln(f^2-\omega^2)=\ln f^2+\ln(1-\omega^2/f^2)=2\ln f-\omega^2/f^2+\omega^4/2f^4-\omega^6/3f^6+\cdots, \tag{2.109}$$

i.e. $2\ln f$ plus a convergent Taylor series in which only integer powers of ω appear. The recovery of only integral powers of ω implies that we need only find the inverse Fourier transform of $\tilde{\sigma}(\omega)$ multiplied by integral powers of ω, and hence only instantaneous time derivatives of $\sigma(t)$ are required: no integral over the past history of evolution, such as (2.105), need be evaluated.

Technically, any finite truncation of this expansion defines a balanced model for the single compact vortex. One could perhaps argue that, in a source whose frequencies lie largely, but not entirely, below the inertial frequency, taking a few terms in the expansion of $\ln(f^2-\omega^2)$ might lead to a general improvement to the $O(F^4)$ dynamics, even though the series would ultimately diverge. This sort of behaviour is qualitatively familiar from the studies of Norton (1988) and McIntyre & Norton (1993), where a hierarchy of balanced models produces successively better approximations to shallow water dynamics at the first few orders, but ultimately fails to converge.

The notions discussed above have some bearing on the concept of "superbalance", as proposed by J. J. Tribbia (personal communication). In a "superbalance", one is supposed to diagnose all the past history of gravity wave radiation consistent with the given potential vorticity distribution. "Superbalance" might therefore be regarded as a gravity wave minimization, and as such deserves some consideration.

Tribbia has proposed the following scheme:

- Choose height and velocity fields consistent with the current PV distribution
- Integrate backwards in time (in principle to $t=-\infty$)
- Compute a time-integrated measure of total gravity wave activity

- Iterate the height and velocity velocity fields at $t = 0$ (subject to the prescribed PV field) to minimise the integrated gravity wave activity

In a sense, we might regard the flow given by the low Froude number matched asymptotic analysis as precisely the flow which minimises the total gravity wave activity, since we include only that gravity wave field which is essential for an asymptotic match onto the vortex dynamics. If so, then the foregoing analysis gives some idea of the characteristics which supposed superinversion operators are likely to possess. In particular, it suggests (a) that they are unlikely to converge unless some "initial instant" is assumed for the model, before which there is assumed to be no gravity wave activity, and (b) that the superinversion operator will in general be sensitive (at $O(F^4)$) to the choice of initial instant.

2.4 The effect of gravity wave radiation upon a rotating elliptical patch of uniform potential vorticity – an explicit example of generalized adjustment

In a pioneering paper, Broadbent & Moore (1979) investigated the stability of a Rankine vortex to two-dimensional perturbations. A Rankine vortex is an axisymmetric vortical column, with uniform vorticity within the column and zero vorticity without. In the low Mach number limit, therefore, the Rankine vortex corresponds to a vortex of uniform potential vorticity. They showed numerically that disturbances with axial mode numbers of two, three, four and six were unstable over a wide range of Mach numbers, and obtained an expression for the growth rate of the mode two instability at low Mach number by a matched asymptotic analysis.

Subsequently, Kop'ev & Leont'ev (1983) argued that the expression for the growth rate at low Mach number which was obtained by Broadbent & Moore (1979) could also be derived from energetic arguments, which made it possible to obtain growth rates for higher axial modes without significantly greater effort. Their analysis depends on assuming that the boundary perturbations are of small amplitude, of the form $e^{im\theta}$.

Recently, Zeitlin (1988, 1991) has suggested that the energetic arguments of Kop'ev & Leont'ev (1983) could be applied to flows with nonlinear departures from axisymmetry. He used these arguments to predict the way in which a class of exact solutions to the two-dimensional Euler equations found by Abrashkin & Yakubovich (1984) would respond to acoustic wave

radiation.

The Abrashkin & Yakubovich flows are categorized according to their degree of rotational symmetry, and the simplest class, with two-fold rotational symmetry, corresponds to the rotating ellipse of uniform vorticity found by Lamb (1932).

The analysis of Zeitlin (1988, 1991) assumed that the Abrashkin & Yakubovich flows adjusted to take account of gravity wave radiation simply by evolving to another such flow with the same degree of rotational symmetry and the same circulation but with less energy. For a rotating ellipse, this corresponds to increasing the aspect ratio of the ellipse while keeping its area constant. Most significantly, it implicitly assumes that, to a first approximation at least, the ellipse remains elliptical as it adjusts to the effect of gravity wave radiation.

Zeitlin's analysis might be regarded as unsatisfactory, however, since nothing is done to check that ellipses will simply elongate without significant change of form. The purpose of this section is to investigate the evolution of the rotating ellipse by a matched asymptotic analysis, thus enabling us to obtain the significant characteristics of the flow at every order in Froude number up to the order at which the vortical flow loses energy in response to gravity wave radiation. The present analysis is therefore able to investigate the validity of Zeitlin's assumption that the ellipse remains elliptical.

2.4.1 Evolution of the vortex boundary

A compact description of the rotating elliptical vortex requires construction of an "elliptical" coordinate system in order to describe the flow outside the vortex by means of elementary functions.

It is convenient to work in the complex plane, in which $z = x + iy$, where x and y are cartesian coordinates in physical space. One can then define elliptical coordinates ξ and η, via a new complex variable $w = \xi + i\eta$, such that $z = c\cosh w$. In w-space, the azimuthal coordinate η runs from 0 to 2π, and the ellipse in z-space lies within the region $0 < \xi < 1$ in w-space. For an ellipse with semi-major axis a and semi-minor axis b, Lamb (1932) showed that c is given by

$$c = (a^2 + b^2)^{1/2}. \tag{2.110}$$

An alternative description, which appears to be more readily generalizable in the present

context, is to work in $\ln w$-space, to which we assign the complex variable ζ. In the following analysis, we use a conformal mapping from z-space to ζ-space such that the ellipse in z-space is mapped onto the unit disc $|\zeta| < 1$ in ζ-space.

Recently, Legras & Zeitlin (1992) have used this formalism to develop the elliptical moment model of Legras & Dritschel (1991), Dritschel & Legras (1991). They begin by postulating a conformal mapping $f(\zeta)$ from the exterior of the unit disk in the ζ-plane to the exterior of a simply connected area in the z-plane, given by

$$f(\zeta) = \Gamma\zeta + \frac{\nu}{\zeta} + \sum_{i=3}^{\infty} \frac{\mu_i}{\zeta^i}. \tag{2.111}$$

Without loss of generality, Γ is taken to be real throughout. They were interested in the interaction between a number of different ellipses in two dimensional incompressible flow, in which the shape of each ellipse was represented in the form (2.111). The essence of their approach was that the evolution of the ellipses could be described by obtaining evolution equations for ν and the μ_i for each ellipse. They developed their so-called elliptical moment model by assuming that the μ_i were small, and so neglecting nonlinear products of the μ_i in the derivation of the evolution equations.

To obtain the evolution equations for the coefficients of the conformal map, it is convenient to consider the Lagrangian time derivative of z.

We start from the statement

$$\dot{z} \equiv \frac{Dz}{Dt} = u + iv \tag{2.112}$$

and convert this via (2.111) into its equivalent statement in the ζ–plane

$$\frac{Df}{Dt} \equiv \frac{\partial f}{\partial t} + \frac{\partial f}{\partial \zeta}\dot{\zeta} = u + iv. \tag{2.113}$$

Rearranging (2.113), we obtain

$$\frac{\dot{\zeta}}{\zeta} + \frac{1}{\zeta\frac{\partial f}{\partial \zeta}}\frac{\partial f}{\partial t} = \frac{u + iv}{\zeta\frac{\partial f}{\partial \zeta}}. \tag{2.114}$$

Now, since the elliptical vortex boundary is a material line in z-space, so it must also be a material line in ζ–space. Recalling that in ζ–space the vortex boundary is the unit circle, particle velocities on $|\zeta| = 1$ must be tangent to the unit circle, and therefore on $|\zeta| = 1$, we

will have

$$\mathrm{Re}\left[\frac{\dot{\zeta}}{\zeta}\right] = 0, \tag{2.115}$$

and hence

$$\mathrm{Re}\left[\frac{1}{\zeta f'}\frac{\partial f}{\partial t}\right] = \mathrm{Re}\left[\frac{u+iv}{\zeta f'}\right]. \tag{2.116}$$

Legras & Zeitlin (1992) now invoke a classical theorem of complex analysis, which states that a complex function which is analytic in $|z| < 1$ is known, up to a purely imaginary constant, if its real part is known in the unit circle $|z| = 1$. Hence, the right hand side of (2.116) can be used to define a function $h(\zeta)$, which is analytic in $1/\zeta$, and for which

$$\mathrm{Re}\, h(\zeta)|_{|\zeta|=1} = \mathrm{Re}\left[\frac{u+iv}{\zeta f'}\right]_{|\zeta|=1}. \tag{2.117}$$

The evolution of the conformal mapping function $f(\zeta)$ can then be obtained from

$$\frac{\partial f}{\partial t} = \zeta\frac{\partial f}{\partial \zeta}h(\zeta). \tag{2.118}$$

The temporal evolution of the vortex is now described entirely by the temporal evolution of the conformal map $f(\zeta)$, using (2.118). If $h(\zeta)$ is expressed in the form of a Laurent series in ζ^{-1}, setting the (arbitrary) imaginary part of the constant term in the expansion to zero is equivalent to imposing that Γ remains real throughout the evolution of the vortex.

2.4.2 The solution at leading order in F

We shall begin by obtaining Kirchoff's famous solution for the rotation rate of the elliptical vortex (see Lamb 1932) using the method outlined in the previous section. Although there are many ways to derive the solution, the presentation given here is intended to describe how the method presented above will work when we proceed to obtain evolution equations for the coefficients of the conformal map at higher orders in F. Without loss of generality, we shall assume that the potential vorticity within the ellipse exceeds its value outside the ellipse by unity.

To obtain the leading order streamfunction ψ_0, we must solve

$$\nabla^2\psi_0 = \begin{cases} 1 & \text{inside ellipse} \\ 0 & \text{outside ellipse} \end{cases}. \tag{2.119}$$

Using the complex variables z inside the ellipse and ζ outside it, (2.119) becomes

$$4\frac{d^2\psi_0^{(i)}}{dzd\bar{z}} = 1, \qquad |\zeta| < 1 \tag{2.120}$$

$$4\frac{d^2\psi_0^{(e)}}{d\zeta d\bar{\zeta}} = 0, \qquad |\zeta| > 1, \tag{2.121}$$

where $\psi_0^{(i)}$ and $\psi_0^{(e)}$ are the expressions for the leading order streamfunction for the interior and exterior of the ellipse respectively. Integrating these equations, and imposing continuity of ψ and its normal derivative on the boundary of the ellipse, we obtain

$$\psi_0^{(i)} = \frac{1}{4}z\bar{z} - \frac{1}{8\Gamma}\left(\bar{\nu}z^2 + \nu\bar{z}^2\right) - \frac{1}{4}\left(\Gamma^2 - |\nu|^2\right) \tag{2.122}$$

$$\psi_0^{(e)} = \frac{1}{4}\left(\Gamma^2 - |\nu|^2\right)\ln\zeta\bar{\zeta} + \frac{1}{8\Gamma}\left(\Gamma^2 - |\nu|^2\right)\left(\nu\zeta^{-2} + \bar{\nu}\bar{\zeta}^{-2}\right) \tag{2.123}$$

as the leading order solution for ψ.

It is straightforward to show that the velocity, on the boundary of the ellipse, is then

$$\frac{1}{2\Gamma}i(\Gamma^2 - |\nu|^2)\zeta. \tag{2.124}$$

To obtain the evolution equations for Γ and ν, we note that

$$\mathrm{Re}\left[\frac{u+iv}{\zeta f'}\right] = \mathrm{Re}\left[\frac{i}{2\Gamma}\frac{\Gamma^2 - |\nu|^2}{\Gamma - \nu/\zeta^2}\right] = \mathrm{Re}\left[\frac{i}{2\Gamma^2}\frac{\nu(\Gamma^2 - |\nu|^2)}{\Gamma\zeta^2 - \nu}\right], \tag{2.125}$$

and hence, by (2.118),

$$\frac{\partial f}{\partial t} = \frac{1}{2}i\nu\left(1 - \frac{|\nu|^2}{\Gamma^2}\right)\zeta^{-1}, \tag{2.126}$$

which implies

$$\frac{d\Gamma}{dt} = 0; \quad \frac{d\nu}{dt} = \frac{1}{2}i\nu\left(1 - \frac{|\nu|^2}{\Gamma^2}\right), \tag{2.127}$$

with solution

$$\Gamma = \text{constant}; \quad |\nu| = \text{constant}; \quad \nu = |\nu|e^{i\Omega t}; \quad \Omega = \frac{1}{2}\left(1 - \frac{|\nu|^2}{\Gamma^2}\right). \tag{2.128}$$

There are no higher order matching terms which would require the introduction of any of the μ_i terms in (2.111), thus confirming that at leading order the ellipse remains elliptical.

The rotation rate of the vortex is therefore $(1 - |\nu|^2/\Gamma^2)/4$, the factor of four rather than two coming from the fact that the conformal mapping description of the vortex boundary is unable to distinguish between 0^o and 180^o.

2.4.3 The solution to $O(F^2)$

To proceed to higher order in F, we must first compute the leading order height field h_0. It is convenient to work with the Bernoulli function B, for which

$$\nabla^2 B_0 = \begin{cases} 1+f & \text{inside ellipse} \\ 0 & \text{outside ellipse} \end{cases} . \tag{2.129}$$

In the interior of the ellipse, h_0 can be readily obtained from B_0 via the relation $h_0 = B_0 - \frac{1}{2}\boldsymbol{u}_0^2$. Outside the ellipse, a possible difficulty arises, since the calculation of $\boldsymbol{u}_0$ from ψ_0 will introduce a Jacobian factor:

$$h_0^{(e)} = B_0^{(e)} - 2\left(\frac{d\psi_0^{(e)}}{d\zeta}\frac{d\psi_0^{(e)}}{d\bar{\zeta}}\right) \times \left(\frac{df}{d\zeta}\frac{d\bar{f}}{d\bar{\zeta}}\right)^{-1} . \tag{2.130}$$

At first, the appearance of the Jacobian factor in (2.130) would seem to imply that, outside the ellipse, the expression for h_0 will contain all even inverse powers of ζ. and the simplicity of the analytical expression of the rotating elliptical vortex solution would be lost. Fortunately, however, (2.130) can be simplified. After imposing continuity of h_0 and its normal derivative across the elliptical boundary, we obtain

$$\begin{aligned} h_0^{(i)} &= \frac{1}{16}\left(1+2f-|\nu|^2\right)\left(2z\bar{z} - \frac{\bar{\nu}}{\Gamma}z^2 - \frac{\nu}{\Gamma}\bar{z}^2\right) \\ &- \frac{1}{4}\left(\Gamma^2(1+f) - |\nu|^2(2+f)\right) + \text{constant} \qquad (2.131) \\ h_0^{(e)} &= \frac{1}{4}f\left(\Gamma^2 - |\nu|^2\right)\ln\zeta\bar{\zeta} + \frac{1}{16\Gamma^3}\left(\Gamma^4(1+2f) - 2|\nu|^2\Gamma^2(1+f) + |\nu|^4\right)\left(\nu\zeta^{-2} + \bar{\nu}\bar{\zeta}^{-2}\right) \\ &- \frac{1}{8\Gamma^2}\left(\Gamma^2 - |\nu|^2\right)^2(\zeta\bar{\zeta})^{-1} + \text{constant}. \qquad (2.132) \end{aligned}$$

The Jacobian factor has been cancelled exactly from the denominator by the derivates of ψ. It follows that, as in the case of ψ_0, only quadratic terms in z or ζ^{-1} and their conjugates need be retained in the solution.

The arbitrary constant in (2.131) and (2.132) must be determined through the matching conditions to the outer flow.

We first note that in the limit $r \to \infty$, (2.123) implies

$$\psi_0^{(e)} \sim \frac{1}{2}\left(\Gamma^2 - |\nu|^2\right) \ln r. \tag{2.133}$$

From (2.81), this implies an outer scale flow streamfunction

$$\psi_0 = -\frac{1}{2}\left(\Gamma^2 - |\nu|^2\right) K_0(|f|Fr), \tag{2.134}$$

and a height field

$$h_0 = -f\frac{1}{2}\left(\Gamma^2 - |\nu|^2\right) K_0(|f|Fr). \tag{2.135}$$

This in turn induces a uniform correction to h in the vortical flow:

$$h_{0l} = f\frac{1}{2}\left(1 - |\nu|^2\right)(\ln(|f|F\Gamma) + \gamma), \tag{2.136}$$

which implies an $O(F^2)$ streamfunction in the vortical region:

$$\nabla^2\psi_{2l} = \begin{cases} (1+f)h_{0l} & \text{inside ellipse} \\ fh_{0l} & \text{outside ellipse} \end{cases}, \tag{2.137}$$

which has components at $O(F^2)$ and $O(F^2 \ln F)$.

Converting into complex coordinates and solving this equation, we obtain the streamfunction inside the elliptical vortex:

$$\psi_{2l}^{(i)} = h_{0l}\left(\frac{1}{4}z\bar{z}(1+f) - \frac{1}{8\Gamma}(\bar{\nu}z^2 + \nu\bar{z}^2) - \frac{1}{4}(\Gamma^2 - |\nu|^2)\right), \tag{2.138}$$

and the streamfunction outside the ellipse:

$$\begin{aligned} \psi_{2l}^{(e)} &= \frac{1}{8}h_{0l}\Big(2f\Gamma^2\zeta\bar{\zeta} + 2f\Gamma(\bar{\nu}\zeta\bar{\zeta}^{-1} + \nu\bar{\zeta}\zeta^{-1}) \\ &+ (\Gamma^2 - |\nu|^2)\left(2\ln\zeta\bar{\zeta} + \frac{\nu}{\Gamma}\zeta^{-2} + \frac{\bar{\nu}}{\Gamma}\bar{\zeta}^{-2}\right) + 2f|\nu|^2\zeta^{-1}\bar{\zeta}^{-1}\Big). \end{aligned} \tag{2.139}$$

Repeating the procedure to obtain the leading order solution described in §4.2, we obtain an evolution equation for ν at $O(F^2 \ln F)$:

$$\frac{d\nu}{dT_l} = \frac{1}{2}ih_{0l}\nu(2f + 1 - (|\nu|/\Gamma)^2). \tag{2.140}$$

There is no correction to the higher μ_i coefficients at $(F^2 \ln F)$.

Equation (2.140) implies a correction to the rotation rate ω at $O(F^2 \ln F)$, such that

$$\omega = \frac{1}{4}\left(\Gamma^2 - |\nu|^2 + F^2 \ln F\frac{1}{2}f(\Gamma^2 - |\nu|^2)(2f + 1 - (|\nu|/\Gamma)^2) + O(F^2)\right). \tag{2.141}$$

Recalling that $\ln F < 0$, this corresponds to a reduction in the rotation rate if and only if $f(2f + 1 - (|\nu|/\Gamma)^2) > 0$. The implication is that, as $|f|$ becomes large, the vortex always slows down compared with its incompressible rotation rate. Its rotation rate increases only if $-(1 - (|\nu|/\Gamma)^2)/2 < f < 0$.

We are now in a position to write down the equations for the second order velocity potential and streamfunction ϕ_2 and ψ_2 respectively.

$$4\frac{d^2\phi_2^{(i)}}{dzd\bar{z}} = -\frac{1}{32\Gamma^5}i(\Gamma^2 - |\nu|^2)(\Gamma^2(1+2f) - |\nu|^2)(\bar{\nu}z^2 - \nu\bar{z}^2) \tag{2.142}$$

$$\begin{aligned} 4\frac{d^2\phi_2^{(e)}}{d\zeta d\bar{\zeta}} = &- \frac{1}{32\Gamma^4}i(\Gamma^2 - |\nu|^2)^2(\Gamma^2(1+2f) - |\nu|^2)(\nu^2\zeta^{-4} - \bar{\nu}^2\bar{\zeta}^{-4}) \\ &- \frac{1}{32\Gamma^3}i(\Gamma^2 - |\nu|^2)^2(\Gamma^2(1-2f) - |\nu|^2)(\nu\zeta^{-2} - \bar{\nu}\bar{\zeta}^{-2}) \\ &- \frac{1}{16\Gamma^5}(\Gamma^2 - |\nu|^2)^2(\Gamma^4 - |\nu|^4 - f\Gamma^2|\nu|^2)(\nu\zeta^{-4}\bar{\zeta}^{-2} - \bar{\nu}\bar{\zeta}^{-4}\zeta^{-2}) \\ &+ \frac{1}{8\Gamma^3}i(\Gamma^2 - |\nu|^2)^3(\nu\zeta^{-3}\bar{\zeta}^{-1} - \bar{\nu}\bar{\zeta}^{-3}\zeta^{-1}) \end{aligned} \tag{2.143}$$

$$4\frac{d^2\psi_2^{(i)}}{dzd\bar{z}} = (1+f)\left[\frac{1}{16}\left(1 + 2f - |\nu|^2\right)\left(2z\bar{z} - \frac{\bar{\nu}}{\Gamma}z^2 - \frac{\nu}{\Gamma}\bar{z}^2\right) - \frac{1}{4}\left(\Gamma^2(1+f) - |\nu|^2(2+f)\right)\right] \tag{2.144}$$

$$\begin{aligned} 4\frac{d^2\psi_2^{(e)}}{d\zeta d\bar{\zeta}} = f(\Gamma - \nu\zeta^{-2})(\Gamma - \bar{\nu}\bar{\zeta}^{-2}) \Big[&\tfrac{1}{4}f\left(\Gamma^2 - |\nu|^2\right)\ln\zeta\bar{\zeta} \\ &+ \tfrac{1}{16\Gamma^3}\left(\Gamma^4(1+2f) - 2|\nu|^2\Gamma^2(1+f) + |\nu|^4\right)(\nu\zeta^{-2} + \bar{\nu}\bar{\zeta}^{-2}) \\ &\tfrac{1}{8\Gamma^2}\left(\Gamma^2 - |\nu|^2\right)^2(\zeta\bar{\zeta})^{-1}\Big] \end{aligned} \tag{2.145}$$

The result is that ϕ_2 and ψ_2 will require only constant, logarithmic, quadratic and quartic terms in their expressions, and the full solution of the problem to $O(F^2)$ can be written down in a finite expression involving only products of algebraic and logarithmic functions. The evolution of the boundary of the ellipse will require μ_3 to be non-zero at order $O(F^2)$, but all the other μ_i may be set to zero without approximation.

A considerable amount of manipulation is required to obtain expressions for ϕ_2 and ψ_2, and a program was written to undertake the integration and matching using the REDUCE symbolic manipulation language.

After obtaining the $O(F^2)$ velocity fields and substituting into (2.111 - 2.118), one obtains:

$$\begin{aligned}
\frac{d\mu_3}{dt} &= -\frac{i}{2}\bar{\mu_3}\frac{\nu^4}{\Gamma^4} - 2i\mu_3|\frac{\nu|^2}{\Gamma^2} + \frac{3i}{2}\mu_3 \\
&+ \frac{i\Gamma\nu^2}{96}\left(1-(|\nu|/\Gamma)^2\right)\ \Big[f^2\left(6-2\left(|\nu|/\Gamma\right)^2\right) \\
&\qquad +f\left(1-(|\nu|/\Gamma)^2\right)\left(7+3\left(|\nu|/\Gamma\right)^2\right) \\
&\qquad +2\left(1-(|\nu|/\Gamma)^2\right)^2\left(1+(|\nu|/\Gamma)^2\right)\Big] \qquad (2.146)\\
\frac{d\mu_1}{dt}+\frac{d\nu}{dT} &= \frac{i\nu|\nu|^2}{2\Gamma^3}(\mu_{-1}+\bar{\mu_{-1}}) \\
&+ \frac{i}{2}(\mu_1 - 2(|\nu|/\Gamma)^2\mu_1 - (\nu/\Gamma)^2\bar{\mu_1}) \\
&+ \frac{i}{4}(1-(|\nu|/\Gamma)^2)(4(\nu/\Gamma)^3\bar{\mu_3}+2(\bar{\nu}/\Gamma)\mu_3+(\bar{\nu}|\nu|^2/\Gamma^3)\mu_3) \\
&+ \frac{i\nu}{96}(1-(|\nu|/\Gamma)^2)\ (f^2(4+18(|\nu|/\Gamma)^2-2(|\nu|/\Gamma)^4) \\
&\qquad -f(1-(|\nu|/\Gamma)^2)(29-2(|\nu|/\Gamma)^2-3(|\nu|/\Gamma)^4) \\
&\qquad -(1-(|\nu|/\Gamma)^2)^2(11+(|\nu|/\Gamma)^2-2(|\nu|/\Gamma)^4)) \\
&+ \frac{i}{4}f\nu(\Gamma^2-|\nu|^2)(2f+1-(|\nu|/\Gamma)^2)(\ln(|f|\Gamma)+\gamma) \qquad (2.147)\\
\frac{d\mu_{-1}}{dt} &= \frac{1}{4}((\nu^2|\nu|^2/\Gamma^4)\bar{\mu_3}+(\bar{\nu}/\Gamma)^2\mu_3-(\nu/\Gamma)^2\bar{\mu_3}-(\bar{\nu}^2|\nu|^2/\Gamma^4)\mu_3). \qquad (2.148)
\end{aligned}$$

The solution for ν is known on the shortest timescale t, and this system of equations describes oscillations of μ_3, μ_1 and μ_{-1}, where μ_1 and μ_{-1} are used to represent $O(F^2)$ corrections of ν and Γ respectively. The oscillations are forced in the μ_3 equation, with a forcing frequency of 2Ω – i.e. four times the rotational frequency of the vortex. Forcing in the μ_1 equation is secular, and is absorbed into the $d\nu/dT$ component, leading to an $O(F^2)$ modification to the rotation rate of the vortex.

It is convenient to investigate solutions for μ_3 with the frequency of the forcing. These solutions will give weakly perturbed elliptical vortex shapes which rotate without change of form. Vortical patches which rotate without change of form have been termed V-states by Deem & Zabusky (1978), the simplest example of a V-state being the rotating ellipse of uniform

vorticity in the two-dimensional incompressible Euler equations.

Once the V-states of our system are found, the forcing is effectively removed from the system of equations describing the $O(F^2)$ perturbations to the elliptical vortex shape. They are then the same equations which describe free perturbations to an elliptical vortex boundary in incompressible flow. The perturbations will therefore be oscillatory provided the vortex in stable to incompressible mode-4 perturbations, and exponential otherwise.

The stability of an incompressible elliptical vortex was investigated by Love (1893). He found that the ellipse was always stable if it had an aspect ratio $\lambda = (\Gamma + |\nu|)/(\Gamma - |\nu|)$ of less than 3. At an aspect ratio $\lambda = 3$, the ellipse became unstable to mode 3 perturbations (i.e. $\mu_2 \neq 0$). In the present study, we impose 180^o rotational symmetry, and therefore we do not encounter mode 3 perturbations. As the aspect ratio is increased further, so successively more modes become unstable. The first one of interest to us here is mode 4, which becomes unstable when the aspect ratio $\lambda = (\sqrt{2} + 2\sqrt{\sqrt{2}-1})(1 + 1/\sqrt{2}) \approx 4.61$. In the variables Γ and $|\nu|$ to be used here, this corresponds to $|\nu|/\Gamma = \sqrt{\sqrt{2}-1}$.

2.4.4 V-states for weakly divergent flow

In finding the V-state with 180^o rotational symmetry for incompressible flow, the conformal map (2.111) from the unit disc in ζ-space to the shape of the rotating vortex patch in z-space was postulated. The evolution equations for the coefficients showed that $\mu_i = 0$ for all i was a consistent solution. A single evolution equation remained for ν, and it followed that $|\nu|$ was a constant, corresponding to vortex patch rotating at a constant rate.

With the effects of divergence introduced, we have seen that μ_3 may not be assumed to be zero for all time, although all the other μ_i for $i > 3$ may be taken to be zero.

We start by searching for a solution for μ_3 of the form

$$\mu_3(t) = Me^{2i\Omega t}, \tag{2.149}$$

where M is a constant (which will depend on $|\nu|$), and $\Omega = (\Gamma^2 - |\nu|^2)/2$. This solution should be regarded as the particular integral of (2.148). Substituting (2.149) into (2.148) and factorizing,

we obtain

$$M = -\frac{\Gamma|\nu|^2(1-(|\nu|/\Gamma)^2)}{48(1-2(|\nu|/\Gamma)^2-(|\nu|/\Gamma)^4)}\ (f^2(6-2(|\nu|/\Gamma)^2)+f(1-(|\nu|/\Gamma)^2)(7+3(|\nu|/\Gamma)^2) \\ +2(1-(|\nu|/\Gamma)^2)^2(1+(|\nu|/\Gamma)^2))\,. \tag{2.150}$$

Thus, provided that the denominator $1-2(|\nu|/\Gamma)^2-(|\nu|/\Gamma)^4 \neq 0$, there is a unique solution for M in terms of $|\mu|$. This is equivalent to the condition $(|\nu|/\Gamma)^2 \neq \sqrt{2}-1$. One can readily verify that μ_1 and μ_{-1} are may be set to zero with this solution. The rotation rate of the vortex is changed by $O(F^2)$.

It is also straightforward to show that the solution describes a vortex which is rotating without change of form. The conformal mapping function $f(\zeta)$ is now

$$f(\zeta) = \Gamma\zeta + |\nu|e^{i\Omega t}\zeta^{-1} + F^2 M e^{2i\Omega t}\zeta^{-3}. \tag{2.151}$$

Moving into a frame of reference rotating with the vortex, we define the complex coordinate in the rotating frame Z by $\zeta = Ze^{i\Omega t/2}$. Then

$$f(\zeta) = e^{i\Omega t/2}\left(\Gamma Z + |\nu|Z^{-1} + F^2 M Z^{-3}\right). \tag{2.152}$$

In the rotating Z–frame, therefore, the conformal mapping is rotating at a constant rotation rate $\Omega/2$. Apart from this uniform background rotation, the coefficients of the mapping are constants, and hence the vortex rotates without change of shape.

From (2.150), we can see that M can be positive or negative, depending upon $|\nu|/\Gamma$ and f. In figures 2.1–2.4 rotating V-state shapes are shown for various $|\nu|$ and various M, both positive and negative.

The ellipses are normalised to have a semi-major axis of unit length. A clear distinction is to be drawn between positive M and negative M. When M is positive, the ellipses seem to become more distorted towards square shapes, and for larger values of M appear to develop cusps. When M is negative, however, the ends of the ellipses tend to round out, and the V-states become more peanut-shaped. Now, it also follows from (2.150) that for moderate to large $|f|$, we will have $M < 0$, and therefore the $M < 0$ solutions should be qualitatively similar to the V-states of the single layer quasi-geostrophic equations. A study of these V-states was carried

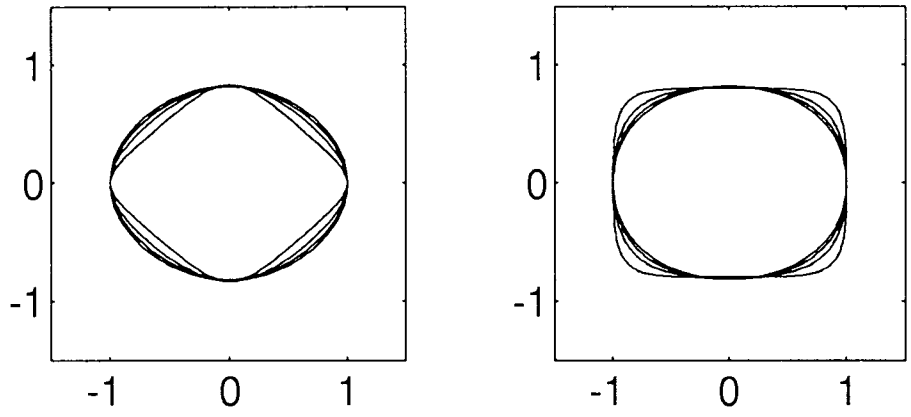

Figure 2.1: Shapes of rotating weakly compressible steadily rotating V-states for positive μ_3 (left) and negative μ_3 (right), with small aspect ratio ($|\nu|/\Gamma = 0.1$)

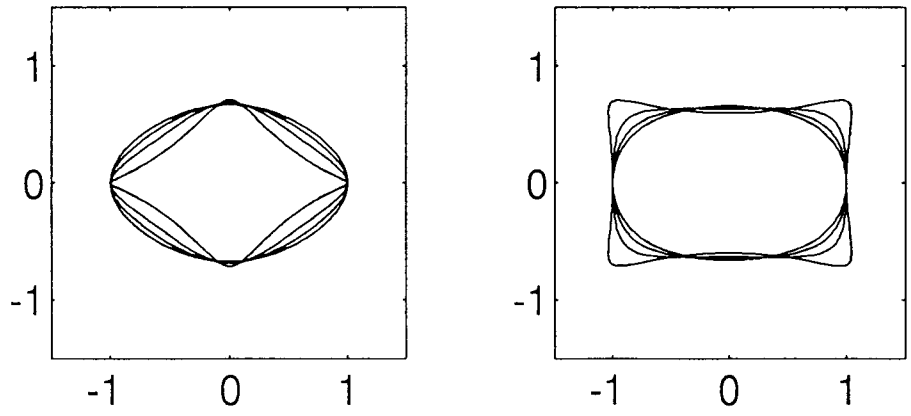

Figure 2.2: As figure 2.1, but with $|\nu|/\Gamma = 0.2$

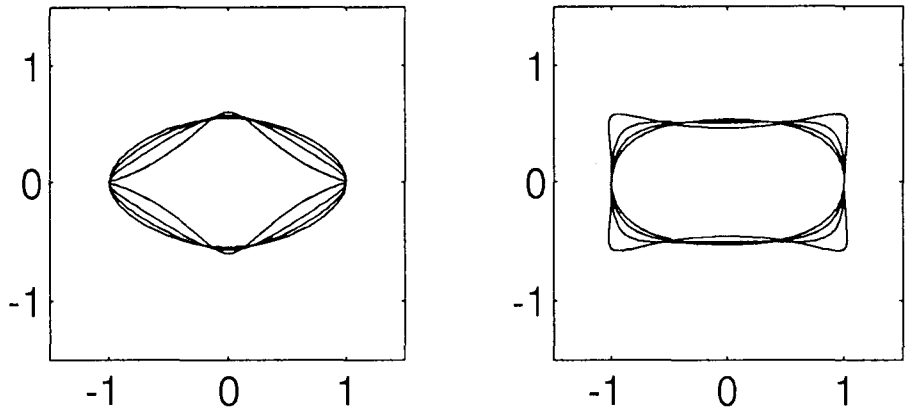

Figure 2.3: As figure 2.1, but with $|\nu|/\Gamma = 0.3$

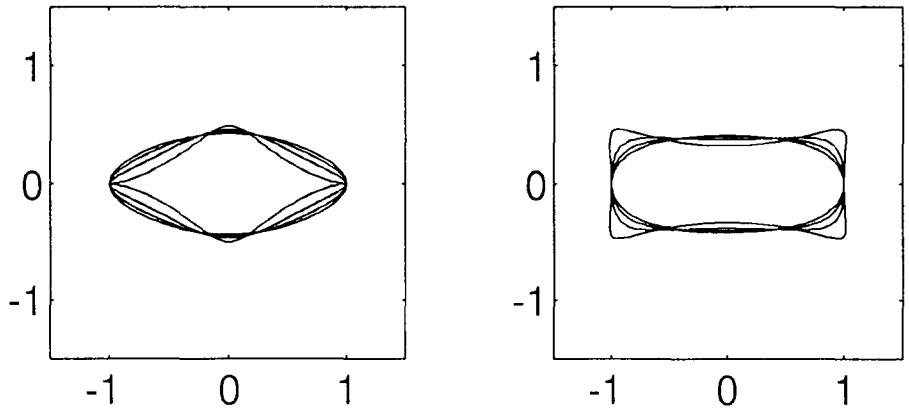

Figure 2.4: As figure 2.1, but with $|\nu|/\Gamma = 0.4$

out by Polvani *et al.* (1989), who found that the V-states of the single layer quasigeostrophic equations were more peanut-shaped than their elliptical counterparts for the incompressible Euler equations. It seems, therefore, that the asymptotic expansion presented here is capable of capturing the qualitative of V-states of the quasigeostrophic system.

In addition to the $O(F^2)$ change of shape of the V-states, the rotation rate is adjusted by an amount of $O(F^2)$, due to local divergence effects. However, except when the background rotation is absent, the dominant correction to the rotation rate comes about from matching conditions with the wave scale flow. The correction introduced from the matching conditions when background rotation is present is $O(F^2 \ln F)$ (equation 2.141).

2.4.5 The effect of gravity wave radiation

We turn now to the effect of gravity wave radiation on the rotating nearly-elliptical vortex. As we have seen, the effect of wave radiation does not enter the problem at $O(F^2)$, but does enter the problem at $O(F^4)$, in the form of a matching condition in the far field, imposing a uniform straining flow.

If one attempts to perform a complete asymptotic analysis of the fields to $O(F^4)$, it is not possible to express them in closed analytical form, unlike the $O(1)$, $O(F^2)$ and $O(F^2 \ln F)$ fields. The problem arises because, although the Bernoulli function to second order in F^2 outside the ellipse can be expressed in a finite sum of powers of ζ and $\bar{\zeta}$, multiplied, by logarithms of ζ and $\bar{\zeta}$, obtaining the height field from the Bernoulli function involves dividing by the Jacobian of the transformation. At $O(F^2)$, unlike the leading order analysis, it does not seem possible to factor out the Jacobian from the corresponding numerator. Thus although the second order height field may be expressed in closed (albeit cumbersome) form, integration with respect to ζ and $\bar{\zeta}$ will not lead to a closed form expression for the velocity potential at $O(F^4)$.

It follows that at $O(F^4)$, the representation of any V-state by a conformal mapping of form (2.111)) will require $\mu_i \neq 0$ for all odd i. However, it is clear that even if it were possible to obtain equations for the evolution of the μ_i, the contributions from the fields obtained in the way described above would give rise only to adjustments to the rotation rate of the structure at $O(F^4)$, and some further $O(F^4)$ corrections to the amplitudes of ν and the μ_i.

On the other hand, matching of the leading order solution to the gravity wave region will

give rise to a radiating wave field, one result of which is to introduce in the wave field a Hankel function of the appropriate type, corresponding to a radiating boundary condition. Matching conditions then imply that a large scale straining flow of form $r^2 \sin 2\theta$ will be introduced at $O(F^4)$ in the region of the vortex, in a sense which will cause the ellipse to elongate and lose energy, consistent with the associated radiating wave field. Since we know that ellipses remain elliptical under the influence of a large scale straining flow (Kida, 1981), it follows that we may simply regard ν as a slowly varying parameter.

To see this in detail, we must first obtain the wave-like part of the far field. First, therefore, we must obtain the time fluctuating part of the far field of $\psi_0^{(i)}$ in the limit $r \to \infty$. In doing so, however, we must recall that the ζ-coordinate is itself evolving in time, and hence the $\ln \zeta\bar{\zeta}$ term will contribute to the quadrupolar far field in (2.123).

From (2.123), the time-fluctuating part of $\psi_0^{(e)}$ is

$$-\frac{\Gamma}{8r^2}|\nu|(\Gamma^2-|\nu|^2)\left(e^{-i(2m\theta-\Omega t)}+e^{i(2m\theta-\Omega t)}\right). \tag{2.153}$$

Matching onto the wave field, this implies a leading order ($O(F^2)$) wave field, which consists of wavelike perturbations for streamfunction ψ and velocity potential ϕ, related via (2.85). In this case, we therefore have

$$-i\Omega\psi + f\phi = 0 \tag{2.154}$$

$$\phi + i\psi \sim \frac{i\Gamma}{8r^2}|\nu|(\Gamma^2-|\nu|^2)\left(e^{-i(2m\theta-\Omega t)}+e^{i(2m\theta-\Omega t)}\right) \quad \text{as } r \to 0, \tag{2.155}$$

which implies $O(F^2)$ wave fields:

$$\psi_2 = \frac{i\pi\Gamma}{16}\frac{f}{\Omega+f}|\nu|(\Gamma^2-|\nu|^2)(\Omega^2-f^2)\mathrm{H}_2^{(1)}((\Omega^2-f^2)^{1/2}R)e^{i(2m\theta-\Omega t)} \tag{2.156}$$

$$\phi_2 = -\frac{\pi\Gamma}{16}\frac{\Omega}{\Omega+f}|\nu|(\Gamma^2-|\nu|^2)(\Omega^2-f^2)\mathrm{H}_2^{(1)}((\Omega^2-f^2)^{1/2}R)e^{i(2m\theta-\Omega t)}. \tag{2.157}$$

The imaginary part of this corresponds to a streamfunction at $O(F^4)$ in the vortical region:

$$\psi_4 = -\frac{\pi\Gamma}{128}\frac{\Omega-f}{\Omega+f}(\Gamma^2-|\nu|^2)(\Omega^2-f^2)^2(\bar{\nu}z^2-\nu\bar{z}^2). \tag{2.158}$$

Adding this streamfunction to the velocity field at $O(F^4)$ and using (2.116), we obtain

$$\frac{d\Gamma^2}{dt} = F^4\frac{\pi}{32}\Gamma^2|\nu|^2(\Gamma^2-|\nu|^2)(\Omega^2-f^2)(\Omega-f)^2 \tag{2.159}$$

$$\frac{d|\nu|^2}{dt} = F^4\frac{\pi}{32}\Gamma^2|\nu|^2(\Gamma^2-|\nu|^2)(\Omega^2-f^2)(\Omega-f)^2. \tag{2.160}$$

Conservation of the circulation, $(\Gamma^2 - |\nu|^2)/4$, was not used explicitly in deriving these equations, and serves as an independent check on the analysis.

If we introduce the constant C, defined such that $C^2 = \Gamma^2 - |\nu|^2$, we can obtain an evolution equation for Γ^2:

$$\frac{d\Gamma^2}{dt} = F^4 \frac{\pi}{32\Gamma^6} C^2(\Gamma^2 - C^2)\left(\frac{1}{4}C^4 - \Gamma^4 f^2\right)\left(\frac{1}{2}C^2 - f\Gamma^2\right)^2. \tag{2.161}$$

Let us consider first the non-rotating case, which was considered by Zeitlin (1991). In this case, (2.161) reduces to:

$$\frac{d\Gamma^2}{dt} = \frac{\pi F^4}{512\Gamma^6} C^{10}(\Gamma^2 - C^2). \tag{2.162}$$

In this case, we may obtain the solution:

$$\Gamma^6/3 + C^2\Gamma^4/2 + C^4\Gamma^2 + C^6 \ln(\Gamma^2 - C^2) = \frac{\pi F^4 C^{10} t}{512} + \text{constant}. \tag{2.163}$$

Since $\Gamma^2 > C^2$, we know that Γ is a monotonically increasing function of time, and hence as $t \to \infty$ we will have

$$\Gamma \sim \left(\frac{3\pi}{512}\right)^{1/6} C^{5/3}(F^4 t)^{1/6} + O(1). \tag{2.164}$$

Since Γ increases without bound in this case, it follows from conservation of $\Gamma^2 - |\nu|^2$ that, for large t, $|\nu| \sim \Gamma - O(\Gamma^{-1})$. The ellipse has thus become infinitely long and this, with semi-major axis $\Gamma + |\nu| \to \infty$, and semi-minor axis $\Gamma - |\nu| \to 0$ as $t \to \infty$. The result is that the vortex evolves through a succession of V-states, with rapid oscillations about them on the $O(1)$ timescale.

However, we already know that if $(|\nu|/\Gamma)^2 = \sqrt{2} - 1$, the perturbation expansion breaks down because the ellipse departs from elliptical form as μ_3 in the conformal mapping (2.111) becomes unbounded. In the case $f = 0$, we also know that $\mu_3 < 0$, and hence we can make some qualitative statement about the nature of distortion of the ellipse.

In figure 2.5, the evolution of an ellipse with $f = 0$ is shown approaching the critical aspect ratio $(|\nu|/\Gamma)^2 = \sqrt{2} - 1$. The perturbation expansion suggests that, as the critical aspect ratio is reached, the ellipse becomes progressively more "peanut"-shaped. Eventually, the expansion procedure breaks down, and the mapping $f(\zeta)$ ceases to be single-valued. By this time, the lobes of the "peanut" have grown significantly, and there is a tendency to pinch in the middle, creating two separate vortices.

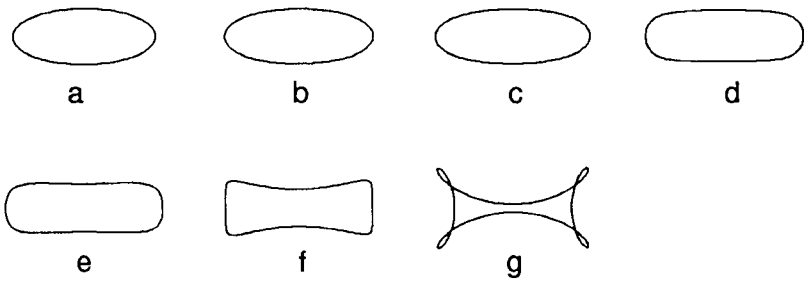

Figure 2.5: V-states of the rotating ellipse in the non-rotating frame ($f = 0$). Fig (a) represents the aspect ratio at which mode 3 instability would first occur, if 180^o symmetry were relaxed. Figures (a) to (g) show the V-states as the ellipse extends due to wave radiation. The splitting ratio is $(|\nu|/\Gamma)^2 = 0.4142$.

Some support for this scenario is provided by the analytical work of Williams (1992), and the numerical work of Chan *et al.* (1993). Williams performs a weakly nonlinear version of the present analysis, equivalent to assuming that $|\nu|/\Gamma = O(F^2)$. He shows that the weakly nonlinear development of the elliptical perturbation also leads to a "pinch" at a time of order $\ln F/F^4$. The numerical work of Chan *et al.* confirms this, but their Froude number is of order one. It seems that this analysis is in agreement with the existing literature, though not with Zeitlin's (1991) remarks, where he supposed that a secondary barotropic instability mechanism would have to be invoked to explain the subsequent breakup of the ellipse into two vortices. That is not the conclusion of the present study, nor is it the conclusion of Williams. The present study provides an interesting counterpart to the study of Williams in that it shows that $O(F^2)$ terms are sufficient to explain the principal dynamics, and one does not need to take into account terms at high order in F to obtain the nonlinear breakdown of the ellipse, even though they are required for the weakly nonlinear analysis.

Now, we notice that, as the aspect ratio of the ellipse increases, the frequency of the radiated waves $\Omega = (1-(|\nu|^2/\Gamma^2)/2 = C^2/(2\Gamma^2)$ decreases. Provided $\Omega > |f|$, waves will radiate and the ellipse will continue to elongate. However, if $\Omega < |f|$, then waves will not radiate, Γ^2 and $|\nu|^2$ will be constant, and the ellipse will not elongate with time. The values of the constants $|f|$ and C will determine whether the ellipse reaches the splitting aspect ratio, at which it breaks in two. At the splitting aspect ratio, the frequency of radiated waves is $\Omega_c = 1 - 1/\sqrt{2}$. Therefore,

if $|f| > 1 - 1/\sqrt{2}$, the ellipse will gradually approach the aspect ratio, at which it no longer excites radiating gravity waves. If, on the other hand, $|f| < 1 - 1/\sqrt{2}$, we expect the ellipse to split in two as it approaches the critical aspect ratio. It will then be necessary to determine the sign of μ_3 to describe the nature of the breakup of the ellipse.

To determine the sign of μ_3 at the splitting aspect ratio, we set $(|\nu|/\Gamma)^2 = \sqrt{2} - 1$ in (2.150) and determine the roots of $M = 0$ as a function of f. This leads to the equation

$$(4 - \sqrt{2})f^2 + (\sqrt{2} - 1)f + 6\sqrt{2} - 8 = 0, \tag{2.165}$$

which has solutions

$$f_1 = -(1 - 1/\sqrt{2}) \approx -0.29; \qquad f_2 = -2(3\sqrt{2} - 2)/7 \approx -0.64. \tag{2.166}$$

If f lies between f_1 and f_2, then $M > 0$, otherwise $M < 0$.

The magnitude of f_1, the smaller of the two roots of (2.166), is the same as the magnitude of the critical background rotation rate, above which the inhibiting effect of background rotation on the radiation will prevent ellipses from reaching their splitting aspect ratio. It follows that if $|f| < 1 - 1/\sqrt{2}$, we will always have $M < 0$ at the critical aspect ratio $(|\nu|/\Gamma)^2 = \sqrt{2} - 1$. Therefore, the nature of the breakup of an elliptical vortex by elongation due to gravity wave radiation can be described entirely by considering a succession of V-states in which $\mu_3 \to -\infty$ while $(|\nu|/\Gamma)^2 = \sqrt{2} - 1$ — the same as for the case without background rotation.

Finally, in cases where the background rotation is sufficiently strong to inhibit the breakup of the vortex, it is interesting to note the differences in the approach to the equilibrium aspect ratio of the ellipse between positive and negative f.

Returning to (2.161), we can write

$$\int \left(\frac{\alpha}{\Gamma^2 - C^2} + \frac{\beta}{f\Gamma^2 + C^2/2} + \frac{\gamma}{f\Gamma^2 - C^2/2} + \frac{\delta}{(f\Gamma^2 - C^2/2)^2} + \frac{\epsilon}{(f\Gamma^2 - C^2/2)^3} \right) d\Gamma^2 = \int \frac{F^4 \pi C^2}{32} dt \tag{2.167}$$

for constants $\alpha, \beta, \gamma, \delta, \epsilon$. For $f > 0$, at large times we will have

$$\int \frac{\epsilon d\Gamma^2}{(f\Gamma^2 - C^2/2)^3} \sim \int \frac{F^4 \pi C^2}{32} dt, \tag{2.168}$$

where $\epsilon = -C^2/(64f^2(1 - 2f))$. Hence, for large times, we will have

$$\Gamma^2 \sim \frac{C^2}{2f} - \frac{1}{2\sqrt{\pi} f (1 - 2f)^{1/2}} (F^4 t)^{-1/2}. \tag{2.169}$$

The cyclonic ellipse approaches its final aspect ratio algebraically in time for large times.

On the other hand, if $f < 0$ then, for large t, we have

$$\int \frac{\beta d\Gamma^2}{f\Gamma^2 + C^2/2} \sim \int \frac{F^4 \pi C^2}{32} dt, \tag{2.170}$$

where $\beta = 1/(64f^2C^2(1+2f))$. From this it follows that

$$\Gamma^2 - \frac{C^2}{2|f|} \propto \exp(-2\pi C^4 |f|^3 (1-2|f|) F^4 t), \tag{2.171}$$

so that, when $-1/2 < f < 0$, the final approach of the anticyclonic ellipse to its steady aspect ratio is exponential in time, and hence rather more rapid than the corresponding cyclonic case.

The particular case $f = 1 - 1/\sqrt{2}$ requires special attention. In this case, the radiating ellipse equilibrates at the critical aspect ratio. However, μ_3 is unbounded at the critical aspect ratio (unlike the corresponding anticyclonic case $f = -(1 - 1/\sqrt{2})$, in which case it remains bounded as it approaches its critical aspect ratio). Since only other radiation terms can affect the growth of Γ, it is probably necessary to consider higher order radiation fields to resolve this singularity, perhaps with f differing from $1 - 1/\sqrt{2}$ by $O(F^2)$. However, it seems that the principal features of the response of the ellipse to gravity wave radiation have been captured by the present analysis, and no further analysis has been attempted to clarify this remaining limiting case.

2.5 Discussion

The material presented in this chapter has focussed on the asymptotic limit of small Froude number. This is the limit in which the Lighthill analysis of aerodynamic sound generation is formally valid.

We have seen that it is possible to perform a matched asymptotic analysis and recover a quadrupolar far field, in a manner similar to Crow (1970) for the three-dimensional case. That result alone is non-trivial: if the incompressible velocity field is used in computing the Lighthill source term for a single two-dimensional eddy, the resulting integrals for the quadrupole moments are divergent.

The matched asymptotic analysis enabled us to analyse the general form of the back-reaction — i.e. the effect of the radiating gravity waves on the vortical flow. We showed that it was not

in general possible to determine the back reaction, which occurs at $O(F^4)$ in the source flow, in terms of the instantaneous potential vorticity field, even if one is permitted to integrate the equations of motion backwards in time. This is because history integrals are in general sensitive to the initial instant which is selected in the integration over the past times. However, if no radiating gravity waves were present, it was possible to obtain an expression for the $O(F^4)$ flow evaluating only instantaneous time derivatives of the potential vorticity field, and without reference to any initial instant. It follows that, at low Froude number, it is not in general possible to construct a balanced model which incorporates gravity wave emission without specifying a time in the past before which there are supposed to be no gravity waves.

An example of a flow subject to gravity wave radiation is the rotating ellipse of uniform potential vorticity. This flow was analysed to elucidate some more features of the effect of gravity wave radiation in a low Froude number limit. It was found that the ellipse tended to elongate in response to gravity wave radiation until it reached a certain aspect ratio, at which point it appeared to split into two vortices, and beyond which point the asymptotic analysis is not valid. The effect of the elongation is to reduce the radiation frequency of the quadrupolar gravity waves. Therefore, if the background rotation is sufficiently rapid, the ellipse might not reach its splitting aspect ratio, whereas for weaker background rotation the splitting aspect ratio is always attained on times such that $t = O(F^{-4})$.

If the splitting aspect ratio is not achieved, a remarkable degree of asymmetry in f is observed in the way in which the final aspect ratio of the ellipse is approached – exponentially in F^4t for anticyclones, but algebraically in F^4t for cyclones.

From time to time it is suggested that the nonlinear shallow water equations might exhibit a phenomenon of generalized adjustment, in which the vortical flow is continually adjusting itself to emit as few gravity waves as possible. Although the general analysis suggests that this is never truly possible for flows with a full spectrum of frequencies. the generalized adjustment hypothesis is supported by the model problem of the rotating ellipse. The ellipse elongates, and if the background rotation is sufficiently strong, will ultimately stop emitting gravity waves. If the background rotation is not sufficiently strong, it will split into two vortices, which will presumably move apart until they no longer radiate gravity waves. At that point, if they are sufficiently far apart, elliptical perturbation might once again grow on the boundaries of each separately, and the process will repeat itself. By this mechanism, the overall intensity of

radiation will decrease as more and more smaller vortices are responsible for the radiation. To see this, first note that the scaling law (2.9) can be modified to take account of the effect of the Coriolis force:

$$h' \sim \begin{cases} h_0 \left(\frac{l}{|\boldsymbol{x}|}\right)^{1/2} \left(\frac{u}{c_0}\right)^2 \left(\frac{(\omega^2 - f^2)^{1/2} l}{c_0}\right)^{3/2} & \omega^2 > f^2 \\ 0 & \omega^2 < f^2 \end{cases} . \tag{2.172}$$

Now, ω is set by the vorticity, and $u \sim \omega l$. Hence, keeping $l/|\boldsymbol{x}|$ fixed, we have

$$h' \sim l^{7/2}. \tag{2.173}$$

Each time the vortex splits, two vortices are formed, each with $l \longrightarrow l/\sqrt{2}$. Ultimately, we suppose that there are n vortices, each of dimension $l/\sqrt{n}$. Then

$$h' \sim n \times \left(\frac{l}{n^{1/2}}\right)^{7/2} \sim n^{-3/4}. \tag{2.174}$$

Alternatively, keeping $|\boldsymbol{x}|$ fixes, $h' \sim n^{-1}$. Consequently, as $n \to \infty$, the overall radiated gravity wave amplitude decreases, supporting the concept of generalized adjustment, in which the flow evolves so as to decrease the amplitude of the gravity waves it radiates.

There is, however, one key point about the generalized adjustment hypothesis. In the usual Rossby adjustment problem, the adjustment happens on the timescale of the inertial period, which is assumed short compared with the timescale of motions. Rossby adjustment is a fast process, as far as the balanced dynamics are concerned. For the type of adjustment due to gravity wave radiation experienced by the rotating ellipse, the opposite is true: the adjustment occurs on a very long timescale compared with the balanced dynamics.

2.6 Appendix A

The aim of this appendix is to show that the far field of (2.50) takes the form of the expected dipole when the logarithmic kernel is expanded for $|\boldsymbol{x}'| \ll |\boldsymbol{x}|$, and the error is an order of magnitude smaller, except for a logarithmic factor. We note that Crow (1970) remarks that his integrals will fail to converge after a certain number of moment expansions, but he does not rigorously address their asymptotic form. Ting & Miksis (1990) have presented a more careful analysis of the corresponding asymptotic forms in the three-dimensional problem, and

the analysis presented here is in the spirit of their paper, although the details are somewhat different.

In this appendix, we are considering the far field form of

$$\int_{\mathbb{R}^2} \nabla.((h_0 - f\psi_0)\boldsymbol{u}_0) \ln|\boldsymbol{x} - \boldsymbol{x}'| d^2\boldsymbol{x}'. \tag{2.175}$$

We note that, integrating (2.175) once by parts, this is equivalent to

$$\int_{\mathbb{R}^2} (h_0 - f\psi_0)\boldsymbol{u}_0 . \frac{\boldsymbol{x} - \boldsymbol{x}'}{|\boldsymbol{x} - \boldsymbol{x}'|^2} d^2\boldsymbol{x}'. \tag{2.176}$$

We start by considering the form of the far field for $\psi_0(\boldsymbol{x})$. In (2.25), we suppose that ζ_0 is a C^∞ function of two variables. We assume further that ζ_0 is of compact support, so $\exists \rho > 0$ such that $\zeta_0(\boldsymbol{x}) = 0 \ \forall |\boldsymbol{x}| > \rho$. Therefore $|\zeta_0|$ is bounded with $|\zeta_0| < \mathcal{Q} \ \forall \boldsymbol{x}$. It follows that, $\forall |\boldsymbol{x}| > 2\rho$,

$$\left|\frac{\partial \psi}{\partial x_i}\right| = \frac{1}{2\pi}\left|\int_{\mathbb{R}^2} \zeta_0(\boldsymbol{x}') \frac{x_i - x_i'}{|\boldsymbol{x} - \boldsymbol{x}'|^2} d^2\boldsymbol{x}'\right| \tag{2.177}$$

$$\leq \frac{\mathcal{Q}}{2\pi} \int_{|\boldsymbol{x}'|<\rho} \frac{1}{|\boldsymbol{x}| - \rho} d^2\boldsymbol{x}' \tag{2.178}$$

$$\leq \frac{\mathcal{Q}\rho^2}{|\boldsymbol{x}|}, \tag{2.179}$$

where we obtain (2.178) from (2.177) by using Schwartz' formula in the form $|\boldsymbol{x} - \boldsymbol{x}'| > |\boldsymbol{x}| - |\boldsymbol{x}'|$. Similarly

$$\left|\frac{\partial^2 \psi_0}{\partial x_i \partial x_j}\right| = \frac{1}{2\pi}\left|\int_{\mathbb{R}^2} \zeta_0(\boldsymbol{x}') \left(\frac{\delta_{ij}}{|\boldsymbol{x} - \boldsymbol{x}'|^2} - \frac{2(x_i - x_i')(x_j - x_j')}{|\boldsymbol{x} - \boldsymbol{x}'|^4}\right) d^2\boldsymbol{x}'\right| \tag{2.180}$$

$$\leq \frac{\mathcal{Q}}{2\pi} \int_{|\boldsymbol{x}'|<\rho} \left(\frac{1}{(|\boldsymbol{x}| - \rho)^2} + \frac{2}{(|\boldsymbol{x}| - \rho)^2}\right) d^2\boldsymbol{x}' \tag{2.181}$$

$$\leq \frac{6\mathcal{Q}\rho^2}{|\boldsymbol{x}|^2}. \tag{2.182}$$

Now let $\chi = B_0 - f\psi_0$. Since ζ_0 is a C^∞ function of compact support, so is $\zeta_0 \nabla\psi_0$, which is bounded with bound $\mathcal{U}$ (say). Then

$$|\chi(\boldsymbol{x})| = \frac{1}{2\pi}\left|\int_{\mathbb{R}^2} \zeta_0 \frac{\partial \psi_0}{\partial x_j'} \left(\frac{x_j - x_j'}{|\boldsymbol{x} - \boldsymbol{x}'|^2} - \frac{x_j}{|\boldsymbol{x}|^2}\right) d^2\boldsymbol{x}'\right| \tag{2.183}$$

$$= \frac{1}{2\pi}\left|\int_{\mathbb{R}^2} \zeta_0 \frac{\partial \psi_0}{\partial x_j}\left(\frac{2x_j \boldsymbol{x}.\boldsymbol{x}' - x_j'|\boldsymbol{x}|^2 - x_j|\boldsymbol{x}'|^2}{|\boldsymbol{x}|^2|\boldsymbol{x}-\boldsymbol{x}'|^2}\right) d^2\boldsymbol{x}'\right| \tag{2.184}$$

$$\leq \frac{\mathcal{U}}{2\pi}\int_{|\boldsymbol{x}'|<\rho} \frac{3\rho|\boldsymbol{x}|^2 + \rho^2|\boldsymbol{x}|}{|\boldsymbol{x}|^2(|\boldsymbol{x}|-\rho)^2} d^2\boldsymbol{x}' \tag{2.185}$$

$$\leq \frac{7\mathcal{U}\rho^3}{|\boldsymbol{x}|^2}, \tag{2.186}$$

where here we obtain (2.185) from (2.184) by expanding the numerator as a sum of the modulii of its components, and expand the denominator in the same way as in the step from (2.177) to (2.178). Similarly,

$$\left|\frac{\partial \chi}{\partial x_i}\right| = \frac{1}{2\pi}\left|\int_{\mathbb{R}^2} \zeta_0 \frac{\partial \psi_0}{\partial x_j'}\left(\frac{\delta_{ij}}{|\boldsymbol{x}-\boldsymbol{x}'|^2} - \frac{2(x_i-x_i')(x_j-x_j')}{|\boldsymbol{x}-\boldsymbol{x}'|^4} - \frac{\delta_{ij}}{|\boldsymbol{x}|^2} + \frac{2x x_i x_j}{|\boldsymbol{x}|^4}\right) d^2\boldsymbol{x}'\right| \tag{2.187}$$

$$\leq \frac{\mathcal{U}}{2\pi}\int_{|\boldsymbol{x}'|<\rho}\left(\frac{2|\boldsymbol{x}|\rho+\rho^2}{|\boldsymbol{x}|^2(|\boldsymbol{x}|-\rho)^2} + \frac{12|\boldsymbol{x}|^2\rho + 6|\boldsymbol{x}|^4\rho^2 + 2|\boldsymbol{x}|^2\rho^4}{|\boldsymbol{x}|^4(|\boldsymbol{x}|-\rho)^4}\right) d^2\boldsymbol{x}' \tag{2.188}$$

$$\leq \frac{126\mathcal{U}\rho^3}{|\boldsymbol{x}|^3}. \tag{2.189}$$

Now let $\boldsymbol{g} = (h_0 - f\psi_0)\boldsymbol{u}$. From (2.179, 2.182, 2.186, 2.189) we have:

Lemma 1 *$\exists A, B > 0$ such that $|g_i| < A|\boldsymbol{x}|^{-3}$ and $|\partial g_i/\partial x_j| < B|\boldsymbol{x}|^{-4}$ $\forall |\boldsymbol{x}| > 2\rho$ and for $i = 1,2$; $j = 1,2$.*

To proceed with our analysis of (2.176), we split the domain of integration $\mathbb{R}^2$ into three parts:

I $|\boldsymbol{x}'| < |\boldsymbol{x}| - 1$

II $|\boldsymbol{x}| - 1 < |\boldsymbol{x}'| < |\boldsymbol{x}| + 1$

III $|\boldsymbol{x}'| > |\boldsymbol{x}| + 1$

2.6.1 Region I

In region (I), we consider

$$\int_{|\boldsymbol{x}'|<|\boldsymbol{x}|-1} \boldsymbol{g}(\boldsymbol{x}')\cdot\left(\frac{\boldsymbol{x}-\boldsymbol{x}'}{|\boldsymbol{x}-\boldsymbol{x}'|^2} - \frac{\boldsymbol{x}}{|\boldsymbol{x}|^2}\right) d^2\boldsymbol{x}' \tag{2.190}$$

in (2.176). We split region (I) into three subregions:

Ia $|\boldsymbol{x}'| < 2\rho$

Ib $2\rho < |\boldsymbol{x}'| < |\boldsymbol{x}|/2$

Ic $|\boldsymbol{x}|/2 < |\boldsymbol{x}'| < |\boldsymbol{x}| - 1$

In region (Ia) we have

$$\left| \int_{Ia} g_j(\boldsymbol{x}') \frac{2x_j \boldsymbol{x}.\boldsymbol{x}' - x_j' |\boldsymbol{x}|^2 - x_j |\boldsymbol{x}'|^2}{|\boldsymbol{x}|^2 |\boldsymbol{x} - \boldsymbol{x}'|^2} \right| \tag{2.191}$$

$$\leq \mathcal{G} \int_{|\boldsymbol{x}'|<2\rho} \frac{6\sigma|\boldsymbol{x}|^2 + 4\sigma^2|\boldsymbol{x}|}{|\boldsymbol{x}|^2(|\boldsymbol{x}| - \sigma)^2} d^2\boldsymbol{x}' \tag{2.192}$$

$$\leq 8\pi\mathcal{G}\rho^3 \frac{3|\boldsymbol{x}| + 2\rho}{|\boldsymbol{x}|(|\boldsymbol{x}| - 2\rho)^2} \tag{2.193}$$

$$\sim O\left(\frac{1}{|\boldsymbol{x}|^2}\right), \tag{2.194}$$

where, in (2.192), $\sigma = |\boldsymbol{x}'|$.

In region (Ib) we have

$$\left| \int_{Ib} g_j(\boldsymbol{x}') \frac{2x_j \boldsymbol{x}.\boldsymbol{x}' - x_j' |\boldsymbol{x}|^2 - x_j |\boldsymbol{x}'|^2}{|\boldsymbol{x}|^2 |\boldsymbol{x} - \boldsymbol{x}'|^2} \right| \tag{2.195}$$

$$\leq 4\pi \int_{2\rho}^{\frac{1}{2}|\boldsymbol{x}|} \frac{A}{\sigma^3} \frac{3\sigma|\boldsymbol{x}|^2 + \sigma^2|\boldsymbol{x}|}{|\boldsymbol{x}|^2(|\boldsymbol{x}| - \sigma)^2} \sigma d\sigma \tag{2.196}$$

$$= \frac{4\pi A}{|\boldsymbol{x}|^2} \left[8 - \frac{4|\boldsymbol{x}|}{|\boldsymbol{x}| - 2\rho} + 3\ln(|\boldsymbol{x}| - 2\rho) - 3\ln 2\rho \right] \tag{2.197}$$

$$\sim O\left(\frac{\ln|\boldsymbol{x}|}{|\boldsymbol{x}|^2}\right). \tag{2.198}$$

In region (Ic) we have

$$\left| \int_{Ic} g_j(\boldsymbol{x}') \frac{2x_j \boldsymbol{x}.\boldsymbol{x}' - x_j' |\boldsymbol{x}|^2 - x_j |\boldsymbol{x}'|^2}{|\boldsymbol{x}|^2 |\boldsymbol{x} - \boldsymbol{x}'|^2} \right| \tag{2.199}$$

$$\leq \int_{\frac{1}{2}|\boldsymbol{x}|}^{|\boldsymbol{x}|-1} \frac{3}{|\boldsymbol{x}| - \sigma} \frac{A}{\sigma^3} \sigma d\sigma \tag{2.200}$$

$$= \frac{3A}{|\boldsymbol{x}|^2} \left[\ln(|\boldsymbol{x}| - 1) + 2 - \frac{|\boldsymbol{x}|}{|\boldsymbol{x}| - 1} \right] \tag{2.201}$$

$$\sim O\left(\frac{\ln|\boldsymbol{x}|}{|\boldsymbol{x}|^2}\right). \tag{2.202}$$

2.6.2 Region II

In region II we must consider the subregions

IIa $|\boldsymbol{x}-\boldsymbol{x}'|<1$

IIb $|\boldsymbol{x}-\boldsymbol{x}'|>1$

First we note that, from lemma 1 and Taylor's theorem with differential form of the remainder, we have that, $\forall|\boldsymbol{x}|,|\boldsymbol{x}'|>2\rho$, $\exists C$ independent of $|\boldsymbol{x}|$ such that

$$|\boldsymbol{g}(\boldsymbol{x})-\boldsymbol{g}(\boldsymbol{x}')|<\frac{C}{|\boldsymbol{x}|^4}|\boldsymbol{x}-\boldsymbol{x}'|. \tag{2.203}$$

Thus, we write (IIa) as

$$\int\limits_{|\boldsymbol{x}-\boldsymbol{x}'|<1}\frac{(\boldsymbol{g}(\boldsymbol{x}')-\boldsymbol{g}(\boldsymbol{x})).(\boldsymbol{x}-\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|^2}d^2\boldsymbol{x}'+\boldsymbol{g}(\boldsymbol{x})\cdot\int\limits_{|\boldsymbol{x}-\boldsymbol{x}'|<1}\frac{\boldsymbol{x}-\boldsymbol{x}'}{|\boldsymbol{x}-\boldsymbol{x}'|^2}d^2\boldsymbol{x}'. \tag{2.204}$$

Now,

$$\left|\int\limits_{|\boldsymbol{x}-\boldsymbol{x}'|<1}\frac{(\boldsymbol{g}(\boldsymbol{x}')-\boldsymbol{g}(\boldsymbol{x})).(\boldsymbol{x}-\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|^2}d^2\boldsymbol{x}'\right|<\frac{C}{|\boldsymbol{x}|^4}\int_0^{2\pi}\int_0^1 r\,dr\,d\theta=\pi C/|\boldsymbol{x}|^4, \tag{2.205}$$

whereas

$$\boldsymbol{g}(\boldsymbol{x}).\int\limits_{|\boldsymbol{x}-\boldsymbol{x}'|<1}\frac{\boldsymbol{x}-\boldsymbol{x}'}{|\boldsymbol{x}-\boldsymbol{x}'|^2}d^2\boldsymbol{x}'=|\boldsymbol{g}(\boldsymbol{x})|\int_0^{2\pi}\int_0^1\frac{1}{r}r\,dr\,d\theta=0. \tag{2.206}$$

In (IIb) we have

$$\left|\int_{IIb}\frac{\boldsymbol{g}(\boldsymbol{x}').(\boldsymbol{x}-\boldsymbol{x}')}{|\boldsymbol{x}-\boldsymbol{x}'|^2}d^2\boldsymbol{x}'\right|<8\pi A/|\boldsymbol{x}|^2, \tag{2.207}$$

since $|\boldsymbol{x}-\boldsymbol{x}'|^{-1}<1$ in IIb.

2.6.3 Region III

In III, we consider

$$\left|\int\limits_{|\boldsymbol{x}'|>|\boldsymbol{x}|+1}\boldsymbol{g}(\boldsymbol{x}')\cdot\frac{\boldsymbol{x}-\boldsymbol{x}'}{|\boldsymbol{x}-\boldsymbol{x}'|^2}d^2\boldsymbol{x}'\right| \tag{2.208}$$

$$<\ 2A\int\limits_{|\boldsymbol{x}'|>|\boldsymbol{x}|+1}|\boldsymbol{x}'|^{-3}\left(\frac{1}{|\boldsymbol{x}'|-|\boldsymbol{x}|}\right)d^2\boldsymbol{x}' \tag{2.209}$$

$$= 4\pi A \int_{|\boldsymbol{x}+1|}^{\infty} \frac{1}{r^2}\frac{1}{r-|\boldsymbol{x}|}dr \tag{2.210}$$

$$= 4\pi A \left(\frac{1}{|\boldsymbol{x}|^2}\ln(|\boldsymbol{x}|+1) - \frac{1}{|\boldsymbol{x}|(|\boldsymbol{x}|+1)}\right) \tag{2.211}$$

$$\sim O\left(\frac{\ln|\boldsymbol{x}|}{|\boldsymbol{x}|^2}\right). \tag{2.212}$$

Collecting (2.194, 2.198, 2.202, 2.205, 2.206, 2.207, 2.212) together we arrive at

$$\int_{\mathbb{R}^2} \nabla.((h_0 - f\psi_0)\boldsymbol{u}_0)\ln|\boldsymbol{x}-\boldsymbol{x}'|d^2\boldsymbol{x}' \tag{2.213}$$

$$\sim \frac{\boldsymbol{x}}{|\boldsymbol{x}|^2}.\int_{\mathbb{R}^2}(h_0 - f\psi_0)\boldsymbol{u}_0(\boldsymbol{x}')d^2\boldsymbol{x}' + O\left(\frac{\ln|\boldsymbol{x}|}{|\boldsymbol{x}|^2}\right) \qquad \square \tag{2.214}$$

2.7 Appendix B

We define the Fourier Transform $\tilde{f}(\omega)$ if the function $f(t)$ by

$$\tilde{f}(\omega) = \int_{-\infty}^{\infty} f(t)e^{i\omega t}dt, \tag{2.215}$$

as in equation (2.87). From Lighthill (1958), the Fourier Transform of $\ln|x|H(x)$ is

$$\ln|t|\tilde{H}(t) = -\frac{1}{i\omega}\left(\frac{i\pi}{2}\mathrm{sgn}\omega + \ln|\omega|\right) + \frac{\gamma}{i\omega}. \tag{2.216}$$

Using shifting formulae, it follows that the Fourier Transform of $e^{ift}\ln|t|H(t)$ is

$$e^{ift}\ln|t|\tilde{H}(t) = -\frac{1}{i(\omega-f)}\left(\frac{i\pi}{2}\mathrm{sgn}(\omega-f) + \ln|\omega-f|\right) + \frac{\gamma}{i(\omega-f)}, \tag{2.217}$$

and hence the Fourier transform of the integral

$$\int_0^{\infty} \ln\tau e^{if\tau}\left(g'(t-\tau) - ifg(t-\tau)\right) \tag{2.218}$$

is

$$-\tilde{g}(\omega)\left(\frac{i\pi}{2}\mathrm{sgn}(\omega-f) + \ln|\omega-f| + \gamma\right). \tag{2.219}$$

and hence the Fourier transform of

$$2\int_0^{\infty} \ln\tau\frac{d}{d\tau}\left[\cos f\tau g(t-\tau)\right] \tag{2.220}$$

is

$$-\tilde{g}(\omega)\left[\frac{i\pi}{2}\left(\mathrm{sgn}(\omega-f) + \mathrm{sgn}(\omega+f)\right) + \ln|\omega^2-f^2| + 2\gamma\right]. \tag{2.221}$$

Now,

$$\ln|\omega^2 - f^2| + \mathrm{sgn}(\omega - f) + \mathrm{sgn}(\omega + f) = \ln(\omega^2 - f^2) \mp i\pi, \tag{2.222}$$

where the sign of $\mp$ is (2.222) is set by the choice of analysic branch of the logathm function. Therefore, with the appropriate choice of the branch of the logaritm,

$$-(\omega^2 - f^2)^2\tilde{\sigma}(\omega)\left(\frac{1}{8}\left(\ln(\omega^2 - f^2) + 2\gamma\right) \mp \frac{i\pi}{8}\right) \tag{2.223}$$

has an inverse Fourier transform

$$\int_0^\infty \ln\tau \frac{d}{d\tau}(\cos f\tau g(t-\tau)), \tag{2.224}$$

where

$$\tilde{g}(\omega) = \frac{1}{16}(\omega^2 - f^2)^2\tilde{\sigma}(\omega), \tag{2.225}$$

and where (2.224) is an integral over the entire past history of the dynamics. If the other analytic branch of the logarithm is taken in (2.222), the result is that the integral (2.224) becomes an integral over the entire future evolution of the dynamics. The radiation condition is equivalent to imposing the choice of branch of logarithm which gives rise to (2.224).

Chapter 3

Instability of vortices and jets

3.1 Introduction

In chapter 2, some general properties of gravity wave generation by vortical motions were derived in the asymptotic limit of low Froude number F. It was shown that, in the vortical region, the first corrections to the incompressible vortical dynamics which are required to take account of non-zero divergence occur at $O(F^2)$ and $O(F^2 \ln F)$. On the basis of this elementary scale analysis, one might therefore expect gravity wave activity to be observed in the vortical flow at $O(F^2)$. However, the $O(F^2)$ and $O(F^2 \ln F)$ corrections can be determined entirely in terms of the instantaneous vortical flow, and thus represent balanced corrections to the leading order dynamics. The effect of gravity wave radiation is felt in the vortical region at $O(F^4)$, two orders higher in the expansion parameter than might have been expected from elementary scale analysis. The particular flow of the Kirchoff ellipse of uniform potential vorticity was analysed. The ellipse experienced elongation as a result of gravity wave radiation. The elongation either ceased at the aspect ratio at which the radiation from the ellipse was reduced to the inertial frequency, or continued until the ellipse reached a "splitting" aspect ratio of 4.6:1, at which the ellipse split in two. The elongation of the ellipse represents the effect of gravity wave radiation in the vortical flow which generates it, and the elongation rate of the ellipse was therefore $O(F^4)$. If we suppose now that the eccentricity of the ellipse is small, we may regard this elongation as the growth of a mode of instability on an axisymmetric vortex, with an eigenfunction of the form $f(r)e^{i(2\theta-\omega t)}$, where θ is the azimuthal angle, and ω is the eigenfrequency. Here, ω is real at $O(1)$ and $O(F^2)$, but contains an imaginary part at $O(F^4)$. The eigenmode consists of a vortical or Rossby wave on the boundary of the vortex, coupled to a gravity wave far from the vortex. The growth rate of the instability is a measure of the degree of interaction between vortical motions and gravity waves in the system.

The concept of instabilities due to coupling between different waves has been the subject of a paper by Sakai (1989). In the most general form of the theory, he advocates decomposing the system of eigenvector equations to be studied into distinct wave vectors, which are neutral non-interacting modes of some reference system, but which interact in the system of interest due to the presence of a mean flow, second layer or other destabilizing phenomenon. Once the decomposition into a system of wave functions is accomplished, the resulting matrix eigenvalue analysis for the system of interest is lengthy but routine. The structure of the unstable eigenmodes in terms of the modes of the reference system elucidates which wave – wave inter-

actions are responsible for the instability. However, if the eigenmodes can be analysed in some asymptotic limit, as here in the case of low Froude number or high mode number, it is possible to elucidate the nature of the wave mode interactions which are responsible for the instability without recourse to lengthy matrix eigenvalue analysis. This asymptotic approach has been used by Knessel & Keller (1992) in their analysis of a short wavelength instability found by Griffiths *et al.* (1982) which is due to gravity wave – gravity wave interaction.

Within this wave mode instability framework, conventional barotropic instability and baroclinic instability are to be regarded as due to Rossby wave – Rossby wave interactions. They both arise due to opposite signs of the potential vorticity gradient in the flow, either at different horizontal locations (in the case of barotropic instability) or on different vertical levels (in the case of baroclinic instability).

Gravity wave – gravity wave instabilities are also fairly common, and have been found in single layer shear flows with uniform potential vorticity (Satomura 1981; Kubokawa 1986; Hayashi & Young 1987). Kelvin – Helmholtz instability is also a manifestation of gravity wave – gravity wave instability. The instability exists due to gravity waves which develop on either side of a density jump in stratified shear flow, just as Rossby waves develop on either side of a strip of potential vorticity in barotropic instability.

Rossby wave – gravity wave instability, however, is a comparatively unfamiliar phenomenon. Sakai (1989) has clearly demonstrated a Rossby wave – gravity wave instability in a two-layer parallel shear flow at moderate Rossby number. He has also suggested the several previously discovered instabilities are candidates for a description in terms of Rossby wave –gravity wave interaction. In many of the studies he discusses, an interface between two fluids of different density intersects a free surface, and the "gravity wave" part of the Rossby wave – gravity wave instability is supposed to be the wave at the free surface intersection.

Within the context of barotropic shallow water vortex dynamics, which is the topic of this thesis, the model problem consists of a semi-infinite layer of light fluid, of finite depth, on top of an infinite layer of heavy fluid of infinite depth (see figure 3.1). Paldor (1983) has shown that, if the potential vorticity in the upper layer is uniform everywhere where it has non-zero depth, the eigenmodes of the system are always neutral. Killworth & Stern (1982) have shown that an instability will always be present when the potential vorticity in the upper layer increases away from the interface. I believe that this wave is more properly a generalization of a Rossby

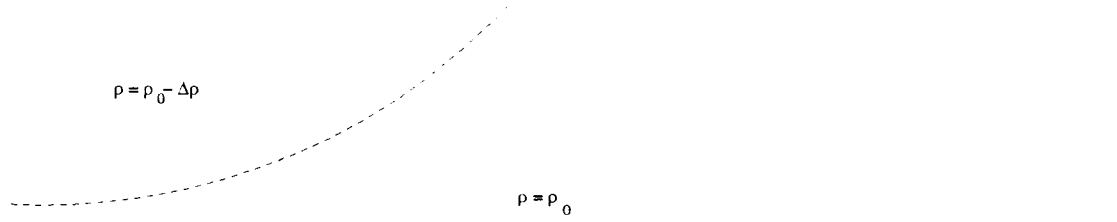

Figure 3.1: Schematic diagram depicting a semi-infinite single layer of fluid.

wave in the upper layer, with finite potential vorticity on one side of the interface, and infinite potential vorticity (zero depth) on the other side. Consider first the case where the potential vorticity is finite on both sides of the interface. In such circumstances, a wave on the boundary between the two regions would clearly be regarded as a Rossby wave. Then, since at all finite values of potential vorticity we would regard the wave on the interface between the two regions of different potential vorticity as a Rossby wave, it seems perverse to suggest, as Sakai (1989) does, that we should regard it as a gravity wave in the singular case of infinite potential vorticity on one side of the interface. The condition for instability found by Killworth & Stern (1982), that the potential vorticity increase away from the interface, is simply a condition which ensures that the interface is a minimum of potential vorticity, and that there is therefore a change in the potential vorticity gradient in the upper layer at the interface.

The shallow water vortex instability, discussed partially in chapter 2 in terms of the elongation of the elliptical vortex, is a clear case of Rossby wave – gravity wave instability in a single layer model. It was discovered first in the non-rotating two dimensional ideal gas equations by Broadbent & Moore (1979). They consider a vortex of radius a, with uniform vorticity 2Ω for $r < a$, and zero vorticity for $r > a$. Such a vortex is commonly referred to as a "Rankine vortex". They define a Mach number M based on the vortex boundary velocity, so that $M = \Omega a/c_0(a)$, where c_0 is the sound speed $c_0^2(r) = \gamma p_0(r)/\rho_0(r)$. They consider eigenfunctions of the form $f(r)\epsilon^{i(m\theta-\omega t)}$, where m represents the azimuthal mode number of the disturbance. They show numerically that, as M is increased away from zero, the growth rates of instabilities are non-zero for mode numbers $m = 2, 3, 4, 6, 8$. For each m, they investigate only one eigenmode, which reduces to the neutral mode found by Kelvin (1880) in the limit $M \to 0$, with eigenfrequency $\omega = \Omega - 1$. At small M the growth rates scale as M^{2m} (Kop'ev & Leont'ev, 1983), meaning that large mode numbers are less unstable than small ones for small M. Indeed, it can be clearly seen from figure 3 of Broadbent & Moore (1979) that, for moderate Mach number M, growth

rates of the instability remain smaller for larger mode numbers than smaller ones.

For $M < 2.236$, modes $m = 2, 3, 4, 6, 8$ are found to be unstable for all M. The maximum growth rates obtained by Broadbent & Moore for a given M were always found at mode $m = 2$. The overall maximum growth rate occurred at $M \approx 1.5$, with $\mathrm{Im}(\omega) \approx 0.012$. The growth rates remain small over the whole range of values of $M < 2.236$, suggesting that the strength of Rossby wave – gravity wave coupling might be small even at quite large Froude numbers. When $M = 2.236$ Broadbent & Moore are obliged to terminate their numerical eigenvalue calculations, since then the density vanishes at the centre of the vortex.

Sozou (1987) showed that the mode investigated by Broadbent & Moore (1979) is not the only unstable mode in the compressible Rankine vortex, and that there are an infinite number of modes for which $\omega = \Omega - O(M^2)$. These modes are singular in the limit $M = 0$, but non-singular for all non-zero M. They typically have growth rates at least an order of magnitude smaller than the corresponding Broadbent – Moore mode (Sozou 1987, table 1).

A general stability theorem for axisymmetric shallow water vortices was given by Ripa (1987). It was derived by variational methods, and therefore provides a sufficient condition for stability. The condition is that the axisymmetric flow with azimuthal velocity $V(r)$ and height field $H(r)$ is stable if

$$(V - \lambda r)^2 < H(r) \tag{3.1}$$

$$(V - \lambda r)\frac{dQ}{dr} \geq 0 \tag{3.2}$$

$$\text{for some } \lambda, \tag{3.3}$$

where $Q = (f + dV/dr + V/r)/H(r)$ is the potential vorticity in the basic state. In the case of an isolated vortex in unbounded shallow water, (3.1) can only be satisfied if $\lambda = 0$. Then, if the vortex is cyclonic, with the potential vorticity inside the vortex exceeding the value outside, we would expect the azimuthal velocity $V(r)$ at the boundary of the vortex to be anticlockwise, i.e. positive. Consequently, VdQ/dr will be zero everywhere except at the boundary of the vortex, where it will be negative. Similarly, if the vortex is anticyclonic, with $dQ/dr > 0$, we expect $V(r) < 0$ at the vortex boundary. In either case, $V(r)dQ/dr < 0$ at the vortex boundary, and (3.2) is not satisfied. Therefore it is not possible to obtain any stability results for an axisymmetric vortex with a monotonic potential vorticity profile by variational methods, no matter how small the Froude and Rossby numbers might be.

A general stability theorem for parallel flow stability in shallow water was given by Ripa (1983). In this case, the sufficient condition for stability of the flow with jet velocity $U(y)$ and layer depth $H(y)$ is

$$(\lambda - U(y))\frac{dQ}{dy} \geq 0 \tag{3.4}$$

$$(\lambda - U(y))^2 < H(y) \tag{3.5}$$

$$\text{for some } \lambda. \tag{3.6}$$

Now, if the potential vorticity gradient is concentrated in a single jump, at $y = 0$, say, then $U(y)dQ/dy < 0$ at $y = 0$, and we may take $\lambda = U(0)$ to satisfy (3.4). The remaining condition (3.5) then states that the flow must be everywhere subsonic with respect to the velocity of the potential vorticity jump $(U(0) - U(y))^2 < H(y)$. Unlike the case of axisymmetric flow, it is now possible to show that the flow is stable provided the ratio of potential vorticities across the jump is less than 4.

One of the aims of this thesis is to investigate the strength of Rossby wave – gravity interactions in the shallow water system. The growth rates of Rossby wave – gravity wave instabilities in axisymmetric and parallel flows are therefore of fundamental interest, and the remainder of the chapter is organised as follows:

In §3.2, the instability of an axisymmetric vortex with a single discontinuity in potential vorticity is analysed. The results at finite Froude number will differ from those of Broadbent & Moore (1979) at finite Mach number, in that in this study the potential vorticity, rather than vorticity, is taken to be constant within the vortex. This prevents the evacuation of the basic state found by Broadbent & Moore. As the background rotation rate f is increased, the low mode number disturbances cease to be unstable. A WKBJ analysis is therefore performed, and it is found that large mode number disturbances to an axisymmetric vortex are always unstable, no matter how small the Froude and Rossby numbers might be.

In §3.3 we investigate the effect of smoothing the potential vorticity profile within the context of the WKBJ analysis. It is found that the instability persists, provided the potential vorticity gradient is confined to within a region of size $o(m^{-1})$, so that Rossby wave critical layers at $\omega = mV/r$ induce phase shifts which are no more than exponentially weak in m. The Sozou modes are shown to exist due to the non-uniform potential vorticity within the Rankine vortex at non-zero Mach number, which therefore supports a spectrum of Rossby waves within

the vortex in addition to the single Rossby wave on the vortex boundary.

In §3.4, we discuss the results of the analysis in §3.2 in relation to the question of existence or non-existence of a slow manifold for the shallow water equations. Since the WKBJ analysis has shown that a Rossby wave – gravity wave instability exists at arbitrarily small Rossby number, the result is that a true slow manifold, in the sense of no identifiable gravity wave – like structure at small non-zero Rossby number, cannot exist, because the large mode number eigenmodes will always possess a gravity wave - like tail. Mathematically, one can show that a slow manifold, if it exists at all, cannot then be unique, precisely because of the presence of the instability at arbitrarily small Rossby number.

In §3.5 the instability of a parallel flow with a single discontinuity of potential vorticity is investigated. The potential vorticity in the region $y < 0$ is taken to be unity, while the potential vorticity in the region $y > 0$ takes a value $q > 1$. It is found via a WKBJ analysis that the stability bound found by Ripa (1983) is an exact stability boundary, with unstable modes for all $q > 4$. The limit $q \to \infty$ is singular, and if q is rescaled such that $q = O(k^{4/3})$, the growth rate of the instability tends to zero, as $q/k^{4/3} \to \infty$, consistent with the analysis of Paldor (1983), and supporting the contention that the interfacial wave should be viewed as a Rossby wave, rather than a gravity wave.

In §3.6, some final conclusions to this chapter are offered.

3.2 Instability of a circular vortex with discontinuous potential vorticity

3.2.1 The basic state

In this section, we shall restrict our attention to basic states with a single radial discontinuity of potential vorticity. Following the same scaling of the shallow water equations as in chapter 2, but not now assuming $F \ll 1$, the basic state equations are

$$\frac{d\overline{h}}{dr} = f\overline{v} + \frac{\overline{v}^2}{r} \tag{3.7}$$

$$\frac{d\overline{v}}{dr} + \frac{\overline{v}}{r} = Q(1 + F^2\overline{h}) - f. \tag{3.8}$$

These must be solved subject to regularity conditions at $r = 0$, and decay conditions as $r \to \infty$. The nonlinearity in (3.7) means that we must use numerical means to solve (3.7,3.8), except in

the limit $F \ll 1$, where they can be solved by matched asymptotic expansion.

The free parameters in the problem are f and F. The nondimensionalizations of chapter 2 allow us to take the vortex to be of unit radius, the potential vorticity jump across the boundary of the vortex to be of unit strength, and the layer to be of unit mean depth. Then $Q = f$ for $r > 1$, and $Q = f + 1$ for $r < 1$.

3.2.2 The disturbance equations

Disturbance equations are derived for a single azimuthal wavenumber m and frequency ω, so that the disturbance variables are expressible in the form $g(r)e^{im\theta - i\omega t}$. They are

$$i\sigma v_r - (f + 2\overline{v}/r)v_\theta + \frac{dh}{dr} = 0 \tag{3.9}$$

$$i\sigma v_\theta + Q(1 + F^2\overline{h})v_r + \frac{1}{r}imh = 0 \tag{3.10}$$

$$F^2\left(i\sigma h + (f\overline{v} + \overline{v}^2/r)v_r\right) + (1 + F^2\overline{h})\left(\frac{dv_r}{dr} + \frac{v_r}{r} + \frac{1}{r}imv_\theta\right) = 0, \tag{3.11}$$

where $\sigma = -\omega + m\overline{v}/r$.

This set of equations must be solved subject to regularity conditions at $r = 0$, and a radiation/evanescence condition as $r \to \infty$.

The equations (3.9 - 3.11) contain only two radial derivatives, and therefore represent a second order differential equation for the eigenfunctions. If one chooses v_r and h as variables, v_θ must be obtained from (3.10). The possibility of a critical layer at $\sigma = 0$ makes it impossible to ensure that this will be a successful method. Instead, we choose to eliminate h. After some algebra, one obtains a pair of first order ordinary differential equations for the eigenmodes:

$$\frac{dv_r}{dr} = A(r)v_r + B(r)v_\theta \tag{3.12}$$

$$\frac{dv_\theta}{dr} = C(r)v_r + D(r)v_\theta, \tag{3.13}$$

where

$$A(r) = \frac{F^2\sigma Q r}{m} - \frac{1}{r}\frac{d}{dr}\ln H \tag{3.14}$$

$$B(r) = \frac{iF^2\sigma^2 r}{Hm} - \frac{im}{r} \tag{3.15}$$

$$C(r) = \frac{iF^2 HQ^2 r}{m} + \frac{im}{r} + \frac{iH}{\sigma}\frac{dQ}{dr} \tag{3.16}$$

$$D(r) = -\frac{F^2 Q\sigma r}{m} - \frac{1}{r}, \tag{3.17}$$

and $H = 1 + F^2\overline{h}$.

The advantage of this formulation over the standard formulation (3.9 - 3.11) is that the critical layer singularity $\sigma = 0$ occurs only where there are radial gradients of the basic state potential vorticity $Q(r)$. If the potential vorticity gradients are confined to a single discontinuity in potential vorticity at the vortex boundary, the eigenfunction equations are non-singular, and at the vortex boundary we impose continuity of h and v_r. Dividing (3.10) by v_r, we thereby obtain a continuity equation

$$\left[\sigma \frac{v_\theta}{v_r}\right] = \left[iQ(1 + F^2\overline{h})\right], \tag{3.18}$$

where $[\alpha]$ represents the jump in a quantity α across the vortex boundary.

3.2.3 The limit $F \ll 1$

Before proceeding to numerical calculation of the eigenvalues of the system (3.12 - 3.17), we consider the limit $F \ll 1$.

In chapter 2 we showed that matching conditions between the vortical region and the gravity wave region led to a wave field in which the principal wave component was a quadrupole. This was forced by unsteady terms of the form $r^{-2}e^{2i\theta}$ present in the streamfunction in the limit of $r \to \infty$. In the case of a mode 2 perturbation to an axisymmetric vortex, these terms appear due to the unsteadiness in velocity and height fields induced by the perturbation of the vortex boundary. The effect of the radiation appears at $O(F^4)$, the effect of which is to destabilize the vortex.

From the viewpoint of an instability, we therefore have growth of a mode 2 perturbation to an axisymmetric vortex, with a growth rate of order F^4. Higher order perturbations to the vortex do not produce quadrupole far fields, since they have m-fold rotational symmetry, and their streamfunction far fields take the form $r^{-m}e^{im\theta}$. Rescaling the radial coordinate to $R = Fr$, appropriate for the wave region, we have wave fields in streamfunction, velocity potential and height of form $H_m(\sqrt{\omega^2 - f^2}R)e^{i(m\theta - \omega t)}$ at order F^m, and therefore the first out of phase contribution in the matching conditions for the inner problem occurs at order $O(F^{2m})$. Hence in general at low Froude number the vortex has mode m instabilities with growth rates $O(F^{2m})$.

However, we must also consider the real part of the frequency, which must lie above the

inertial frequency $|f|$ if waves are to propagate and the out of phase terms are to appear in the matching conditions. The analysis for the circular vortex at $F = 0$ was first performed by Kelvin (1880), who found that

$$\omega = \frac{1}{2}(m-1). \tag{3.19}$$

It follows that we shall require $m > 1+2|f|$ for instability at low F. The fastest growing $m = 2$ modes are inhibited by the presence of background rotation, and for small to moderate Rossby numbers the first unstable mode could occur at quite a large value of m, and hence quite a small growth rate of order F^{2m}.

The basic state

We begin our analysis by establishing the form of the basic state from considering the basic state equations (3.7-3.8) in the limit $F \ll 1$. From the analysis of chapter 2, we require two asymptotic regions – $r = O(1)$ and $r = O(F^{-1})$.

We begin with the region $r = O(1)$. We expand

$$\overline{v} = \overline{v}_0 + F^2\overline{v}_2 + \cdots \tag{3.20}$$

$$\overline{h} = \overline{h}_0 + F^2\overline{h}_2 + \cdots. \tag{3.21}$$

Here we allow for the possibility that the matching conditions might introduce $\ln F$ terms into the expansions (3.20,3.21). Substituting (3.20,3.21) into (3.8) gives, at leading order

$$\frac{d\overline{v}_0}{dr} + \frac{\overline{v}_0}{r} = \begin{cases} 1 & \text{for } r < 1 \\ 0 & \text{for } r > 1 \end{cases}. \tag{3.22}$$

Imposing regularity ar $r = 0$, and r^{-1} decay ar $r \to \infty$, we have

$$\overline{v}_0 = \begin{cases} \frac{1}{2}r & \text{for } r < 1 \\ \frac{1}{2}r^{-1} & \text{for } r > 1 \end{cases}. \tag{3.23}$$

The equation for $\overline{h}_0$ is

$$\frac{d\overline{h}_0}{dr} = f\overline{v}_0 + \frac{\overline{v}_0^2}{r}. \tag{3.24}$$

Substituting (3.23) into (3.24) we find

$$\overline{h}_0 = \begin{cases} \frac{1}{8}(2f+1)r^2 + C_1 & \text{for } r < 1 \\ \frac{1}{2}f\ln r - \frac{1}{8}r^{-2} + C_2 & \text{for } r > 1 \end{cases}, \tag{3.25}$$

where C_1 and C_2 are constants, to be determined by continuity of $\overline{h}_0$ at $r = 1$, and matching to the outer solution.

Proceeding now to the outer region, we define a long range variable $R = Fr$. Since $\overline{v}_0 \sim r^{-1}$ as $r \to \infty$, we rescale $\overline{v}_0$ by F, so

$$\overline{h}_0 = H(R) + O(F^2) \tag{3.26}$$

$$\overline{v}_0 = FV(R) + O(F^3). \tag{3.27}$$

Then substituting (3.26, 3.27) into (3.7,3.8) we obtain

$$\frac{dV}{dR} + \frac{V}{R} = fH \tag{3.28}$$

$$\frac{dH}{dR} = fV. \tag{3.29}$$

Combining (3.28) & (3.29) into a single equation for $V(R)$, we have

$$\frac{d^2V}{dR^2} + \frac{1}{R}\frac{dV}{dR} - \left(f^2 + \frac{1}{R^2}\right)V = 0. \tag{3.30}$$

Imposing decaying boundary conditions as $R \to \infty$, (3.30) has solution

$$V(R) = A\mathrm{K}_1(|f|R), \tag{3.31}$$

where K_1 is the modified Bessel function of order one, and A is a constant. Matching to the velocity field in the vortical region (3.23) gives

$$A = \frac{1}{2}|f|. \tag{3.32}$$

It follows that

$$H(R) = -\frac{1}{2}f\mathrm{K}_0(|f|R). \tag{3.33}$$

For small R, we have

$$H(r) = \frac{1}{2}f\left(\ln\left(\frac{1}{2}|f|R\right) + \gamma\right) + O(R^2 \ln R). \tag{3.34}$$

and matching to (3.25) gives

$$C_2 = \frac{1}{2}f\left(\ln\left(\frac{1}{2}|f|F\right) + \gamma\right). \tag{3.35}$$

Note the appearance of the $\ln F$ term. This means that $\overline{h}_0$ starts at $O(\ln F)$. Then finally

$$C_1 = \frac{1}{2}f\left(\ln\left(\frac{1}{2}|f|F\right) + \gamma\right) - \frac{1}{4}(f+1). \tag{3.36}$$

The analysis presented is valid in the limit $f \to 0$, in which limit

$$V(R) = \frac{1}{2R}; \quad H(R) = O(F^2); \quad C_1 = -\frac{1}{4}; \quad C_2 = 0. \tag{3.37}$$

Having obtained the leading order solutions for $\overline{v}_0$ and $\overline{h}_0$ in both asymptotic regions, we could now go on to develop perturbation expansions to obtain equations for $\overline{v}_2, \overline{h}_2 \ldots$. However, as we shall see, such corrections are not required to compute the growth rate of the instability, and serve only to correct the real part of the eigenfrequency. Indeed, the expression for $\overline{h}_0$ is not really essential to the $F \ll 1$ analysis, although it is required to initialize the numerical eigenvalue calculations in the $F \ll 1$ limit.

The disturbance equations

As for the analysis of the basic state, we expand v_r and v_θ in asymptotic series with F^2 as the expansion parameter. The asymptotic expansions are matched between two regions, with range variables r and $R \equiv Fr$ as before (see also chapter 2). Additionally, the eigenvalue ω must be expanded in powers of F^2, with logarithmic terms as necessary.

Substituting (3.14 - 3.17) into (3.12,3.13) in the limit $F \ll 1$ gives equations for v_r and v_θ

$$\frac{dv_r}{dr} = -\frac{1}{r}v_r - \frac{im}{r}v_\theta \tag{3.38}$$

$$\frac{dv_\theta}{dr} = \frac{im}{r}v_r - \frac{1}{r}v_\theta. \tag{3.39}$$

The solutions are

$$v_r = r^{m-1}; \qquad v_\theta = ir^{m-1} \tag{3.40}$$

or

$$v_r = r^{-m-1}; \qquad v_\theta = -ir^{-m-1}. \tag{3.41}$$

Regularity as $r \to 0$ implies we take an eigenfunction of form (3.40) in $r < 1$. Decay as $r \to \infty$ implies we take an eigenfunction of form (3.41) in $r > 1$. Then, substituting into the continuity equation (3.18) gives $\omega = m\overline{v}(1) - 1/2$, which gives Kelvin's result (3.19) on substitution of the basic state (3.23), for which $\overline{v}(1) = 1/2$, valid in the limit $F = 0$.

Rather than proceeding to consider higher orders in F in the inner expansion, we will

consider the leading order outer expansion. There the disturbance equations are

$$\frac{dv_r}{dR} = -\left(\frac{\omega f R}{m} + \frac{1}{R}\right) v_r + \left(\frac{i\omega^2 R}{m} - \frac{im}{R}\right) v_\theta \tag{3.42}$$

$$\frac{dv_\theta}{dR} = \left(\frac{if^2 R}{m} + \frac{im}{R}\right) v_r + \left(\frac{f\omega R}{m} - \frac{1}{R}\right) v_\theta. \tag{3.43}$$

They have solution

$$v_r = A\left[i\omega\lambda \mathrm{H}_{m-1}(\lambda R) - i\frac{m}{R}(\omega + f)\mathrm{H}_m(\lambda R)\right] \tag{3.44}$$

$$v_\theta = A\left[f\lambda \mathrm{H}_{m-1}(\lambda R) - \frac{m}{R}(\omega + f)\mathrm{H}_m(\lambda R)\right], \tag{3.45}$$

where $\lambda^2 = (\omega^2 - f^2)$, H_m is a Hankel function of degree m, of the first or second kind, and A is an arbitrary constant. The kind of the Hankel function is chosen to give radiation conditions at infinity. With $e^{-i\omega t}$ time dependence, one chooses Hankel functions of the first kind for radiation conditions.

Now the outer limit of the inner expansions for v_r and v_θ have r^{-m-1} behaviour. Therefore in the outer region we start our expansions for v_r and v_θ at $O(F^{m+1})$. This is consistent with waves in ψ, ϕ and h at $O(F^m)$. If a formal expansion is carried out for the inner region, we see from (3.14 - 3.17) that it proceeds by first obtaining the fields at a given order, and then obtaining ω at that order from the matching conditions. To obtain v_r and v_θ to order F^{2n} for some integer n, one need only know ω to order $F^{2(n-1)}$. The continuity condition (3.18) then gives ω at order F^{2n}.

Since the eigenvalue equations are linear in v_r and v_θ, the amplitude of the leading order solution given by (3.40) for $r < 1$ and (3.41) for $r > 1$ is not specified uniquely, and at higher orders in the perturbation expansion it is possible to add to the solution at that order a component of the leading order eigenfunction. To specify the eigenfunction uniquely, we impose the condition that the coefficients of r^{m-1} in the expansions of v_r and v_θ in the limit $r \to 0$ are zero at all orders in F except the leading order. This then fixes the amplitude and phase of the eigenfunction at all orders in F. Then, without reference to the outer expansion, one can see that the velocity components v_r and v_θ remain $\pi/2$ out of phase with each other at all subsequent orders in F in the inner expansion, and therefore ω remains real until the matching conditions with the wave region must be taken into account.

Matching (3.41) onto (3.44,3.45) to determine the amplitude of the gravity waves in the outer expansion gives

$$A = -\frac{\pi\lambda^m}{2^m m!(\omega + f)}. \tag{3.46}$$

Then matching the out-of-phase J_m terms in the Hankel functions (3.44, 3.45) back onto the inner solution at order $O(F^{2m})$ gives a contribution to the inner solution of the form

$$v_r = -iBr^{m-1}; \qquad v_\theta = Br^{m-1}, \tag{3.47}$$

where B is determined from A and the properties of the Hankel function in the limit $R \to 0$. It is given by

$$B = \frac{\pi m}{(m!)^2}\left(\frac{\omega^2 - f^2}{4}\right)^m \left(\frac{\omega - f}{\omega + f}\right). \tag{3.48}$$

As we discussed above, to make the expansion procedure well defined, the expansions for v_r and v_θ in $r < 1$ are to be $o(r^{m-1})$ for $r \ll 1$, and hence we must add to (3.47) functions of form (3.41) to ensure continuity of v_r at $r = 1$. All other contributions to v_r and v_θ at all orders up to and including F^{2m} contribute only to the real part of ω, and not to the growth of the instability.

To calculate the growth rate of the instability, it is therefore sufficient to consider the velocity fields

$$v_r = \begin{cases} r^{m-1} & \text{for } r < 1 \\ r^{-m-1} - iBF^{2m}(r^{m-1} - r^{-m-1}) & \text{for } r > 1 \end{cases} \tag{3.49}$$

$$v_\theta = \begin{cases} ir^{m-1} & \text{for } r < 1 \\ -ir^{-m-1} + BF^{2m}(r^{m-1} + r^{-m-1}) & \text{for } r > 1 \end{cases}. \tag{3.50}$$

Returning to the jump condition (3.18), we obtain

$$\mathrm{Im}(\omega) = \frac{\pi m F^{2m}}{2(m!)^2}\left(\frac{\omega^2 - f^2}{4}\right)^m \left(\frac{\omega - f}{\omega + f}\right) + O(F^{2m+2}). \tag{3.51}$$

3.2.4 Numerical eigenvalue calculations

Numerical technique

We start by considering techniques for solving numerically the basic equations (3.7, 3.8) for the basic state variables $\overline{v}$ and $\overline{h}$. The numerical difficulties arise in that both $r = 0$ and $r = \infty$ are singular points of the system, and we can only apply boundary conditions there by making use of some expansion of the solutions for small r and large r respectively. Given initial guesses for $\overline{h}(0)$ and $\overline{h}(\infty)$, the basic state equations can then be integrated to $r = 1$. and iteration on $\overline{h}(0)$ and $\overline{h}(\infty)$ used to make $\overline{h}$ and $\overline{v}$ continuous across the vortex boundary $r = 1$.

We consider first the singular point $r = \infty$. In this limit, we will impose conditions that $\overline{v}$ and $\overline{h}$ tend to zero as $r \to \infty$. By manipulation of the equations (3.7, 3.8), one obtains

$$\frac{d^2\overline{h}}{dr^2} + \frac{1}{r}\frac{d\overline{h}}{dr} - F^2 f^2 \overline{h} = \frac{2\overline{v}}{r}\frac{d\overline{v}}{dr} \tag{3.52}$$

$$\frac{d^2\overline{v}}{dr^2} + \frac{1}{r}\frac{d\overline{v}}{dr} - \left(F^2 f^2 + \frac{1}{r^2}\right)\overline{v} = F^2 f \frac{\overline{v}^2}{r}. \tag{3.53}$$

Imposing evanescence conditions as $r \to \infty$, we note that the nonlinear right hand sides of (3.52) and (3.53) will be of small order compared with $\overline{v}$ and $\overline{h}$ in the limit $r \to \infty$. A convenient form of solution for $r \to \infty$ is therefore

$$h = \mathrm{K}_0(\alpha r) H(r) \tag{3.54}$$

$$v = \mathrm{K}_1(\alpha r) V(r), \tag{3.55}$$

where $H(r)$ and $V(r)$ tend to some finite non-zero limits H_∞ and V_∞ respectively as $r \to \infty$, and $\alpha^{-1} = (F|f|)^{-1}$ is the Rossby deformation radius for this problem. Differential equations for H and V are

$$\frac{dV}{dr} = \frac{\mathrm{K}_0(\alpha r)}{\mathrm{K}_1(\alpha r)}(\alpha V + F^2 f H) \tag{3.56}$$

$$\frac{dH}{dr} = \frac{\mathrm{K}_1(\alpha r)}{\mathrm{K}_0(\alpha r)}\left(fV + \alpha H + \frac{\mathrm{K}_1(\alpha r)}{r} V^2\right), \tag{3.57}$$

from which it follows that

$$V_\infty = -\frac{\alpha}{f} H_\infty. \tag{3.58}$$

Then, given an initial estimate for H_∞, and taking some $R \gg \alpha^{-1}$, we take $H = H_\infty$ at $r = R$, and (3.58) as the relationship between H and V at $r = R$. We can then integrate (3.56, 3.57) backwards to the boundary of the vortex.

The sole exception is in the case $f = 0$, where the form of the solution for $\overline{v}$ is known outside the vortex boundary:

$$\overline{v} = \frac{A}{r}; \quad \overline{h} = -\frac{A^2}{2r^2}, \tag{3.59}$$

where A is an arbitrary constant, and hence $\overline{v}$ and $\overline{h}$ are known in terms of the constant A rather than the constant H_∞.

In the vicinity of $r = 0$, $\overline{h} \sim O(1)$ and $\overline{v} \sim O(r)$ as $r \to 0$. In this case, simple power series expansions in r of the form

$$\overline{h}(r) = h_0 + h_2 r^2 + h_4 r^4 + h_6 r^6 + \cdots \tag{3.60}$$

$$\overline{v}(r) = v_1 R + v_3 r^3 + v_5 r^5 + v_7 r^7 + \cdots \tag{3.61}$$

are sufficient to give $\overline{h}(r)$ and $\overline{v}(r)$ at some small, non-zero r, given a guess h_0 for $h(0)$. We can then integrate (3.7, 3.8) forwards in r to the boundary of the vortex.

At the boundary of the vortex, we impose continuity of $\overline{h}$ and $\overline{v}$. A Newton method was used to iterate on h_0 and H_∞ (and h_0 and A in the case of $f = 0$) until the discontinuities in $\overline{h}$ and $\overline{v}$ across the boundary fell below some prescribed tolerance. To employ a Newton method, the differential equations (3.7, 3.8, 3.56, 3.57) and the starting series (3.58, 3.60, 3.61) were differentiated with respect to the parameters h_0 and H_∞, so that the variation of $\overline{v}$ and $\overline{h}$ with respect to h_0 and H_∞ on either side of the vortex boundary could be obtained (in the case $f = 0$, it is trivial to obtain expressions for the derivatives of the boundary velocity and height with respect to A). For $F \ll 1$, good initial guesses for h_0 and H_∞ or A were obtained from a matched asymptotic analysis, with $\overline{h}$ given by C_1 due to (3.25) and (3.36), and $H_\infty = -f/2$ due to (3.33), or $A = 1/2$.

We now turn to the disturbance equations.

The analysis of the eigenvalue equations is simplified by realising that the amplitude of the eigenfunctions is irrelevant, and that only the ratio of v_r/v_θ on either side of the vortex boundary is required to compute the eigenvalue ω.

As for the basic state, both $r = 0$ and $r = \infty$ are singular points of the equations, and

some use must be made of the asymptotic form of the solution in these limits to apply the appropriate boundary conditions, which are boundedness at $r = 0$ and evanescence as $r \to \infty$.

We start by considering the limit $r \to 0$. Here, we may take $v_r = r^{m-1} + k_1 r^{m+1} + \cdots$. Regularity at $r = 0$ then implies that $v_\theta = ir^{m-1} + k_2 r^{m+1} + \cdots$. The constants k_1 and k_2 can then be obtained from the eigenvalue equations, and

$$v_r/v_\theta = -i + K_2 r^2 + O(r^4). \tag{3.62}$$

The constant K_2 depends on the eigenvalue ω. Hence, given an initial guess for ω, the ratio of v_r to v_θ is known in the limit $r \to 0$ from the series (3.62). The ratio is used to initialize the r-integration of the eigenvalue equations with a starting value of $r = 0.01$. In all eigenvalue calculation, the starting series (3.62) was terminated at $O(r^2)$. Hence, the ratio v_r/v_θ is known just inside the vortex boundary.

At infinity, since the background flow is exponentially small there, we have

$$h \sim H_m^{(1)}(\lambda r) \tag{3.63}$$

with exponentially small corrections, where

$$\lambda^2 = (\omega^2 - f^2)F^2, \tag{3.64}$$

and the type of the Hankel function is chosen to satisfy the radiation condition. Rearranging (3.9, 3.10, 3.11) we have a relationship between v_r and v_θ through

$$(f^2 - \omega^2)v_r + i\omega\frac{dh}{dr} + \frac{1}{r}imfh = 0 \tag{3.65}$$

$$(f^2 - \omega^2)v_\theta - f\frac{dh}{dr} - \frac{1}{r}m\omega h = 0. \tag{3.66}$$

In the case where $\omega^2 \sim f^2$ we can still find a non-singular expression for the ratio v_r/v_θ by expanding the Hankel function representation of h. Again, the amplitude of h is not important – it is sufficient to know the ratio of the velocities v_r/v_θ.

Note that there is no need to integrate the disturbance equations in from the radiation far field of the Hankel function. This is fortunate, since, if $\omega^2 \sim f^2$, this would require a very large range of integration indeed. The equations (3.65, 3.66) assume negligible basic state velocity and height fields, but not a far field form of the wave field. Therefore, it is sufficient to integrate in from a radius where the basic state is sufficiently small. Since the basic state decay

is independent of the eigenvalue, the required position of the integration for the eigenfunction equations in the region $r > 1$, is fixed for given F and $|f|$, and decreases as F and $|f|$ increase.

Given an initial guess for ω, we must iterate on ω to satisfy the continuity equation (3.18). Here it is not so convenient to use a Newton method, due to the non-analytic behaviour of the solution at $\omega = \pm f$. However, iteration from two initial guesses using linear interpolation to predict the location of the root was found to perform reasonably well, typically converging in 5 or 6 iterations.

At low Froude number, we supply an initial guess for ω by considering the Kelvin modes on a circular incompressible vortex, with frequency given by (3.19). This can be used as a first guess ω_0 for the eigenfrequency, and a second guess can be supplied which is not too far away ($\omega_0 - 0.05$ say).

At low Froude number, growth rates are typically very low, and this places a strain on the numerical accuracy required. In all cases presented here, NAG routines were used for integrating the ODEs for both the basic state problem and the eigenvalue problem. In the exterior of the vortex, the differential equations are stiff, and a backward differencing method was used. A forward differencing method was used for the interior of the vortex. Tolerances of 10^{-15} were specified in all numerical integrations. In the disturbance problem, the computational values of the eigenfunctions were kept of order unity throughout the ranges of integration by applying the scaling function $(1+(Fr)^{2m})^{-1}r^{-1/2}e^{-\lambda_r r}$ to the variables in the exterior of the vortex (where λ_r is the real part of λ, and λ is given by (3.64)), and the function r^{m-1} to the interior variables. The very low tolerance specification, together with the rescaling to make the computational variables of order unity throughout the domains of integration, means that we can have some confidence in the imaginary parts of the eigenvalues down to around 10^{-14}.

Results of the eigenvalue calculations

The growth rate of the instability of the axisymmetric vortex depends on three parameters: the Froude number F; the Rossby number f^{-1}; and the azimuthal mode number of the instability m.

We begin by investigating the growth rates of the instability in the case of infinite Rossby number ($f = 0$). This limit is most similar to the study of Broadbent & Moore (1979), except

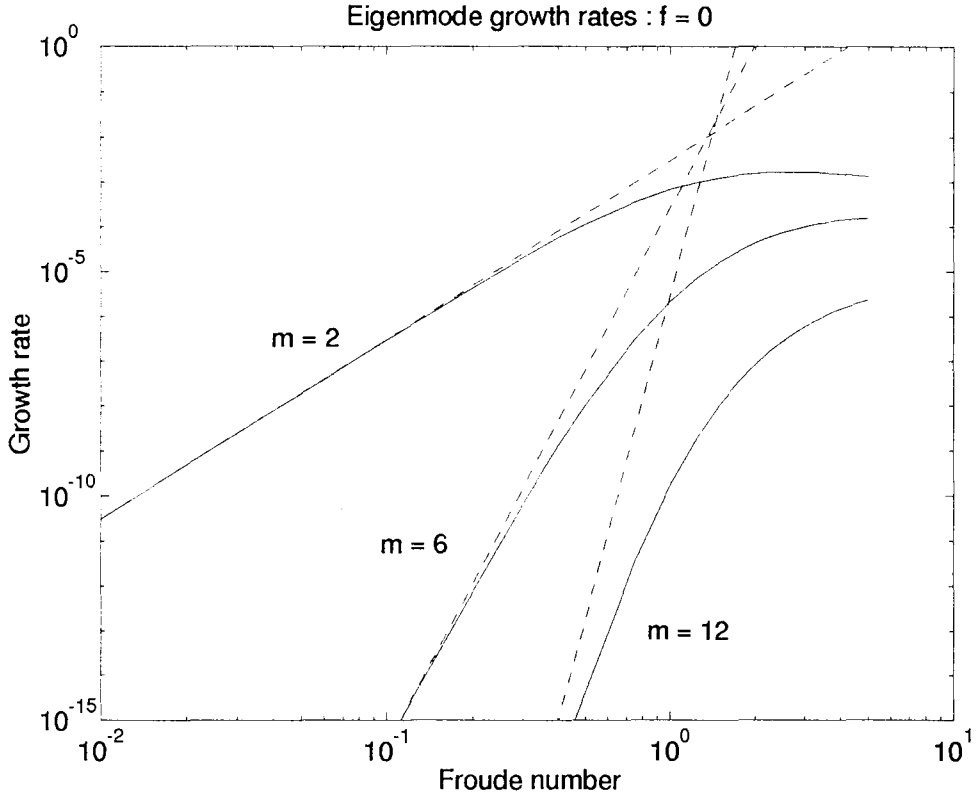

Figure 3.2: Axisymmetric vortex with $f = 0$. Growth rates of unstable modes (solid lines), and their low Froude number limits (dashed lines).

here we take the vortex to have uniform potential vorticity, rather than uniform vorticity as they did.

Figure 3.2 shows the growth rates of the instability for Froude numbers from 0 to 5 and for mode numbers $m = 2, 6, 12$. Solid lines are growth rates obtained from the numerical eigenvalue calculation, and dotted lines are the growth rates given by the low Froude number analysis (equation 3.51). The graph is plotted on a log-log scale, so that at low Froude number the slope of the lines is $2m$. Mode 2 is found to be the most unstable, and grows more slowly with Froude number than the higher mode numbers. The numerical eigenvalue calculations are apparently reproducing the eigenvalues obtained from low Froude number limit with growth rates down to 10^{-14}, and we can be confident that numerical algorithm used to integrate (3.12) & (3.13) is performing adequately.

The real part of the eigenfrequency divided by m is shown in figure 3.3. It is always bounded between 0 and $m \times V(1)$, apparently approaching $m \times V(1)$ at large m.

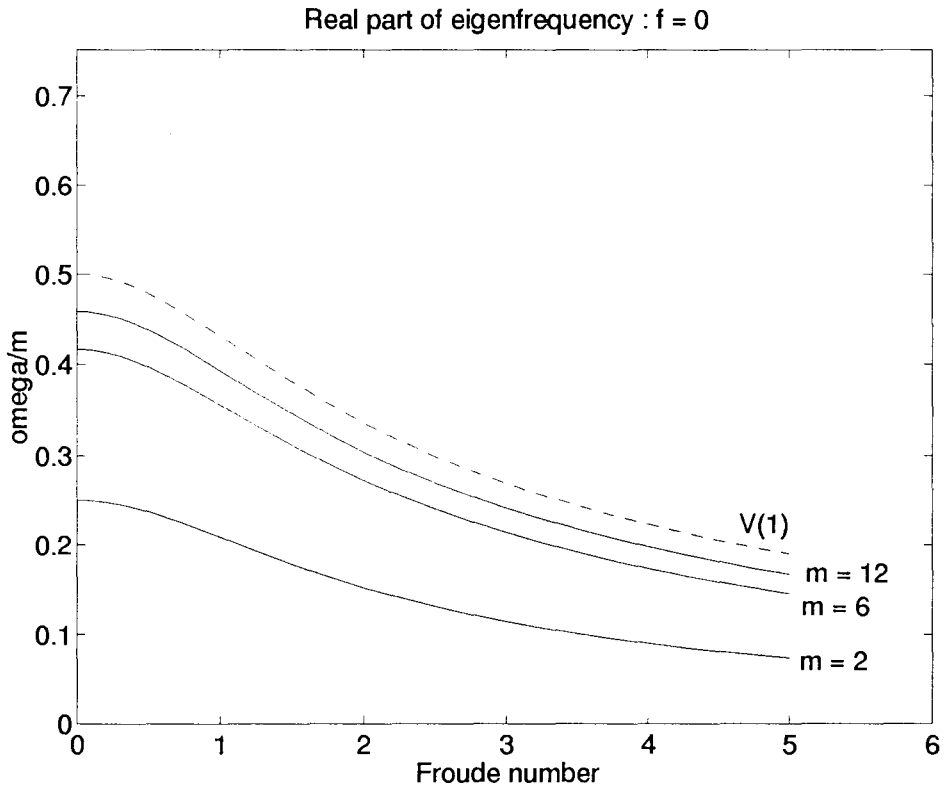

Figure 3.3: Axisymmetric vortex with $f = 0$. Real parts of eigenfrequencies / m (solid lines), with $V(1)$ (dashed line) for comparison.

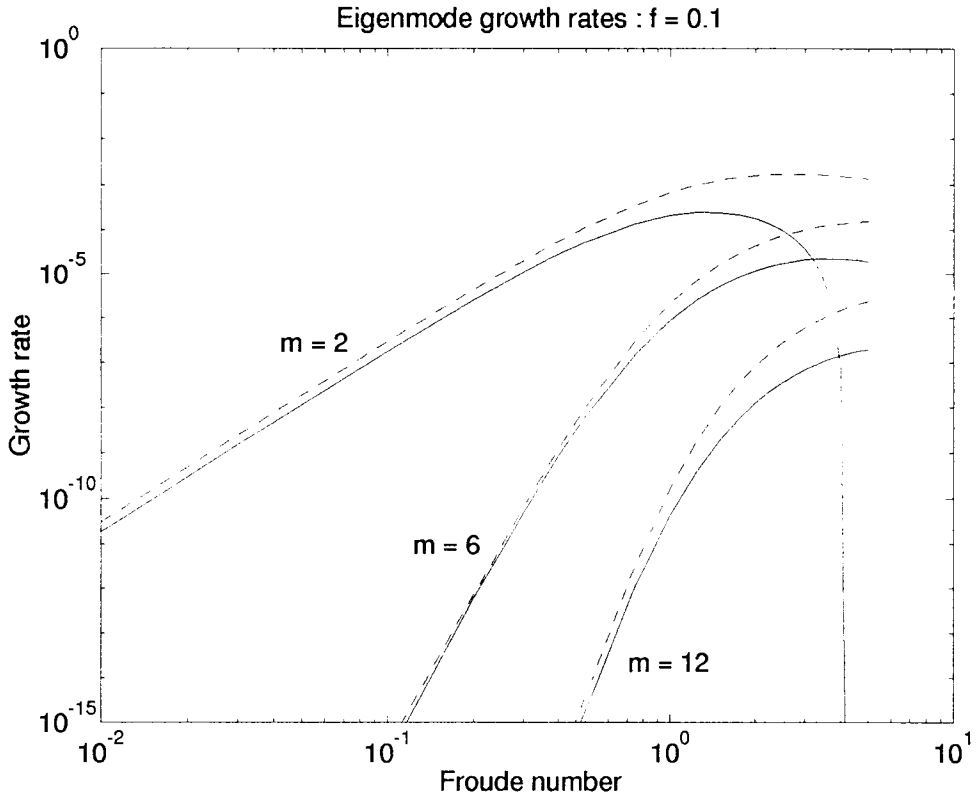

Figure 3.4: Axisymmetric vortex with $f = 0.1$. Growth rates of unstable modes (solid lines), together with growth rates of modes with $f = 0$ (dashed lines) for comparison.

We now turn to investigating the instability at non-zero f. In particular, it is important to note that for f between 0 and -1, the vortices are anticyclones with potential vorticity of opposite sign to the background potential vorticity. For $f > 0$ the vortices are always cyclones, and for $f < -1$, they are anticyclones with potential vorticity of the same sign as the background. If $f \neq 0$, we expect the effect of background rotation to inhibit the instability if the real part of the eigenfrequency is below $|f|$. We start by investigating the effect on the instability of weak background rotation, in the first case taking $|f| = 0.1$.

In figure 3.4, growth rates are shown for $f = 0.1$, and in figure 3.5 they are shown for $f = -0.1$. For reference, the dashed lines in figures 3.4 & 3.5 show the corresponding growth rates of the instability for $f = 0$. In the case $f = 0.1$, the vortices should be regarded as very intense cyclones, with potential vorticity equal to 11 times the background value, whereas in the case $f = -0.1$ they are very intense anticyclones, with potential vorticity equal to -9 times the background value. The corresponding real parts of the eigenfrequencies divided by m are

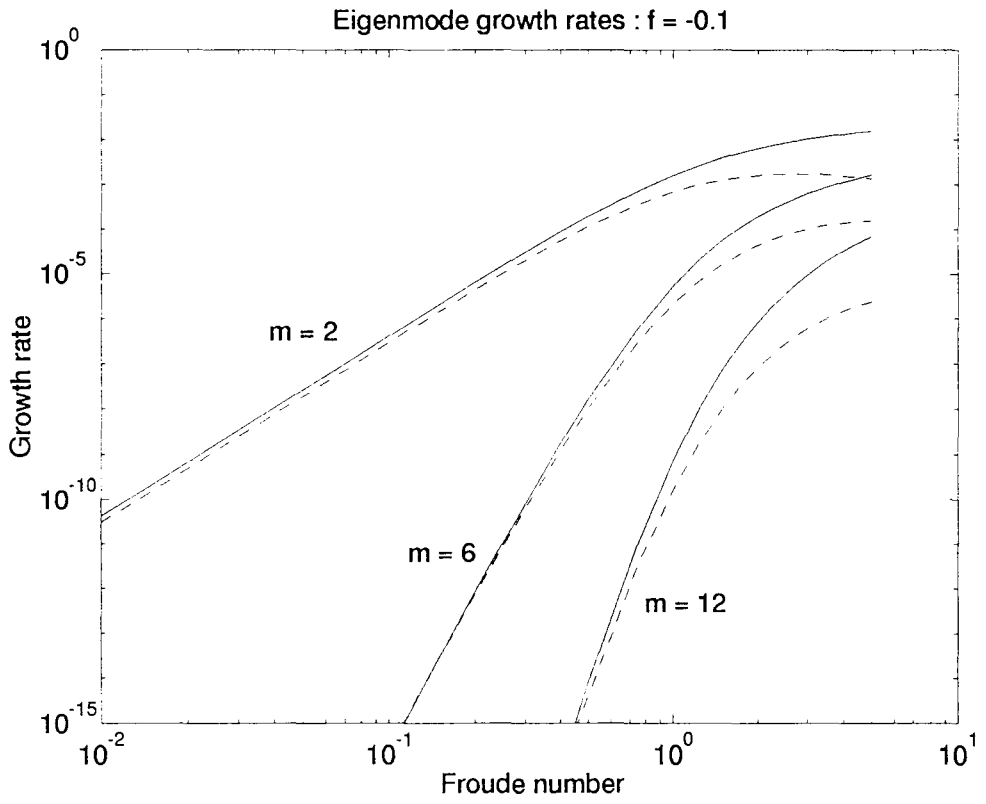

Figure 3.5: Axisymmetric vortex with $f = -0.1$. Growth rates of unstable modes (solid lines), together with growth rates of modes with $f = 0$ (dashed lines) for comparison.

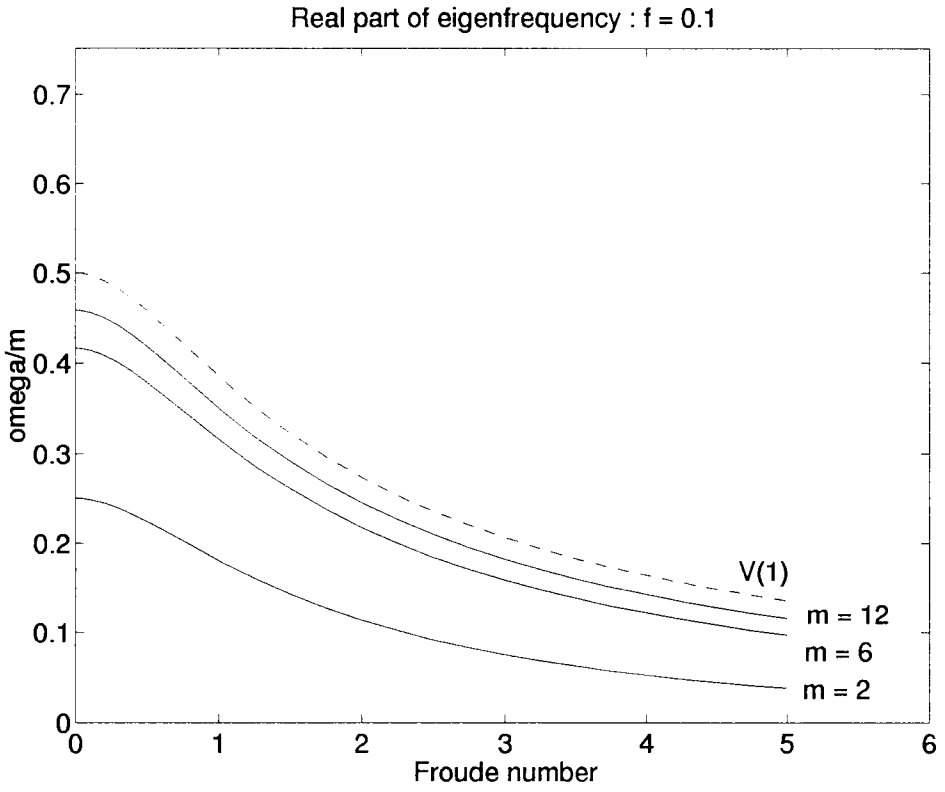

Figure 3.6: Axisymmetric vortex with $f = 0.1$. Real parts of eigenfrequencies / m (solid lines), with $V(1)$ (dashed line) for comparison.

shown in figures 3.6 & 3.7.

Notice that $V(1)$ is quite different for $f > 0$ and $f < 0$ as F is varied, but that the real part of the eigenfrequency is still bounded between 0 and $m \times V(1)$, approaching $m \times V(1)$ at large m.

Figures 3.4 & 3.5 show that a small amount of background rotation has a significant effect on the growth rate of the instability in both the cyclonic and anticyclonic cases, although in opposite senses. In figure 3.4 we see that the background rotation inhibits the instability of the cyclone. One would expect it to do so, but to completely cut off the instability the real part of the eigenfrequency must be reduced from 0.5 at $F = 0$ to 0.1 at $F \approx 4$. It is perhaps surprising that the velocity at the boundary of the vortex, and hence the real part of the eigenfrequency, decreases so markedly with increasing Froude number. By contrast, in the anticyclonic case $f = -0.1$, the growth rates of the instability are markedly increased over their corresponding $f = 0$ values, and the real part of the eigenfrequency does not decrease nearly so rapidly with

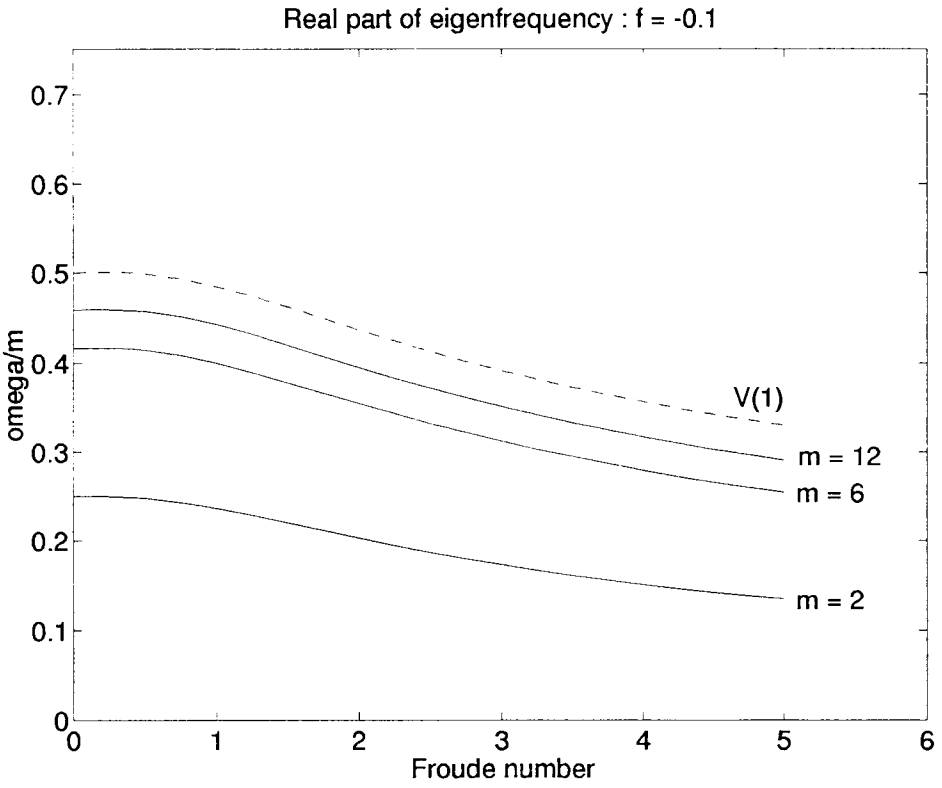

Figure 3.7: Axisymmetric vortex with $f = -0.1$. Real parts of eigenfrequencies / m (solid lines), with $V(1)$ (dashed line) for comparison.

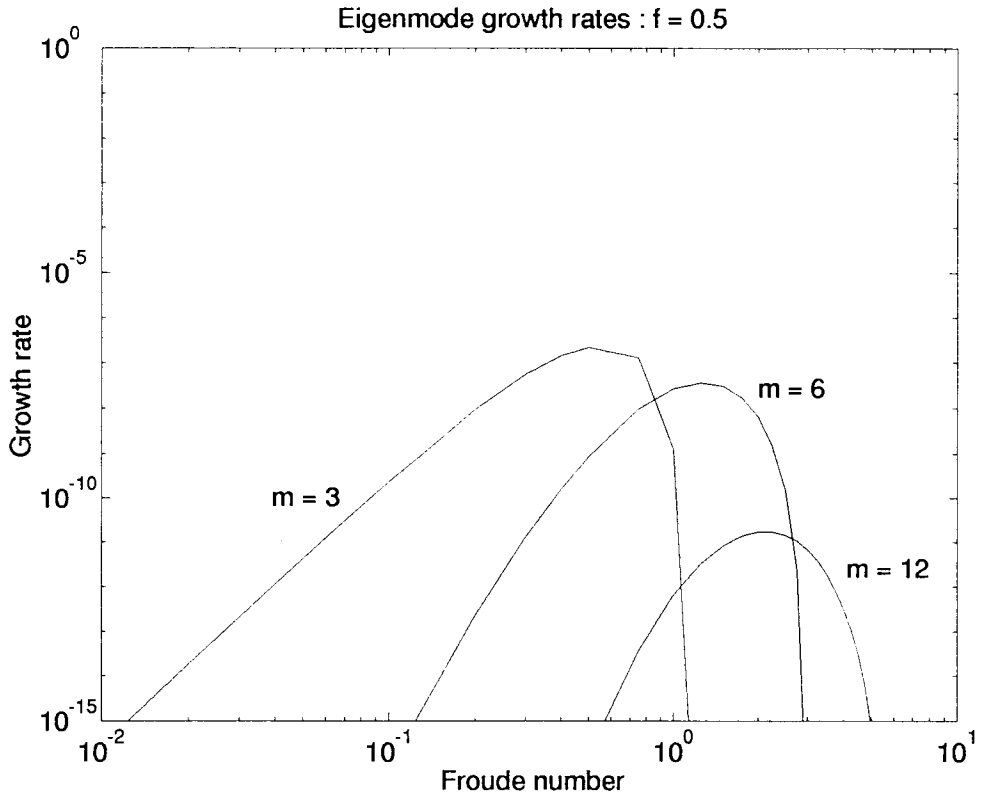

Figure 3.8: Axisymmetric vortex with $f = 0.5$. Growth rates of unstable modes.

increasing Froude number.

When $|f| = 0.5$, we reach the situation where the mode $m = 2$ instability is not unstable at leading order in Froude number, since then we have $\omega = |f|$ at leading order in F. In figure 3.8 growth rates are shown for $f = 0.5$. Mode 2 is stable over all Froude number shown on the graph, and growth rates for modes 3,6 and 12 are shown. As F is increased, so more and more modes become stabilized, as the vortex boundary velocity decreases and the real part of the eigenfrequency falls below f. This is shown in figure 3.9. The instability of the vortex at $f = 0.5$ is summarized in figure 3.10. In figure 3.10a we see that the maximum growth rate, over all Froude numbers, occurs at a Froude number of about 0.9. As F is increased further, the mode number of the fastest growing mode increases, apparently almost linearly with F (see figure 3.10b), and the growth rate of the fastest growing mode decreases, being barely greater than 10^{-15} at $F = 5.0$.

In the anticyclonic case $f = -0.5$, shown in figure 3.11, the mode 2 instability persists for

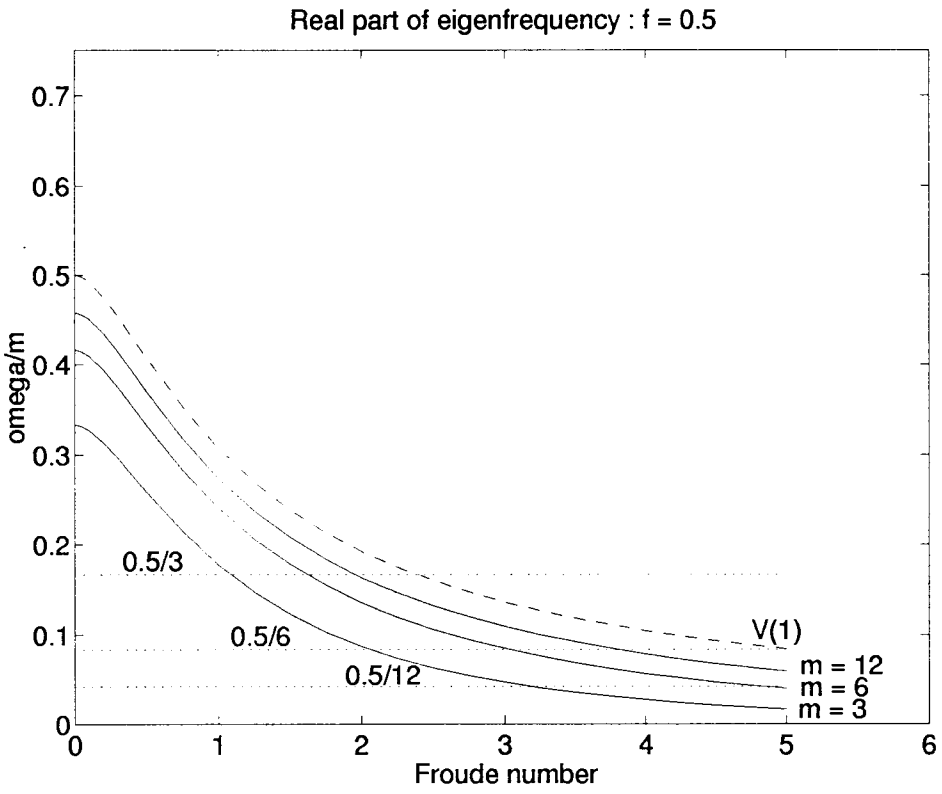

Figure 3.9: Axisymmetric vortex with $f = 0.5$. Real parts of eigenfrequencies / m (solid lines), with $V(1)$ (dashed line) for comparison. Dotted lines are the critical values of ω/m, below which the instability is inhibited for each given m. Modes $m = 3$ and $m = 6$ are inhibited at some $F < 5$. Mode 12 is not inhibited for $F < 5$, but the growth rate of mode 12 is less than 10^{-15} at $F = 5$ (see figure 3.8).

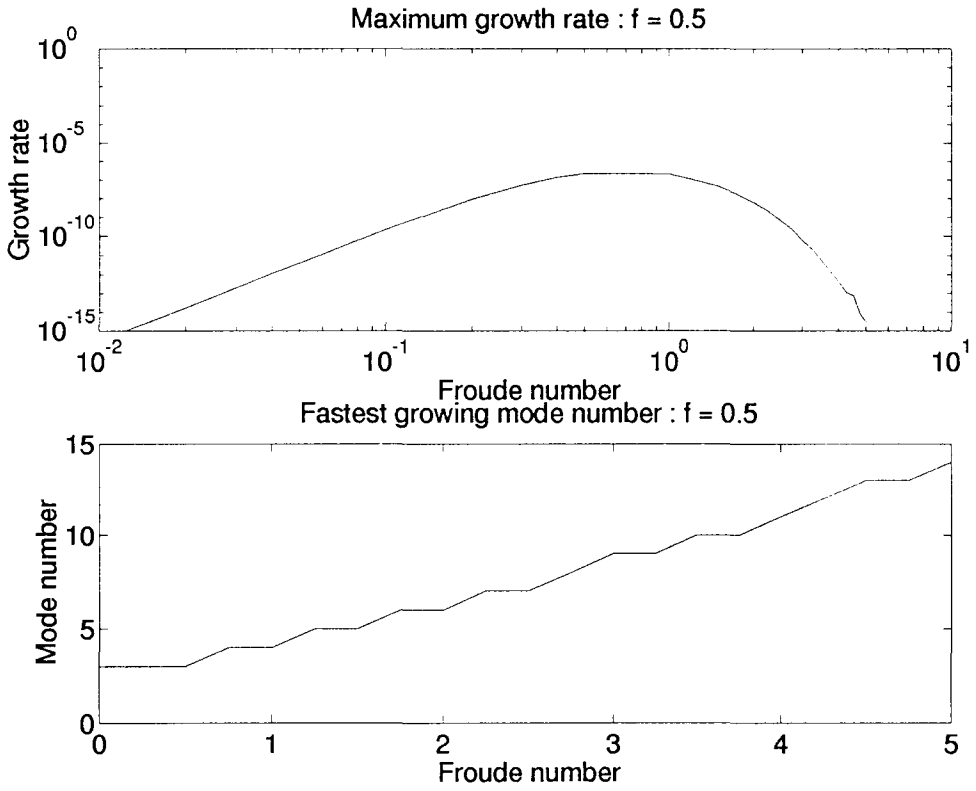

Figure 3.10: Axisymmetric vortex with $f = 0.5$. (a): Growth rate of fastest growing mode, and (b): Mode number of fastest growing mode

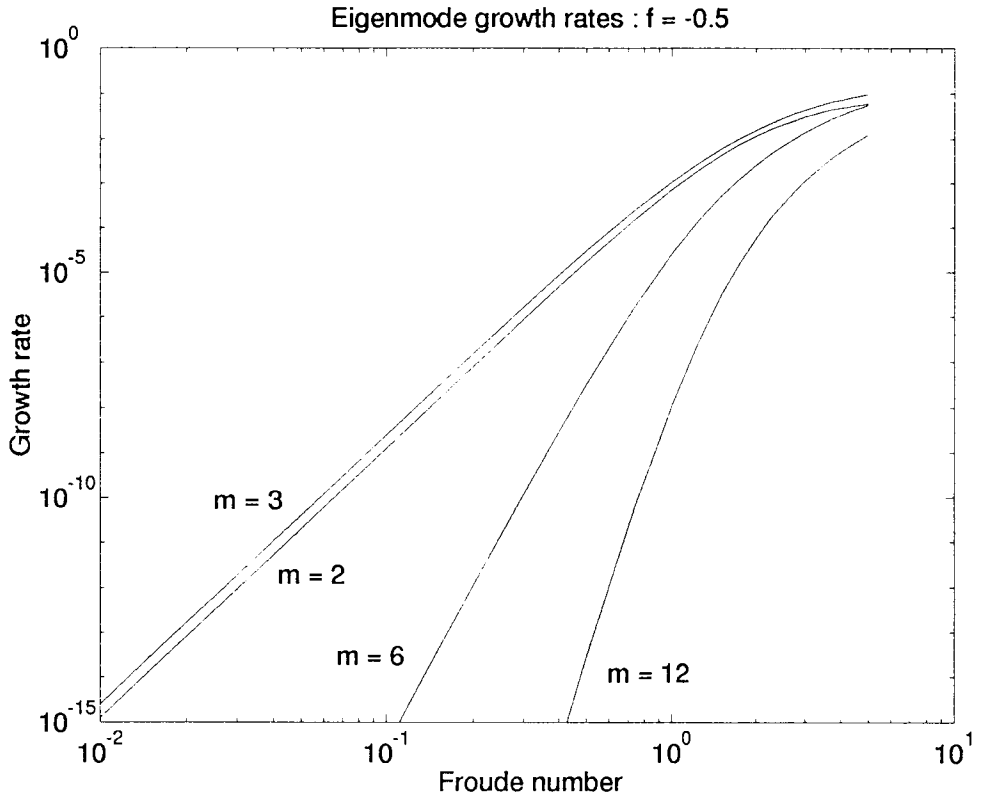

Figure 3.11: Axisymmetric vortex with $f = -0.5$. Growth rates of unstable modes.

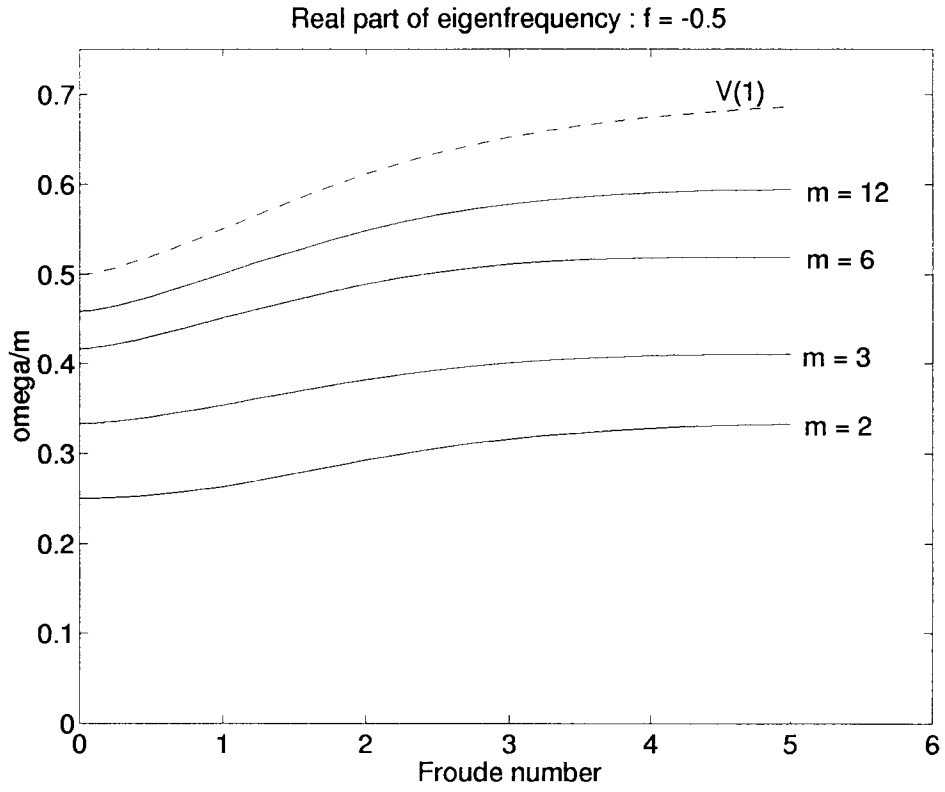

Figure 3.12: Axisymmetric vortex with $f = -0.5$. Real parts of eigenfrequencies / m (solid lines), with $V(1)$ (dashed line) for comparison.

all non-zero F, but its behaviour at small F is changed, increasing with the 6th power of the Froude number, rather than the 4th. In this case, the real part of the eigenfrequency tends to increase as F is increased, consistent with an increase of $V(1)$ (figure 3.12).

When $|f| = 1.0$, mode 3 ceases to be unstable at small Froude number. Moreover, for $|f| > 1.0$ the anticyclones have potential vorticity $(f + 1)$ of the same sign as the background potential vorticity f, and the case $f = -1$ corresponds to a vortex of zero potential vorticity. Figure 3.13 shows the growth rates of the instability for $f = 1$. The maximum growth rate never exceeds 10^{-10}, and the growth rate of mode $m = 12$ never exceeds 10^{-15}. The real part of the eigenfrequency behaves much as before, with $V(1)$ now decreasing very rapidly as F is increased (figure 3.14).

In figure 3.15, the growth rates of the instability are shown for $f = -1.0$. In contrast to the case $f = 1.0$, the instabilities persist over a wide range of F. The vortex boundary velocity is always 0.5, and the real parts of the eigenfrequencies do not decrease markedly as

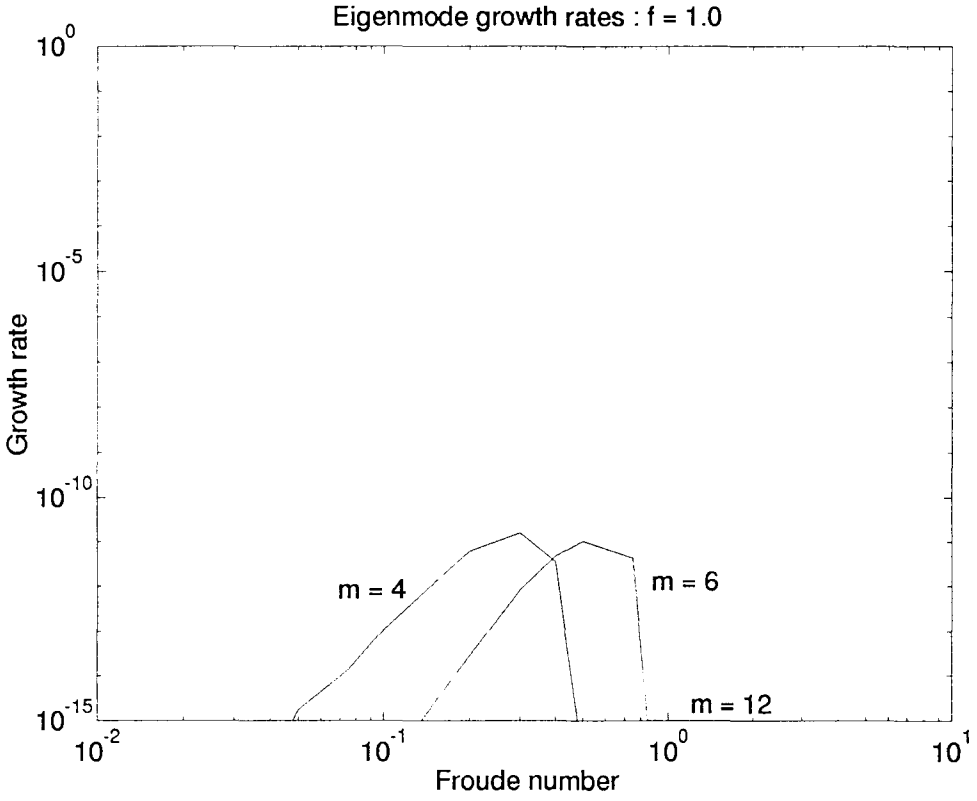

Figure 3.13: Axisymmetric vortex with $f = 1.0$. Growth rates of unstable modes.

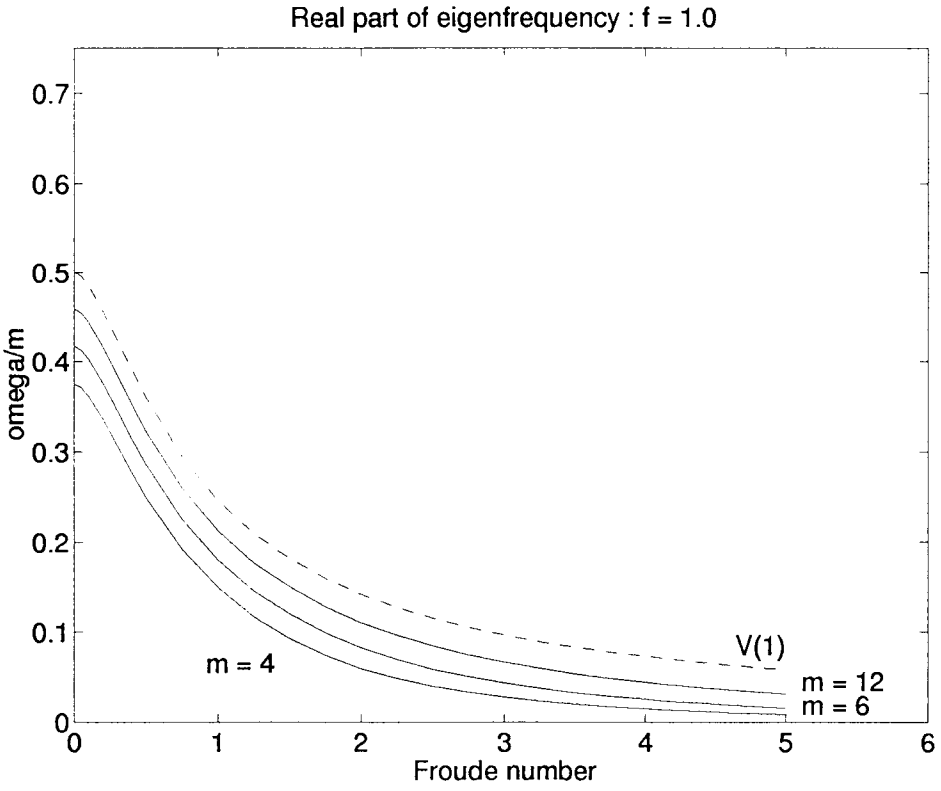

Figure 3.14: Axisymmetric vortex with $f = 1.0$. Real parts of eigenfrequencies / m (solid lines), with $V(1)$ (dashed line) for comparison.

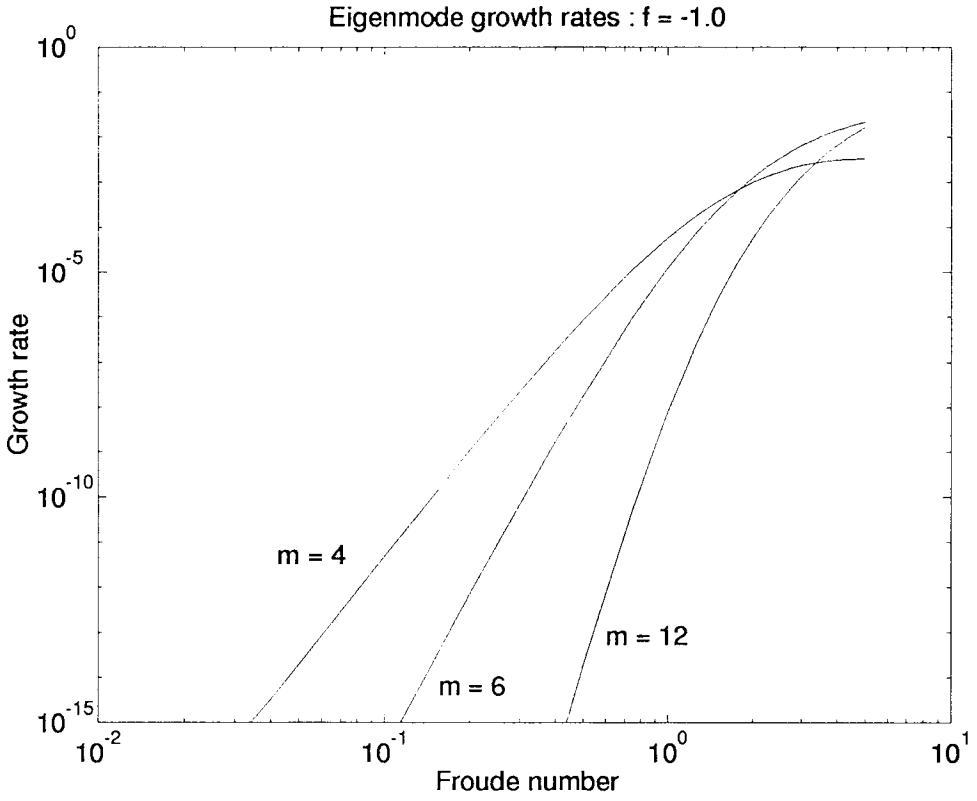

Figure 3.15: Axisymmetric vortex with $f = -1.0$. Growth rates of unstable modes.

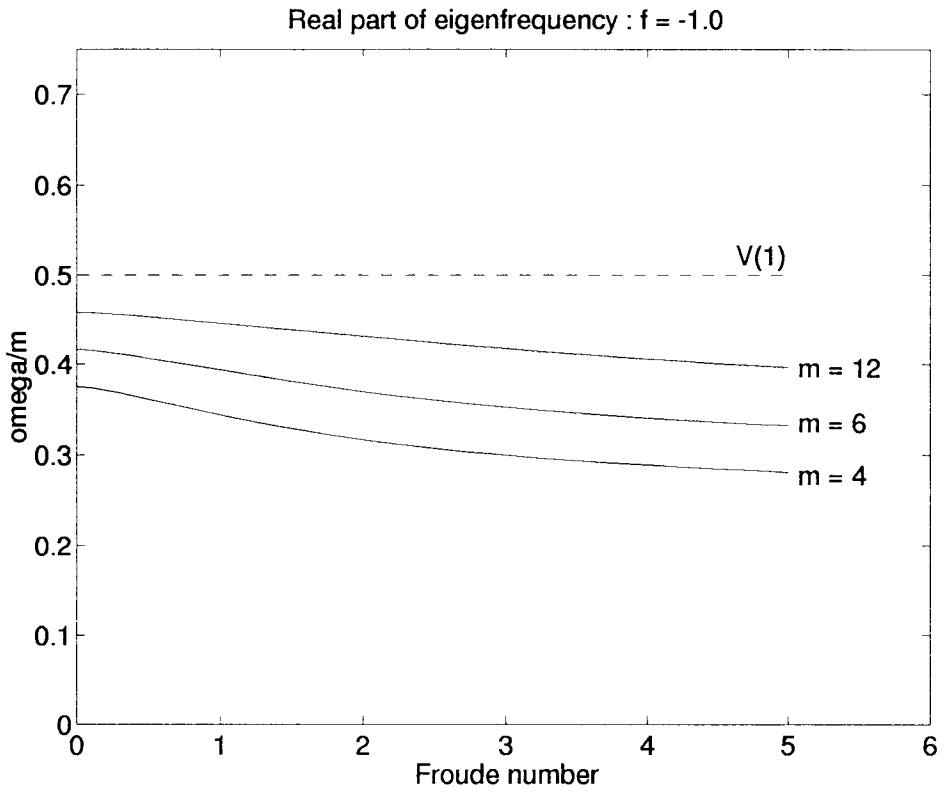

Figure 3.16: Axisymmetric vortex with $f = -1.0$. Real parts of eigenfrequencies / m (solid lines), with $V(1)$ (dashed line) for comparison.

F is increased (see figure 3.16). Mode 3, which is marginally stable at $F = 0$, for $f = \pm 1.0$, is never unstable for $|f| = 1.0$, either for positive or negative f. This is quite different from the case $f = -0.5$, where the marginally stable mode, $m = 2$, became unstable in the anticyclonic case, but remained stable in the cyclonic case.

For $f \sim 1$ it appears that the cyclones have instabilities with only very weak growth rates, if at all, and it seems likely that increasing f still further will continue to reduce the growth rates, at the same time requiring larger and larger m for the instability to exist at all. However, for $f \sim -1$, the anticyclones still have comparatively large growth rates, and in figures 3.17 & 3.18 we see the the effect of increasing $|f|$ above 1 in the anticyclonic case.

In figure 3.17 the growth rates of mode 4 instabilities are shown for $f = -1.1, -1.2, -1.3$. We can see that as $|f|$ is increased beyond 1.0, the effect of background rotation very rapidly reduces instability at mode number 4, the maximum growth rate at $f = -1.3$ being four order of magnitude smaller than the maximum growth rate at $f = -1.1$. Figure 3.18 shows growth

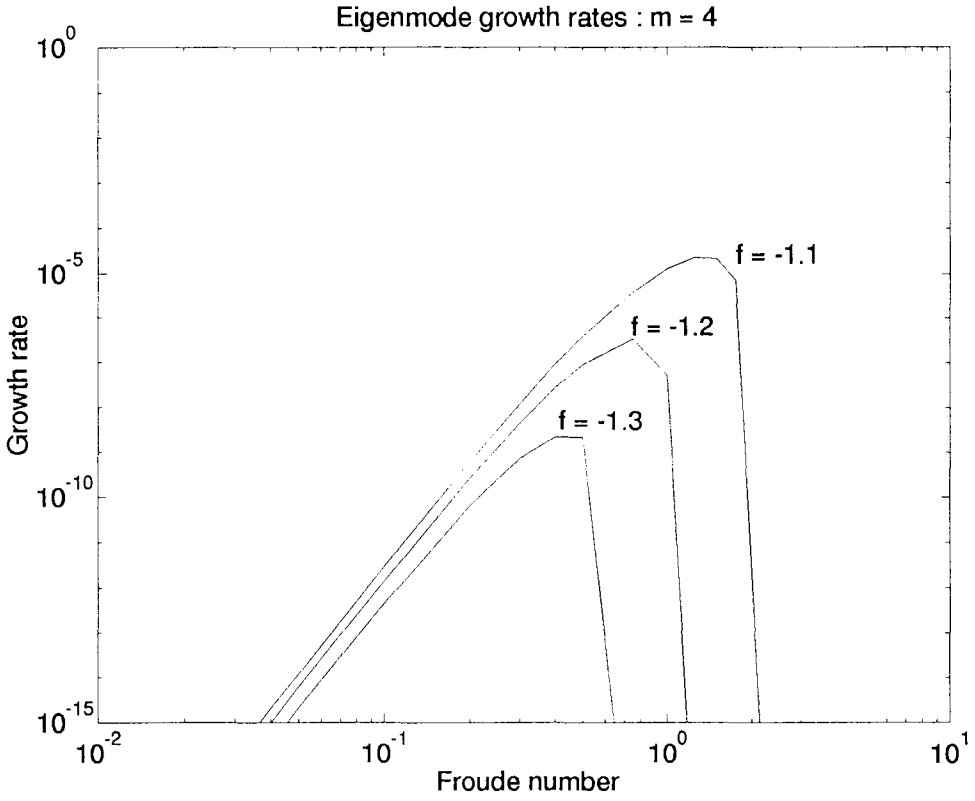

Figure 3.17: Growth rates of mode number 4 disturbances to vortices with $f = -1.1, -1.2, -1.3$.

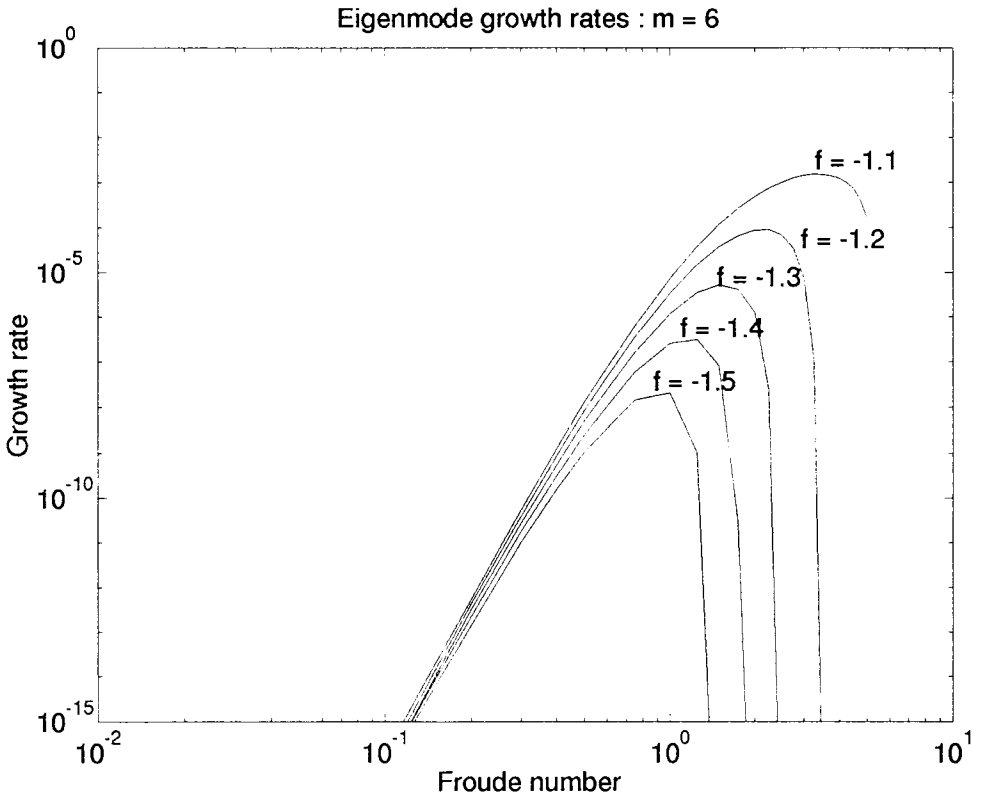

Figure 3.18: Growth rates of mode number 6 disturbances to vortices with $f = -1.1, -1.2, -1.3, -1.4, -1.5$.

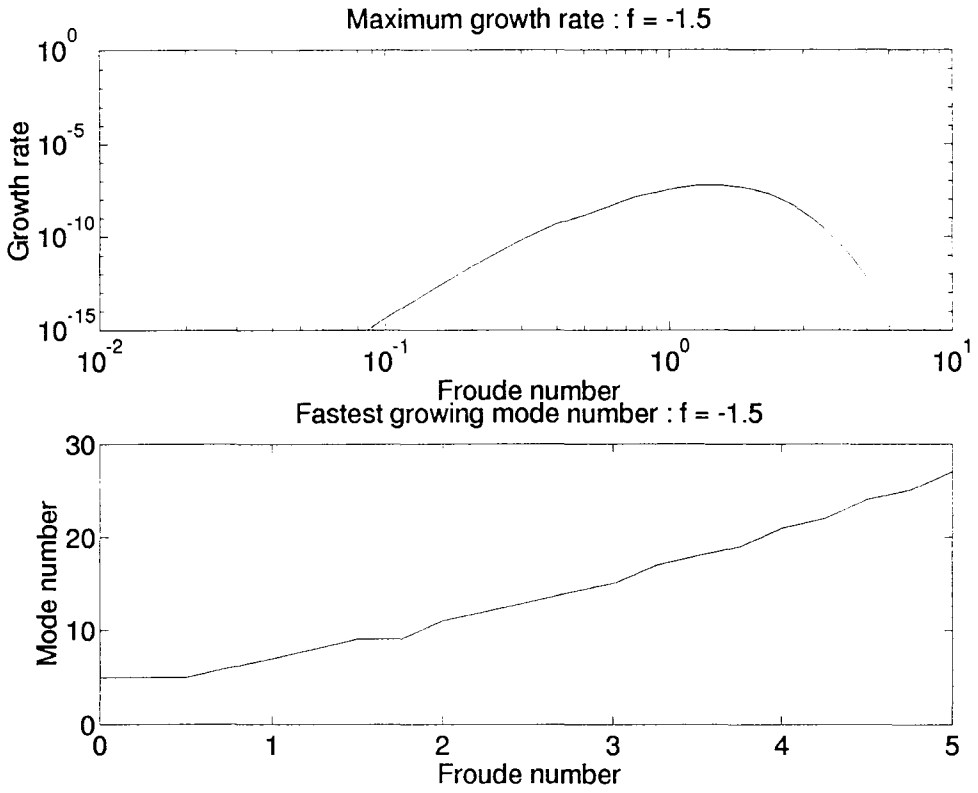

Figure 3.19: Axisymmetric vortex with $f = -1.5$. (a): Growth rate of fastest growing mode, and (b): Mode number of fastest growing mode.

rates of mode 6 instabilities for $f = -1.1, -1.2, -1.3, -1.4, -1.5$. For this higher mode number the instabilities persist for larger $|f|$ than in the case $m = 4$, but are still significantly inhibited as $|f|$ is increased. It seems that the instabilities of the anticyclones with $f < -1$ are very similar to instabilities of the cyclones $f > 1$, with the instability at moderate to large Froude numbers persisting only at very high mode numbers.

The instability of the vortex at $f = -1.5$ is summarized in figure 3.19, which is to be compared with figure 3.10 for the vortex with $f = 0.5$. The overall maximum growth rate now occurs at a Froude number of about 1.1, with the fastest growth rate reducing to about 10^{-12} at $F = 5.0$. The mode number of the fastest growing mode increases almost linearly with m, reaching $m = 27$ at $F = 5.0$. The picture is broadly similar to the case $f = 0.5$, shown in figure 3.10, although the mode numbers in this case are larger, and the growth rates slightly greater at larger values of F. It is in contrast to what is found for $0 > f \geq -1$, where the growth rates apparently increased without bound as F was increased.

We turn now to an explanation of the difference in behaviour of the instability between cyclonic and anticyclonic vortices. At low Froude number, a difference between positive and negative f exists in the expression (3.51) for the growth rate of the instability in the $F \ll 1$ limit. The difference is a factor of $(\omega - f)/(\omega + f)$, which is smaller if ω and f have the same sign than it is if they are of opposite sign. Since ω is always positive, this factor means that anticyclones are always more unstable to Rossby wave – gravity wave instability than cyclones. The difference lies in the nature of the coupling between the vortical region and the wave region. This difference is small, however, and amounts only to a constant factor. It cannot explain why low wave number disturbances to cyclonic vortices are stabilized as the Froude number is increased, whereas low wave number disturbances to anticyclonic vortices are destabilized.

The key to understanding the difference lies in the nature of the basic states. For small F, the azimuthal velocity at the vortex boundary is always 0.5. Since the wave on the boundary of the vortex is a Rossby wave, we expect it to propagate in a pseudo-westward direction – i.e. with a real frequency between 0 and $m \times V(1)$ in the case of a vortex of unit radius. Therefore the azimuthal velocity at the boundary of the vortex sets a bound for the real part of the eigenfrequency.

Of course, one reason why eigenmodes with comparatively high frequencies will be more unstable is that they are less influenced by the inertial cut-off $\omega = |f|$. While this is one explanation, it is not the only one, and is probably not the most significant. Regardless of the inertial cut-off frequency, we would still expect higher frequency eigenmodes to be more unstable than lower frequency modes, because at higher frequencies the interaction between vortical and gravitational motions becomes stronger.

To see this, first recall that we expect the growth rate of the instability to depend on the strength of coupling between the Rossby wave, on the vortex boundary, and the gravity waves, found distant from the vortex boundary. The character of the eigenmodes changes from being Rossby wave - like to gravity wave - like at the "sonic radius", at which the intrinsic angular phase speed of disturbances, $\omega r/m - V(r)$, is equal to the gravity wave phase speed $F^{-1}H^{1/2}(r)$. At a given F, it follows that, the larger the value of ω, the smaller r will have to be to achieve a given angular phase speed, and hence the closer the sonic radius will be to the boundary of the vortex. We should expect this to lead to an enhanced coupling between the Rossby

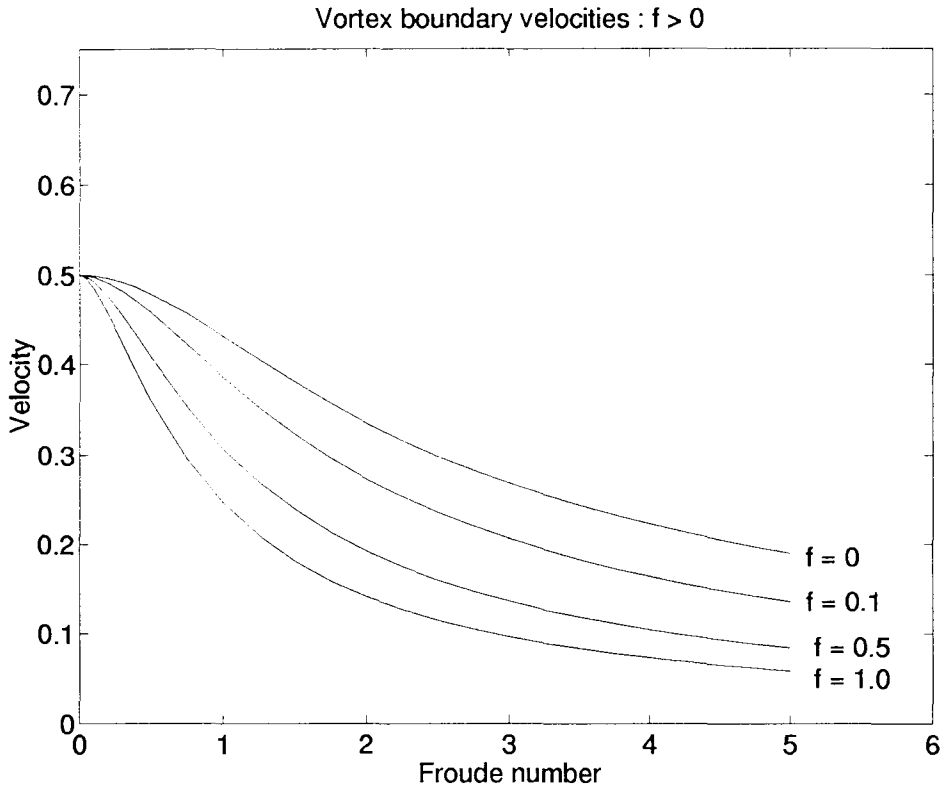

Figure 3.20: Azimuthal velocity at boundary of vortices, $f > 0$.

wave on the vortex boundary and the gravity wave beyond the sonic radius in cases where ω is comparatively large.

We shall return to this point in the next section, with reference to the WKBJ analysis. The analysis enables us to distinguish between the effect of the inertial cut-off, which primarily affects the growth rates of low mode number disturbances, and the effect of variation in the location of the sonic radius, which affects the growth rates at all mode numbers. For the present, however, we shall simply examine the large degree of variation in the vortex boundary velocities which is experienced as F and f are varied, and defer a quantitative discussion to the end of the next section.

In figure 3.20, the azimuthal vortex boundary velocity is shown as a function of Froude number for cyclones with various values of f. In all cases the vortex boundary velocity decreases very rapidly as the Froude number is increased, from a velocity of 0.5 at $F = 0$ to less than 0.2 at $F = 5$. Therefore, we expect the real part of the eigenfrequency to decrease as F is

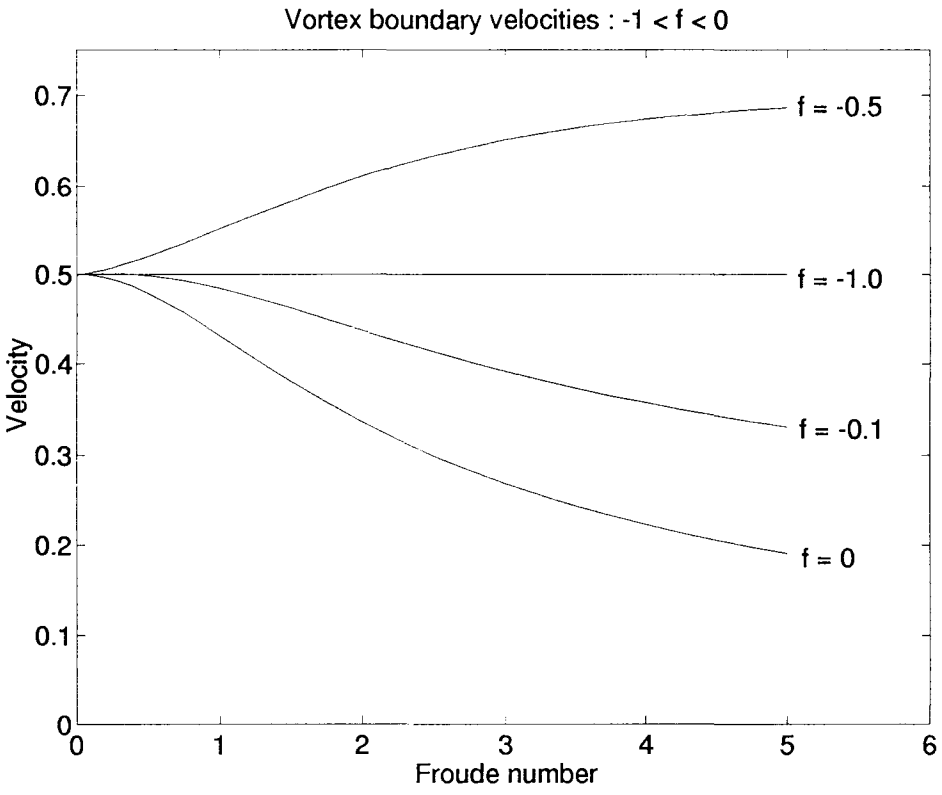

Figure 3.21: Azimuthal velocity at boundary of vortices, $-1 < f < 0$.

increased.

Vortex boundary velocities for anticyclones with $|f| < 1$ are shown in figure 3.21. For small $|f|$, the vortex boundary velocity decreases, just as in the cyclonic case, but much less rapidly. For example, with $f = -1/10$, the velocity decreases from 0.5 to 0.33 as F increases from 0 to 5, whereas with $f = 1/10$ it decreases from 0.5 to 0.14. The most striking difference comes for larger f, where the vortex boundary velocity increases as F is increased. The most extreme example is the case $f = -1/2$, where the velocity increases from 0.5 at $F = 0$ to 0.68 at $F = 5$. When $f = -1$, the vortex boundary velocity is exactly 0.5 for all F.

For $f < -1$, the vortex boundary velocities always decrease as F is increased. This is shown in figure 3.22. The growth rates of these instabilities tend to behave more like those of cyclones than the anticyclones with $-1 < f < 0$.

The results of the eigenvalue calculations may be summarized as follows. In the absence of background rotation, the eigenmode with $m = 2$ is always unstable in the range $0 < F < 5$,

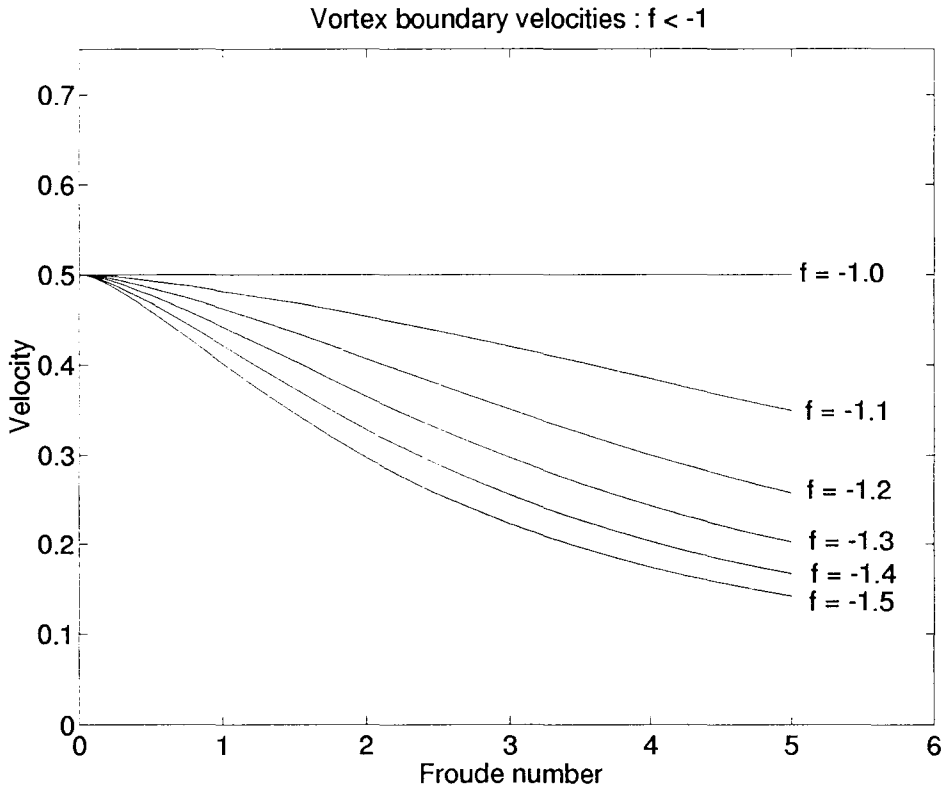

Figure 3.22: Azimuthal velocity at boundary of vortices, $f < -1$.

and is probably unstable for all F. With background rotation present, low mode number eigenmodes may be unstable at small Froude numbers, but become stabilized as the Froude number is increased. This is because the real part of the eigenfrequency decreases as the Froude number is increased, and eventually falls below $|f|$, at which point the instability mechanism no longer exists.

The maximum growth rates (taken over all m) are shown as a function of F and f in figures 3.23a & 3.24a. The growth rate and fastest growing mode number surfaces are shown from two different orientations for ease of visualization. With the exception of the vortices for which $-1 < f < 0$, the growth rate of the instability generally peaks at a finite value of the Froude number, and with a fairly low growth rate. However, when $-1 < f < 0$, it seems that the growth rate of the instability may increase without bound as F is increased. The corresponding fastest growing mode number is shown in figures 3.23b & 3.24b. For $-1 < f < 0$, the fastest growing mode number is typically small (either 2 or 3), whereas for values of f outside this range, the fastest growing mode number can be quite large. In the most extreme case shown, when $F = 5$ and $f = -1.5$, the fastest growing mode number is 27.

Thus, the cyclones all tend to exhibit the same dependence on F and f. As f and F are increased, successively higher mode numbers must be taken to retain the instability, whereas the anticyclones fall into two categories. When $-1 < f < 0$, the vortex has potential vorticity of opposite sign to the background. In these cases, there is no marked tendency to stabilize as F is increased. In the particular case $f = -1/2$ the instability becomes markedly stronger as F increases, with maximum growth rate for $m = 3$. When $f < -1$, however, the dependence of the instability on $|f|$ and F is similar to the cyclonic cases, and again large mode numbers are required to retain the instability. Strong instability by the Rossby wave - gravity wave instability mechanism seems possible only when $-1 < f < 0$ and the mode number m is not too large. These are the cases where the sonic radius is closest to the boundary of the vortex.

From a practical point of view, we have almost certainly identified those cases in which this instability is sufficiently vigorous that it might be observed in nature. However, we are interested not only in cases of practical significance, but also in whether coupling between vortical motions and gravity waves exists at all Rossby numbers, or whether these is a value of $|f|$ above which the instability ceases to exist, at least for some range of F, and in which cases the vortical motions could then be separated from the gravity waves in the problem.

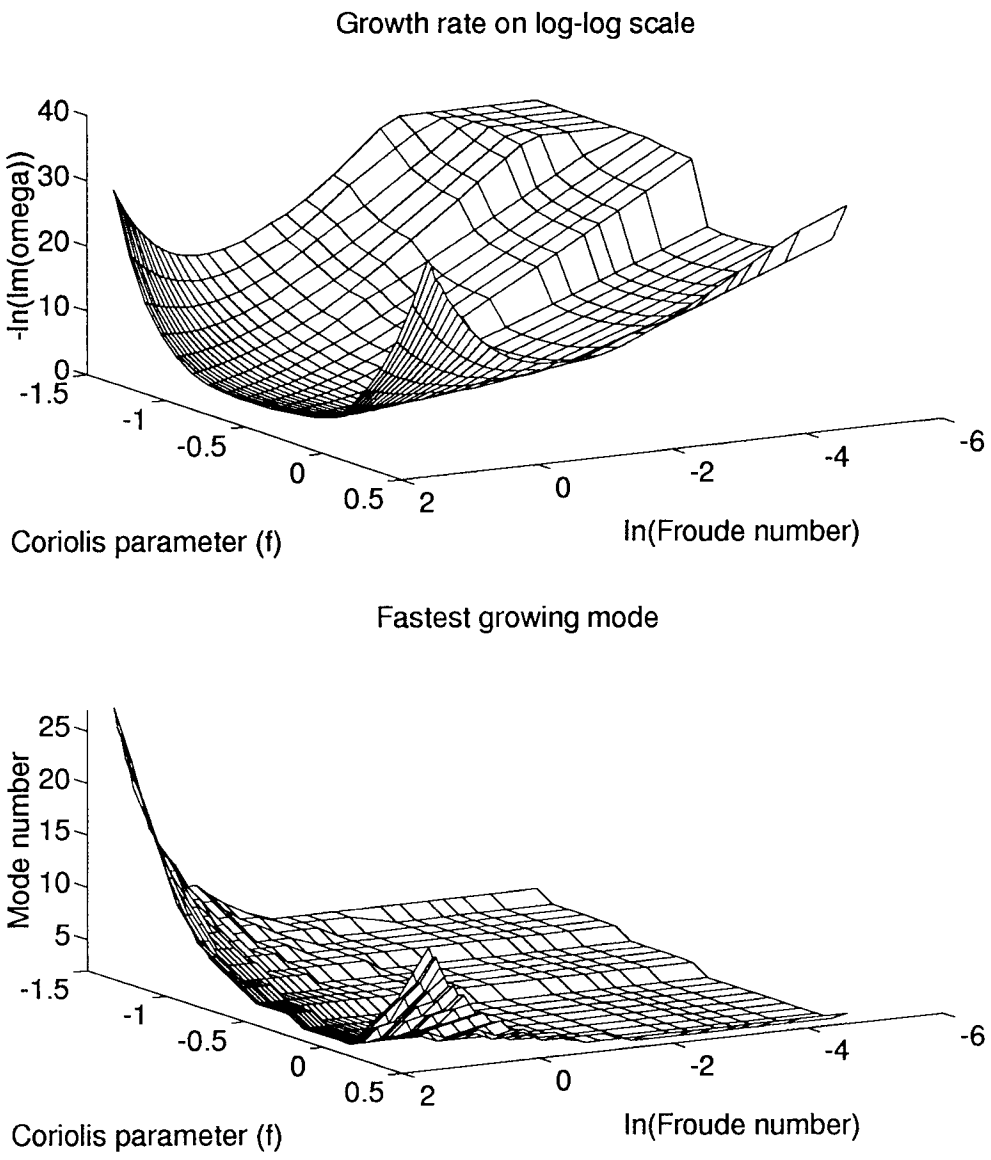

Figure 3.23: Summary of axisymmetric vortex instability calculations, viewed from orientation giving most complete view of growth rate surface.

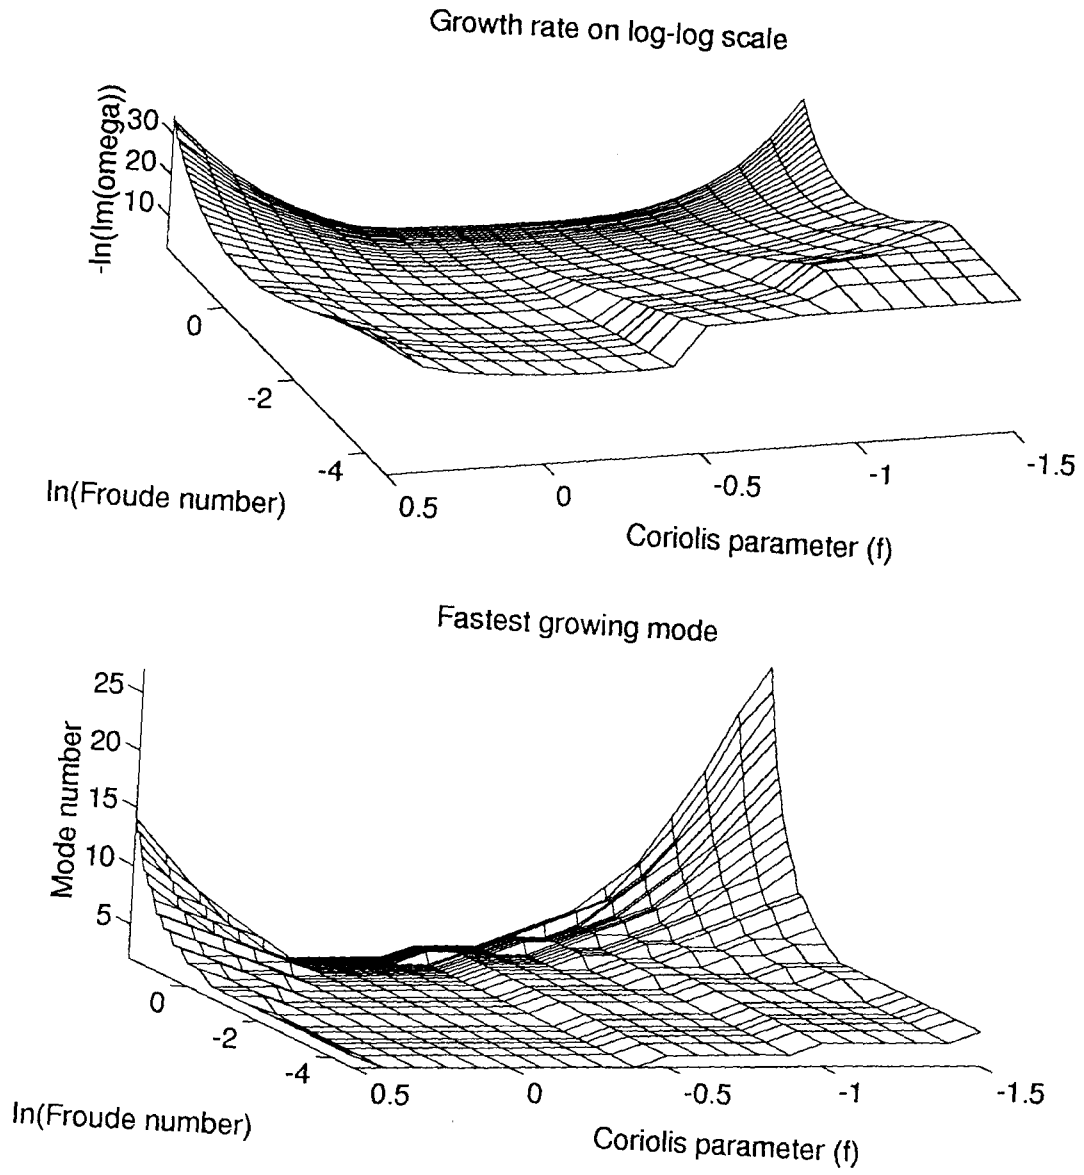

Figure 3.24: As figure 3.23, but viewed from orientation giving most complete view of fastest growing mode number surface. Note that (*a*) is viewed from a greater elevation than (*b*).

The next section therefore examines this instability for arbitrary f and F in the limit $m \gg 1$. The WKBJ analysis has the added advantage that it assumes *a priori* that $\omega \gg f$. Therefore any distinction between cyclones and anticyclones which can be accounted for by the WKBJ analysis must be due to the general nature of the basic state, and the strength of Rossby wave – gravity wave interactions on it, and any distinction not accounted for must be due to the specific effects of the inertial cut-off frequency.

3.2.5 The limit of large mode number

We start by writing (3.12,3.13) as a single second order ordinary differential equation for v_θ:

$$\frac{d^2 v_\theta}{dr^2} + F(r)\frac{dv_\theta}{dr} + G(r)v_\theta = 0, \tag{3.67}$$

where

$$F = -\frac{C'}{C} - A - D; \qquad G = \frac{C'D}{C} + AD - BC - D', \tag{3.68}$$

where here A, B, C and D are given by (3.14-3.17). Equation (3.67) must be solved subject to certain boundary conditions. These are regularity at $r = 0$, and an evanescence/radiation condition as $r \to \infty$. The latter of these conditions requires some care. Any unstable mode must be exponentially weak at infinity, and therefore an evanescence condition should suffice. However, we shall for convenience state the radiation condition, bearing in mind that when the eigenfrequency becomes slightly complex, perhaps at some high order in the expansion parameter m, the solution of (3.67) acquires some weak exponential decay.

Following standard WKBJ analysis, we write

$$v_\theta = A(r)e^{im\psi(r)}, \tag{3.69}$$

where now $A(r)$ is an amplitude function and $\psi(r)$ is a phase function, made rapidly varying through the factor of m in the exponent. Substituting (3.69) into (3.67) gives

$$A'' + 2im\psi'A' + im\psi''A - m^2\psi'^2 A + F(r)(A' + im\psi' A) + G(r)A = 0. \tag{3.70}$$

In general ψ and A must be expanded in inverse powers of the WKBJ expansion parameter m. The decomposition of v_θ into $A(r)$ and $\psi(r)$ is not unique. A small ($O(m^{-1})$, say), correction to v_θ through ψ could just as easily be made by an $O(m^{-1})$ correction to A. However, the decomposition can be made unique, and a great deal more convenient to work with, if we insist

that $A(r)$ and $\psi(r)$ naturally take the roles of amplitude and phase in that, if $\{A(r), \psi(r)\}$ is a solution of (3.70), then so is $\{A(r), -\psi(r)\}$.

Equation (3.70) can then be separated into two equations:

$$A'' - m^2\psi'^2 A + F(r)A' + G(r)A = 0 \tag{3.71}$$

$$2\psi' A' + \psi'' A + \psi' A F(r) = 0, \tag{3.72}$$

which latter equation can be integrated at once to

$$2\ln|A| + \ln|\psi'| + \int F = 0. \tag{3.73}$$

We now start our asymptotic analysis of (3.71). Since we know from (3.19) that ω is of order m, at least in the limit $F \ll 1$, it is convenient to work with an intrinsic angular frequency c defined by $c \equiv \omega/m$. Bearing Kelvin's expression $\omega = (m-1)/2$ in mind, and in the spirit of asymptotic expansions, we must expand c in the form

$$c = c_0 + m^{-1}c_1 + \cdots. \tag{3.74}$$

In fact, it will turn out that c has not only an algebraic expansion in m^{-1}, but also requires terms exponentially small in m to describe the instability.

From (3.14-3.17) we know that, expanding in m, $F(r)$ is $O(1)$, while $G(r)$ takes the form

$$G(r) = m^2\left[\frac{(-c + \overline{v}/r)^2 F^2}{1 + F^2\overline{h}} - \frac{1}{r^2}\right] + O(1), \tag{3.75}$$

which can, by virtue of the expansion (3.74) have terms of order $O(m^2)$ and $O(m)$. From (3.71), at $O(m^2)$, the equation for ψ_0 is

$$\psi_0'^2 = \frac{(-c_0 + \overline{v}/r)^2 F^2}{1 + F^2\overline{h}} - \frac{1}{r^2}. \tag{3.76}$$

The expression for A_0 can be obtained from (3.73). Notice that, since $F(r)$ is regular for all $r \neq 0$, there is a singularity in the expression for A_0 at a radius $r = r_c$ where $\psi_0'(r_c) = 0$. We can see at once that, for $c_0 \neq 0$, there is at least one such radius, since $\psi_0'^2 \sim -r^{-2} < 0$ as $r \to 0$, but $\psi_0'^2 \sim c_0^2 F^2 > 0$ as $r \to \infty$.

Now, $v_\theta = A(r)e^{im(\psi_0 + m^{-1}\psi_1 + \cdots)}$, and since we will require an expression for both the amplitude and phase of v_θ, we must obtain expressions for both ψ_0 and ψ_1. The equation for

ψ_1 is obtained from (3.71) at $O(m)$, and is

$$\psi_0'\psi_1' + \frac{F^2 c_1(-c_0 + \overline{v}/r)}{1 + F^2\overline{h}} = 0. \tag{3.77}$$

Now, the nature of the solutions for v_θ differs significantly on either side of $r = r_c$. On one side, and in particular in the limit $r \to \infty$, the solutions are oscillatory (for real c_0), whereas on the other side, and in particular in the limit $r \to 0$, they are growing and decaying exponentials. We refer to the radius $r = r_c$ as the "turning radius", and in the following analysis we shall assume that there is precisely one turning radius for the vortex. There is always precisely one turning radius for $F \ll 1$, whatever the magnitude of the Coriolis parameter f, and hence the assumption includes the basic state in the "quasigeostrophic" limit, in which one might expect interactions between vortices and gravity waves to be weakest. All vortices investigated numerically in the previous section were found to have precisely one turning radius.

The expansion (3.69) for v_θ is not valid in the neighbourhood of $r = r_c$, since ψ_0' is zero there, and so by (3.73) A would be unbounded. We must therefore rescale the equations in the neighbourhood of $r = r_c$ and derive equations for the perturbation expansion in this inner asymptotic region. In the vicinity of $r = r_c$, we have

$$G(r) = m^2 a_1 (r - r_c) + \cdots, \tag{3.78}$$

where a_1 is a positive constant. Rescaling the radial coordinate as $x = m^{2/3}(r - r_c)$ the leading order equation for v_θ from (3.67) becomes

$$\frac{d^2 v_\theta}{dx^2} + a_1 x v_\theta = 0. \tag{3.79}$$

Equation (3.79) has solutions $v_\theta = A_i(-a_1^{1/3}x), B_i(-a_1^{1/3}x)$, where $A_i(z)$ and $B_i(z)$ are Airy functions (Abramowitz & Stegun, 1965).

Four asymptotic regions have now been established, and the method of matched asymptotic expansions will now be used to relate the solutions in the different regions. The asymptotic regions are

1 : $r > r_c$

2 : $r - r_c = O(m^{-2/3})$

3 : $1 < r < r_c$

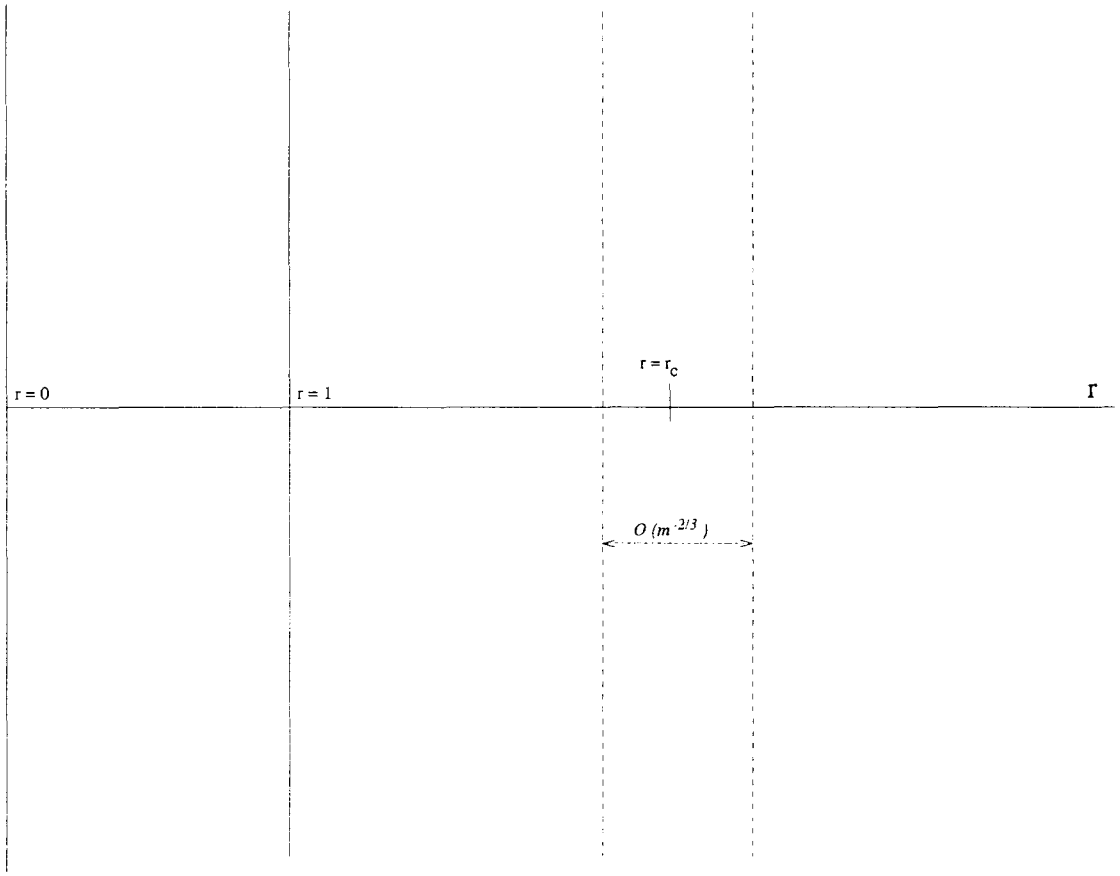

Figure 3.25: Asymptotic regions of shallow water vortex instability analysis.

4 : $0 < r < 1$

The situation is depicted in figure 3.25.

Region 1: $r > r_c$

As $r \to \infty$, we can place conditions on the branch of square root to take in the solution of (3.76) by imposing a radiation boundary condition, so that $\psi_0' > 0$ as $r \to \infty$. This immediately implies, through the matching condition in the limit $x \to \infty$, the ratio of A_i to B_i to take in the solution of (3.79). The expansions of $A_i(z)$ and $B_i(z)$ in the limit $z \to \infty$ then gives, through the matching conditions, the ratio of the growing to decaying exponential solutions to (3.67) for $1 < r < r_c$.

Region 2: $r - r_c = O(m^{-2/3})$

For $z \to -\infty$, the Airy functions take the asymptotic forms

$$A_i(-z) \sim \pi^{-1/2} z^{-1/4} \sin(2/3 z^{3/2} + \pi/4) \tag{3.80}$$

$$B_i(-z) \sim \pi^{-1/2} z^{-1/4} \cos(2/3 z^{3/2} + \pi/4). \tag{3.81}$$

Therefore, if we write $v_\theta = \alpha A_i(-a_1^{1/3} x) + \beta B_i(-a_1^{1/3} x)$, matching to a radiating field as $x \to \infty$ implies $\alpha/\beta = i$.

In the limit $x \to -\infty$ we have

$$A_i(z) \sim \frac{1}{2} \pi^{-1/2} z^{-1/4} e^{-2/3 z^{3/2}} \tag{3.82}$$

$$B_i(z) \sim \pi^{-1/2} z^{-1/4} e^{2/3 z^{3/2}}. \tag{3.83}$$

Region 3: $1 < r < r_c$

Now if we let

$$\Psi_0(r) = -\int_r^{r_c} \left(\frac{1}{r^2} - \frac{(-c_0 + \overline{v}/r)^2 F^2}{1 + F^2 \overline{h}} \right)^{1/2} dr \tag{3.84}$$

and

$$\Psi_1(r) = \int_r^{r_c} \frac{c_1(-c_0 + \overline{v}/r)}{\Psi_0'(1 + F^2 \overline{h})} dr \tag{3.85}$$

then, for $1 < r < r_c$, we have

$$v_\theta = A(r) \left(a e^{m\Psi_0 + \Psi_1} + b e^{-m\Psi_0 - \Psi_1} \right), \tag{3.86}$$

where the ratio of b to a is to be determined by the matching conditions to the Airy function region. Now the $B_i(-a_1^{1/3} x)$ term is, by (3.83), exponentially growing away from $r = r_c$ - i.e. it is exponentially decaying with radius in $1 < r < r_c$. It therefore matches to the term $be^{-m\Psi_0 - \Psi_1}$ in the solution in the region $1 < r < r_c$. Correspondingly, the $A_i(-a_1^{1/3} x)$ term matches to the solution which is exponentially growing with radius – that is, the term $ae^{m\Psi_0 + \Psi_1}$. Hence by considering (3.82-3.83) in the limit $z \to \infty$, the ratio of exponentially growing to exponentially decaying terms in the region $1 < r < r_c$ satisfies the relation $a/b = i/2$. Up to an arbitrary amplitude, therefore, this completes the solution in the range $r > 1$.

Region 4: $0 < r < 1$

In the range $r < 1$, the crucial boundary condition is regularity at $r = 0$. This implies only solutions of the form

$$v_\theta = de^{m\Psi_0 + \Psi_1} \tag{3.87}$$

are possible, where Ψ_0 is given by (3.84), and Ψ_1 by (3.85).

Jump conditions at $r = 1$

The final task, which determines the eigenvalue c at successive orders, is to apply continuity of v_r and h at $r = 1$, which is expressed in the continuity condition (3.18).

To find v_r, we may use to sufficient accuracy

$$\frac{dv_\theta}{dr} \sim \frac{im}{r} v_r. \tag{3.88}$$

For $r < 1$, this leads to

$$\left.\frac{v_\theta}{v_r}\right|_{r=1^-} = i + O(m^{-1}). \tag{3.89}$$

On the other hand, for $r > 1$, we obtain

$$\left.\frac{v_\theta}{v_r} = i\frac{e^{-m\Psi(1)} + i/2e^{m\Psi(1)}}{-e^{-m\Psi(1)} + i/2e^{m\Psi(1)}}\right|_{r=1+}, \tag{3.90}$$

where here

$$\Psi(1) = \Psi_0(1) + m^{-1}\Psi_1(1). \tag{3.91}$$

Recalling that $\Psi < 0$, this takes the asymptotic form for large m:

$$\frac{v_\theta}{v_r} \sim \frac{i}{r\Psi_0'}\left(1 + ie^{2m\Psi(1)}\right). \tag{3.92}$$

There are algebraic corrections to these terms, but because of our judicious decomposition of A and ψ, the expression (3.92) expresses the principal exponential terms. In particular, then, it has the correct expression for the leading order (exponentially small) imaginary part of v_θ/v_r.

Returning to the continuity condition (3.18), at order $O(m)$, we simply have

$$c_0 = \overline{v}(1). \tag{3.93}$$

At the next order, we obtain

$$c_1 = -\frac{1}{2}H_1\left(1 - \frac{1}{2}ie^{2m\Psi(1)}\right), \tag{3.94}$$

where $H_1 = 1 + F^2\overline{h}(1)$.

There are two things to note about (3.94). Firstly, the correction to the real phase speed of the disturbance is negative, and is in accordance with Kelvin's expression (3.19) in the limit $F \ll 1$. This is consistent with the claim that the disturbance on the boundary of the vortex has locally the character of a Rossby wave, with a pseudo-westward phase speed. The second thing is that the imaginary correction to c is always positive, corresponding to a temporally growing disturbance of form e^{-imct} at any value of F or f. Since the asymptotic limit in this case is of a particular type of disturbance, rather than a particular type of basic state, as it was in the $F \ll 1$ analysis of chapter 2, we conclude that all basic states which satisfy the assumption of a single turning point are unstable, at least to large mode number disturbances.

The low Froude number limit

We can obtain an independent check on the expression (3.94) in the limit of low Froude number by expanding it for $F \ll 1$ and comparing the result with the expression (3.51) expanded in the limit of large m.

We start by expanding the expression (3.84) for $\Psi_0(1)$ in the limit $F \ll 1$. Firstly, we recall that $\overline{v}$ is of order $O(F)$ everywhere except where r is of order $O(1)$. Therefore, to leading order in F, and recalling that $c_0 = 1/2$ at leading order in F, we have that $r_c = 2F^{-1}$ at leading order in F.

Now the integrand in (3.84) takes the asymptotic forms

$$\left(\frac{1}{r^2} - \frac{(-c_0 + \overline{v}/r)^2F^2}{1 + F^2\overline{h}}\right)^{1/2} \sim \begin{cases} \frac{1}{r} + O(F) & \text{for } r = O(1) \\ F\left(\frac{1}{F^2r^2} - \frac{1}{4}\right)^{1/2} + O(F^2) & \text{for } r = O(F^{-1}) \end{cases}. \tag{3.95}$$

The technique is to split up the range of integration into two sub domains: $[1, F^{-1/2}]$ and $[F^{-1/2}, 2F^{-1}]$. In the latter of these two domains we use a rescaled variable $R \equiv Fr$. The leading order expansion of $\Psi_0(1)$ is then

$$\Psi_0(1) \sim \int_2^{F^{1/2}} \left(\frac{1}{R^2} - \frac{1}{4}\right)^{1/2} dR + \int_{F^{-1/2}}^1 \frac{1}{r}dr. \tag{3.96}$$

Integrating, substituting, and expanding for small F, we obtain

$$\Psi_0(1) \sim 1 + \ln F - \ln 4 + O(F). \tag{3.97}$$

The asymptotic evaluation of (3.85) for $\Psi_1(1)$ is simpler, because the integrand has a regular expansion in F. The leading contribution comes from the range $r = O(F^{-1})$, and $\Psi_1(1)$ takes the form

$$\Psi_1(1) \sim \frac{1}{4}\int_2^0 \left(\frac{1}{R^2} - \frac{1}{4}\right)^{-1/2} = -1. \tag{3.98}$$

It follows from (3.94) that the growth rate of the instability is

$$\frac{1}{4}e^{2m\Psi(1)} = \frac{1}{4}\left(\frac{F}{4}\right)^{2m} e^{2(m-1)}. \tag{3.99}$$

To compare the expression (3.99) with the predictions of the analysis for $F \ll 1$, we expand $\mathrm{Im}(\omega)$ for large m, where $\mathrm{Im}(\omega)$ is given by (3.51). For large m we have

$$\mathrm{Im}(\omega) \sim \frac{\pi F^{2m}}{2m((m-1)!)^2}\frac{1}{4^{2m}}(m-1)^{2m}. \tag{3.100}$$

Using Stirling's formula for $(m-1)!$:

$$(m-1)! = (2\pi)^{1/2}(m-1)^{m-1/2}e^{-(m-1)}, \tag{3.101}$$

we have

$$\mathrm{Im}(\omega) \sim \frac{1}{4}\frac{e^{2(m-1)}}{4^{2m}}F^{2m}, \tag{3.102}$$

and hence the low Froude number and large mode number analyses agree in the limit in which they are both valid.

Comparison with numerical eigenvalue calculations

In addition to the analysis in the low Froude number limit, we can also test the validity of the general expression (3.94) given for the growth rate of the instability in the WKBJ limit against the numerical eigenvalue calculations.

Growth rates of the instability against mode number are shown in figures 3.26 & 3.27.

The basic states chosen all have Froude number $F = 2.5$ in figure 3.26, and $F = 5$ in figure 3.27, with varying values of f indicated on the graphs. Overall there seems to be good

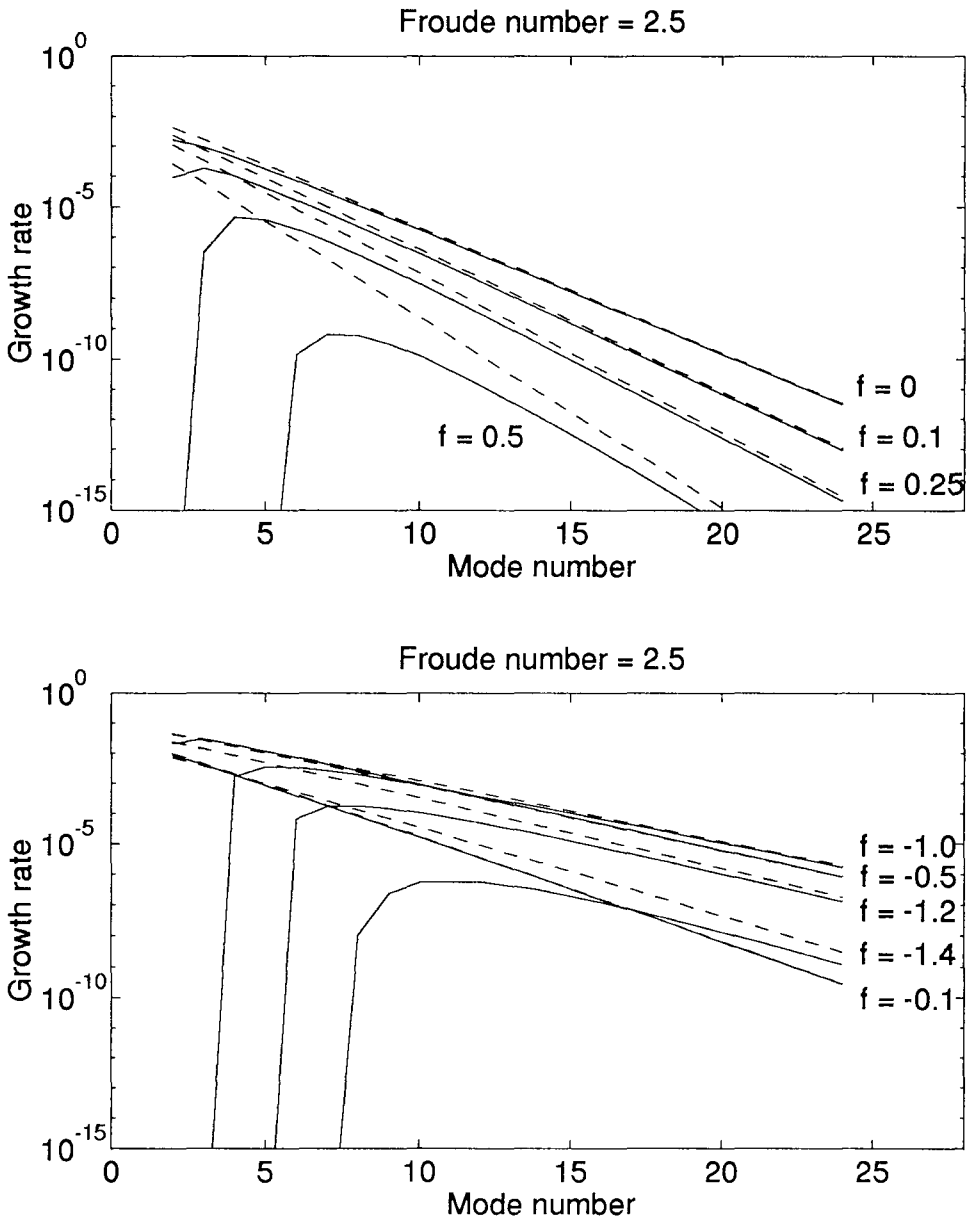

Figure 3.26: Comparison of eigenmode growth rates (solid lines) with WKBJ predictions (dashed lines), $F = 2.5$, for $m = 0$ to 25, at various values of f.

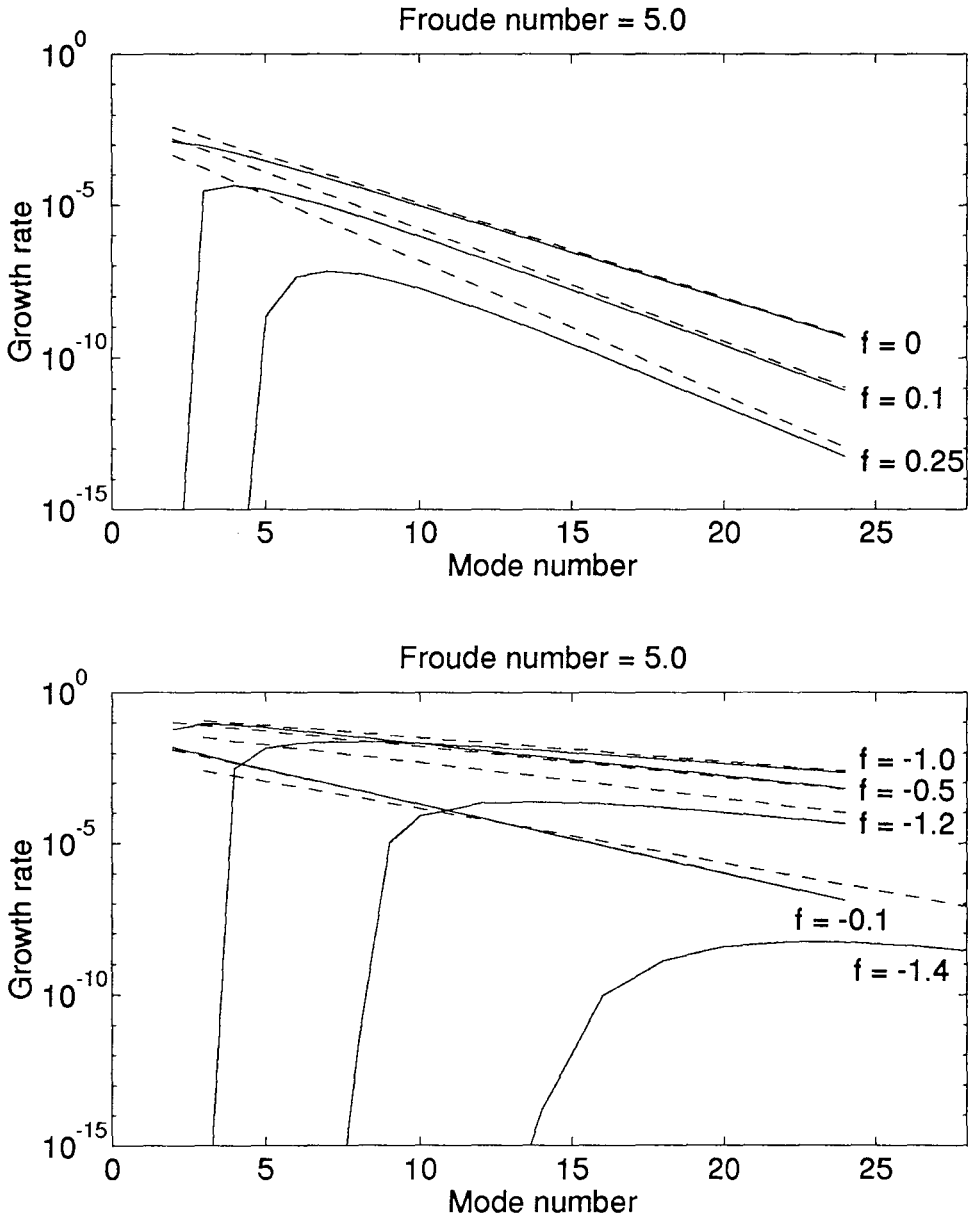

Figure 3.27: Comparison of eigenmode growth rates (solid lines) with WKBJ predictions (dashed lines), $F = 5.0$, for $m = 0$ to 25.

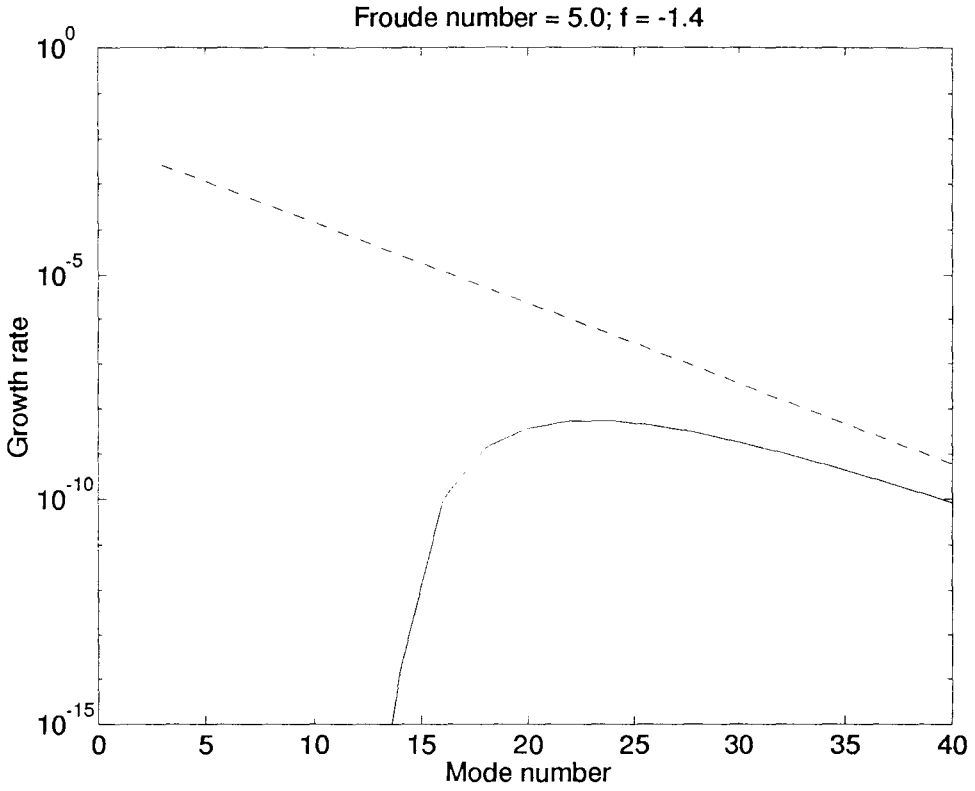

Figure 3.28: Comparison of eigenmode growth rate (solid line) with WKBJ prediction (dashed line) for $F = 5.0$ and $f = -1.4$, extended to $m = 40$.

agreement between the WKBJ analysis (dashed lines) and the numerical eigenvalue code (solid lines), even for quite moderate values of m. The case $F = 5.$ $f = -1.4$ is extended to $m = 40$ in figure 3.28 to demonstrate agreement in this case.

A significant distinction is to be drawn between $f > 0$ and $f < 0$. For given F, the magnitudes of $\Psi_0(1)$ and $\Psi_1(1)$ are always greater when $f > 0$ than when $f < 0$. It follows immediately that the instability will be weaker for $f > 0$ in the limit of large m. This is significant, in that it is dependent entirely upon the nature of the basic state, and independent of the effects of inertial cut-off, which are assumed not to apply, since the WKBJ analysis assumes that f is of order unity, whereas ω is of order $m \gg 1$. Where the numerical eigenvalues are in good qualitative agreement with the WKBJ prediction, any differences between them for different values of f must be directly attributable to the nature of the basic state alone, and independent of the effects of the inertial cut-off.

For small m and small $|f|$, the eigenmodes are unstable, and their growth rates are broadly

in line with the values predicted by the WKBJ analysis. However, as $|f|$ is increased, the eigenmodes become stable at small m. Since this effect is not predicted by the WKBJ analysis, it must be due to the fact that the eigenfrequencies are comparable with the magnitudes of the inertial frequency, and hence the inertial cut-off is significant.

As a heuristic way of thinking about the behaviour of the growth rates, I propose that in the region where they are seen to be increasing with increasing m, it is because the real part of the eigenvalue is increasing. The growth rate is therefore dominated by effects of the inertial cut-off. Examination of figures 3.26 & 3.27 shows that, once the instability has set in, this range of m tends to be quite small. However, in the range where the growth rate of the instability decreases with m, I propose that the WKBJ analysis is broadly valid in this limit, and the dependence of the growth rate of the instability on f is determined largely by the nature of induced basic state, and not directly by the effect of the inertial cut-off. Even in the range where the inertial cut-off is dominating the lower eigenmodes, the nature of the basic state is clearly important, in that it sets the real part of the eigenfrequency, and hence determines whether the eigenmodes are unstable or not.

In conclusion, the axisymmetric vortex is always unstable, but as F and $|f|$ are increased, larger and larger values of m must be taken to obtain the instability. Almost all the asymmetry between cyclones and anticyclones can be explained in terms of the basic state. At large m, the nature of the basic state determines the strength of Rossby wave – gravity wave interactions, and at small m it determines whether and by how much the real part of the eigenfrequency will exceed $|f|$, and hence how significantly the instability is affected by the inertial cut-off.

3.2.6 The Sozou modes

The analysis of the previous sections is distinguished by the fact that only one eigenmode has been found, whereas Sozou (1987) found an infinite set of modes in the Rankine vortex at non-zero Mach number.

The purpose of this section is to explain the difference between Sozou's results, both analytical and numerical, and the present analysis. It turns out that the difference lies in the fact that the Rankine vortex has uniform vorticity and non-uniform potential vorticity for all $M \neq 0$, whereas in the analysis of the previous section, we have assumed the potential vorticity to be piecewise constant.

We start by obtaining the potential vorticity of the Rankine vortex. The Rankine vortex has uniform vorticity, which we shall set to unity. Then

$$\overline{v}(r) = \begin{cases} \frac{1}{2}r & r < 1 \\ \frac{1}{2r} & r > 1 \end{cases} . \tag{3.103}$$

Using $d\overline{h}/dr = \overline{v}^2/r$, and applying continuity of $\overline{h}$ at $r = 1$, we have

$$\overline{h}(r) = \begin{cases} -\frac{1}{4} + \frac{1}{8}r^2 & r < 1 \\ -\frac{1}{8}r^{-2} & r > 1 \end{cases} . \tag{3.104}$$

Hence the potential vorticity and its gradient in the radial direction are given respectively by

$$Q = \frac{1}{1 - \frac{1}{8}F^2(2 - r^2)}; \quad \frac{dQ}{dr} = -\frac{F^2 r}{\left[2 - \frac{1}{4}F^2(2 - r^2)\right]^2}. \tag{3.105}$$

From this we see that $dQ/dr < 0$ for all $r < 1$, and the potential vorticity is zero for $r > 1$. Hence the potential vorticity gradient is monotonic, and the vortex is not unstable to a barotropic Rossby wave – Rossby wave type of instability. However, the non-zero potential vorticity gradient means that, in addition to the Rossby wave on the boundary of the vortex, it is capable of supporting an infinite set of Rossby wave modes within the vortex.

We now consider the limit $m \gg 1$. Returning to the eigenvalue equations (3.12 - 3.17), if additional modes are to be introduced in this large m limit as a result of the non-zero gradient of potential vorticity, it can only be because $(H/\sigma)dQ/dr \sim O(m)$ over a range of order unity within the vortex. Only then is the balance of terms in the equation for ψ_0 changed at leading order in m.

In fact, the uniform vorticity of the Rankine vortex is significant, as well as its non-uniform potential vorticity. Within the vortex, $\sigma = -\omega + m$, i.e. σ is constant within the vortex, and there are no critical layers there (unless $\sigma = 0$ throughout the vortex). In this case we may take $\sigma = m + m^{-1}c_2$, where c_2 is constant, so that σ is of order m^{-1} throughout the vortex. It turns out that the equation for v_θ is singular in the general cases to be described below, and it is more convenient to work with an equation for v_r. Writing $v_r(r) = A(r)e^{im\psi(r)}$, the equation for ψ_0 then becomes

$$\psi_0'^2 = -\left(\frac{1}{r^2} + \frac{F^2}{4c_2 H(r)}\right), \tag{3.106}$$

where $H(r) = 1 + F^2\overline{h}(r)$. In this case, it is convenient to note that $c_1 = 0$, and hence $\psi_1 = 0$.

Now, we consider the continuity condition (3.18). At order unity, it is

$$-\frac{c_2}{m}\left[\frac{v_\theta}{v_r}\right] = [iH(1)Q], \tag{3.107}$$

and therefore we require v_θ/v_r to be of order m at $r = 1^-$. Since $v_\theta \sim (ir/m)dv_r/dr$, this can only be achieved if $v_r = O(m^{-1})$ at $r = 1$.

We must now consider two possible cases: $c_2 > 0$ and $c_2 < 0$. If $c_2 > 0$, we can write down the solution for v_θ over the range $0 < r < 1$ as

$$v_r = A(r)\exp\left[m\int_0^r \left(\frac{1}{r^2} + \frac{F^2}{4c_2H(r)}\right)^{1/2} dr\right]. \tag{3.108}$$

In this case, v_r is always of order 1, and hence it will not be possible to satisfy the continuity conditions at $r = 1$.

Therefore, we seek solutions with $c_2 < 0$. For convenience, we introduce a new constant κ, and let $c_2 = -4F^2\kappa^{-2}$. Then

$$\psi_0'^2 = \left(\frac{\kappa^2}{H(r)} - \frac{1}{r^2}\right). \tag{3.109}$$

There is now a turning point at r_c, given by $H(r_c)/r_c^2 = \kappa^2$ and, provided κ is sufficiently large, this turning point will occur at some $r_c < 1$. It is simple to show from the form $H(r)$ that the turning point is unique for a given κ. The solution in $0 < r < 1$ is now divided into three asymptotic regions

$r < r_c$ Exponentially growing solution

$r - r_c = O(m^{-2/3})$ Airy functions

$r_c < r < 1$ Oscillatory functions

For $0 < r < r_c$, we will have

$$v_r = A(r)\exp\left[m\left(\frac{1}{r^2} - \frac{\kappa^2}{H(r)}\right)^{1/2} dr\right]. \tag{3.110}$$

In the region $r - r_c = O(m^{-2/3})$, the solution will be represented in terms of Airy functions. What is important for the eigenvalue equation is the solution in $r > r_c$. Now, if the solution

in $r < r_c$ consists of only an exponential term which is growing in r, then the solution in the neighbourhood of $r = r_c$ will be represented by $A_i(z)$, where z is proportional to $r^{2/3}$. Then in $r > r_c$, matching to the Airy function gives a solution for v_r:

$$v_r = A(r)\cos\left[m\int_{r_c}^{r}\left(\frac{\kappa^2}{H(r)} - \frac{1}{r^2}\right)^{1/2} dr - \frac{\pi}{4}\right]. \tag{3.111}$$

If we now wish to have $v_r = 0$ at leading order in m then,

$$m\int_{r_c}^{r}\left(\frac{\kappa^2}{H(r)} - \frac{1}{r^2}\right)^{1/2} dr = \left(n - \frac{1}{4}\right)\pi; \quad n = 1, 2, 3, \ldots. \tag{3.112}$$

This equation is the leading order eigenvalue equation for κ at arbitrary Froude number F. To make further progress, and to compare this result with that obtained by Sozou (1987), we shall make the assumption $F \ll 1$, but $\kappa = O(1)$. The only approximation to make is that $H(r) = 1$ in (3.112). Then we obtain a dispersion relation for κ

$$\sqrt{\kappa^2 - 1} - \arccos\kappa^{-1} = m^{-1}\left(n - \frac{1}{4}\right)\pi. \tag{3.113}$$

Sozou works with a frequency divided by the vorticity in the vortex $f = m - 2m\omega^2/s^2$, where ω is the vorticity in the vortex. After rescaling Sozou's (1987) equations, one can show that his variable s should correspond to our variable $m\kappa$. Sozou claims that roots of his dispersion relation satisfy $J_m(s) = 0$. It is more convenient to work with κ than s, so we solve $J_m(m\kappa) = 0$ for large m and κ of order unity.

From Abramowitz & Stegun (1965),

$$J_m(m\sec\beta) \sim \sqrt{2/(\pi m\tan\beta)}\cos(m\tan\beta - m\beta - \pi/4). \tag{3.114}$$

Identifying $\sec\beta \equiv \kappa$ gives $\tan\beta \equiv \sqrt{\kappa^2 - 1}$, and hence Sozou's condition is

$$m\sqrt{\kappa^2 - 1} - m\arccos\kappa^{-1} - \pi/4 = (n - 1/2)\pi, \tag{3.115}$$

which is the same as equation (3.113).

The important point is that the additional roots found by Sozou are only possible at large m because of the uniform vorticity and non-uniform potential vorticity in the Rankine vortex

at non-zero Mach number. The large mode number analysis reveals that there is a turning point within the vortex in these cases, implying that the eigenmodes have a wave-like structure for $r_c < r < 1$. The turning point is possible only because $\sigma = O(m^{-1})$ and $dQ/dr \neq 0$ throughout the vortex region, neither of which can be true for a vortex with uniform potential vorticity, except in the singular limit $F = 0$. The conclusion is that they are associated with Rossby waves propagating on the potential vorticity gradient within the Rankine vortex. The fact that $c_2 < 0$ once again reminds us that they have a retrograde or pseudo-westward phase progression, consistent with their being Rossby-wave like.

An expression for the growth rate of the instability can also be obtained, by considering the leading order real terms in (3.18). Outside the vortex, the equations for the disturbances are the same as before, except that now c_1 in (3.74) is zero, and hence $\Psi_1 = 0$. Outside the vortex, therefore, the first real terms in v_θ/v_r are $\epsilon^{2m\Psi_0(1)}$, where Ψ_0 is given by (3.84).

Now, at $r = 1^+$, $v_\theta/v_r = -i$, whereas at $r = 1^-$, $v_\theta/v_r = -imH_1/c_2 = imH_1\kappa^2/(4F^2)$. Therefore, the real part of (3.18) is

$$-c_i m^2 H_0/c_2 + \frac{c_2}{m}\epsilon^{2m\Psi_0(1)} = 0, \tag{3.116}$$

and hence we may write down an expression for the principal imaginary part of ω

$$\omega_i = c_2^2/(m^2 H_0)e^{2m\Psi_0(1)}. \tag{3.117}$$

3.3 Instability of a circular vortex with smooth potential vorticity

We turn now to showing that, under certain assumptions, the vortex instability found in the previous section can be generalized to vortices with a smooth (analytic) potential vorticity profile, provided the potential vorticity gradient is sufficiently steep. I show how to scale the potential vorticity gradient so that the instability threshold is found at a finite value of the gradient.

3.3.1 Disturbance equations

To begin, we consider how the behaviour of differential equations (3.9-3.11) are modified when there is a non-zero potential vorticity gradient in the basic state.

The equations for the eigenfunctions were stated in the previous section as

$$\frac{dv_r}{dr} = A(r)v_r + B(r)v_\theta \tag{3.118}$$

$$\frac{dv_\theta}{dr} = C(r)v_r + D(r)v_\theta, \tag{3.119}$$

where

$$A(r) = \frac{F^2\sigma Q r}{m} - \frac{d}{dr}\ln H\frac{1}{r} \tag{3.120}$$

$$B(r) = \frac{iF^2\sigma^2 r}{Hm} - \frac{im}{r} \tag{3.121}$$

$$C(r) = \frac{iF^2HQ^2r}{m} + \frac{im}{r} + \frac{iH}{\sigma}\frac{dQ}{dr} \tag{3.122}$$

$$D(r) = -\frac{F^2Q\sigma r}{m} - \frac{1}{r}, \tag{3.123}$$

and $H = 1 + F^2\overline{h}$. We now consider the order of terms in the case where $dQ/dr \neq 0$.

In general, σ is of order $O(m)$, and the principal behaviour of the eigenmodes will not be affected by the term $(H/\sigma)dQ/dr$ in $C(r)$, not present in the case of piecewise uniform potential vorticity. However, we know from the eigenmodes found above that $\sigma > 0$ at the vortex boundary, but tends to a negative constant value as $r \to \infty$. Therefore, there must exist at least one zero of σ in $r > 1$ and, if $\overline{v}$ approaches $r = 1$ faster than linearly in r, there will exist another zero of σ in $r < 1$. In particular, if f is large, then the basic state flow could be taken to be approximated by the quasigeostrophic equations, in which case the velocity field takes the form $I_0(F|f|r)$ for $r < 1$, and $K_0(F|f|r)$ for $r > 1$.

To derive a distinguished asymptotic scaling for the problem, we consider a limit in which the potential vorticity gradient at the boundary of the vortex, although finite, is very sharp. In this limit, we expect to recover the results of the previous section, in which the eigenmode was exponentially growing in r for $r < 1$, and exponentially decaying in r for $r > 1$. To achieve this transition in the form of the eigenmode there must be an asymptotic region in the neighbourhood of $r = 1$ in which the potential vorticity gradient enters the eigenfunction equations at the leading order in m. Across this region the nature of the solution will change from exponentially growing to exponentially decaying. There is only one way in which this can be achieved, and that is by bringing $(H/\sigma)dQ/dr$ into leading order balance in (3.119).

Now, to change the balance in (3.119), we shall require $(H/\sigma)dQ/dr$ to be of order m, in order to balance m/r. Furthermore, in the limit of a very sharp potential vorticity jump

(abbreviated to PV jump), we know that $\sigma = H(1)/2$ at the boundary of the vortex. Over a range of order δ, σ is of order $1 + m\delta$, and if Q varies by order unity across this region, its gradient is of order $1/\delta$.

It remains to show that the required scaling is $\delta \sim m^{-1}$. If we take $\delta \ll m^{-1}$, then $(H/\sigma)dQ/dr \sim 1/\delta$, which is required to balance m/r. This contradicts the assumption $\delta \ll m^{-1}$, and hence we require $\delta \geq O(m^{-1})$. On the other hand, if $\delta \gg m^{-1}$, then $(H/\sigma)dQ/dr \sim 1/(m\delta^2)$. Requiring this to balance m/r leads to another contradiction, and hence we arrive at the scaling $\delta = O(m^{-1})$.

The situation now being considered is a potential vorticity jump of order one over a distance of order m^{-1}, with a gradient of order m. This is internally consistent – if Q' is of order m over a range of order m^{-1} then this will lead to a net PV jump of order one over this range. The amplitude of the eigenfunction $e^{\pm im\Psi}$ varies by order unity over this range, and hence $\delta \sim m^{-1}$ represents the distinguished scaling for the problem, in which the potential vorticity changes by order unity over the length scale of amplitude variations of order unity in the eigenfunctions.

Now recall that the vortex is of unit radius, so the region of sharp PV gradients is centred on $r = 1$. Introducing a new range variable $z = m(r - 1)$, and assuming $\sigma \sim O(1)$, we obtain an equation for v_r at leading order in m:

$$\frac{d^2 v_r}{dz^2} - \left(1 + \frac{H}{\sigma}\frac{dQ}{dz}\right) v_r = 0. \tag{3.124}$$

To make further progress, we may assume initially that the PV jump occupies a small region in z (of order ϵ). In fact, it turns out that this is sufficient to understand the problem in full. We shall assume as before that $Q(r = 1^-) = Q(r = 1^+) + 1$. To fix ideas, we shall assume that the PV across the vortex boundary takes a hyperbolic tangent profile. Then

$$\frac{dQ}{dz} = -\frac{1}{2\epsilon}\mathrm{sech}^2(z/\epsilon), \tag{3.125}$$

so that

$$Q = -\frac{1}{2}\tanh(z/\epsilon) + b, \tag{3.126}$$

where b is an arbitrary constant, required for matching to the outer flow. The equations for the velocity and height fields of the basic state in the asymptotic region $z = O(1)$ are

$$\frac{m}{F^2}\frac{dH}{dz} = f\overline{v} + \frac{\overline{v}^2}{r} \tag{3.127}$$

$$m\frac{d\overline{v}}{dz} = QH - f - \overline{v}(1 + z/m)^{-1}. \tag{3.128}$$

From (3.128) it follows that $\overline{v}(z) = V_0(\text{constant}) + O(m^{-1})$, and from (3.127) it follows that $H(z) = H_0(\text{constant}) + O(m^{-1})$. If we expand $\overline{v} = V_0 + m^{-1}V_1 + \cdots$, then from (3.128) we obtain an equation for V_1:

$$\frac{dV_1}{dz} = QH_0 - f - V_0, \tag{3.129}$$

with solution

$$V_1 = -\frac{1}{2}\epsilon H_0 \ln\cosh(z/\epsilon) + (bH_0 - f - V_0)z. \tag{3.130}$$

Without loss of generality, we may take the associated constant of integration to be zero in this case by absorbing it into V_0. The variable $\sigma = m(-c + V/r)$ now takes the form

$$\sigma = -c_1 - \frac{1}{2}\epsilon H_0 \ln\cosh(z/\epsilon) + (bH_0 - f - 2V_0)z + O(m^{-1}). \tag{3.131}$$

The requirement $\sigma = O(1)$ is met by setting $c_0 = V_0$. This is consistent with equation (3.94) the limit of a single discontinuity in potential vorticity.

We now have sufficient details of the basic state in the region $z = O(1)$ to enable us to analyse the nature of the unstable eigenmode.

We start with the inner region, $z = O(\epsilon)$, across which the PV varies by an amount of order $O(1)$. Introducing a further variable $\zeta = z/\epsilon$, and expanding $v_r = v_r^{(0)} + \epsilon v_r^{(1)} + \cdots$ gives

$$v_r^{(0)} = \text{constant} = 1 \quad \text{say}. \tag{3.132}$$

Then

$$\frac{d^2 v_r^{(1)}}{d\zeta^2} = \frac{H_0}{2c_1}\text{sech}^2\zeta. \tag{3.133}$$

Integrating for $v_r^{(1)}$ gives

$$v_r^{(1)} = \frac{H_0}{2c_1}\ln\cosh\zeta + k_1\zeta + k_2, \tag{3.134}$$

where k_1, k_2 and c_1 are found by matching to v_r in the region $z = O(1)$.

Now, for $z = O(1)$, σ takes the form

$$\sigma \sim -c_1 - \frac{H_0}{2}(|z| - \alpha z), \tag{3.135}$$

where $\alpha = 2(bH_0 - f - 2V_0)/H_0$. If $|\alpha| < 1$, then there are two roots of the equation $\sigma = 0$. As discussed above, this will be the generic case for low Rossby number flow, in which σ has a

zero on either side of the PV jump. Since the WKBJ ($m \gg 1$) analysis was motivated by the difficulty of finding unstable modes numerically in the low Rossby number limit, I shall assume $|\alpha| < 1$ for the remainder of the analysis of this section. The equation governing v_r is then

$$\frac{d^2 v_r}{dz^2} - \left(1 - \frac{1}{2\epsilon\sigma}\mathrm{sech}^2(z/\epsilon)\right) v_r = 0. \tag{3.136}$$

It follows that, to leading order of approximation,

$$\frac{d^2 v_r}{dz^2} - v_r = -\frac{4}{\epsilon}(-2c_1/H_0 - |z| + \alpha z)^{-1} e^{-z^2/\epsilon^2} v_r. \tag{3.137}$$

We retain the exponentially small term on the right hand side of (3.137) due to its possible singularities at $\sigma = 0$. We denote these positions by $z = z_-$ and $z = z_+$.

Analysis of these points shows that they are regular singular points, with indicial exponents 0 and 1. Moreover, writing the solution with the logarithmic term in the form

$$v_r = 1 + \delta(z - z_0)\log(z - z_0) + \cdots, \tag{3.138}$$

(where here z_0 stands for z_- or z_+) we can easily see that δ will be exponentially small in ϵ. It follows that the critical layers $\sigma = 0$ are insignificant to the eigenfunctions at all algebraic orders in ϵ, and the eigenfunctions and their derivatives will be continuous across $\sigma = 0$ at all algebraic orders in ϵ. Hence the leading order solutions are $v_r = e^{\pm z}$.

Now, we know from the analysis for the case of a sharp PV interface that we will require v_r to be exponentially decaying at leading order away from $r = 1$, and hence we take $v_r = e^{-|z|}$ as the leading order solutions in the regions $|z| = O(1)$. It follows from matching to the inner region $z = O(\epsilon)$ that $v_r^{(1)} \sim -|\zeta|$ as $|\zeta| \to \infty$, and this matching to (3.134) fixes $k_1 = k_2 = 0$, and

$$c_1 = -\frac{1}{2}H_0. \tag{3.139}$$

This is consistent with the expression for c_1 given by (3.94) in the analysis for the discontinuous potential vorticity. Hence,

$$\sigma = \frac{H_0}{2}(1 - |z| + \alpha z), \tag{3.140}$$

and the zeros of σ occur at two locations z_+ and z_-, given by

$$z_+ = \frac{1}{1-\alpha} > 0; \qquad z_- = -\frac{1}{1+\alpha} < 0. \tag{3.141}$$

We now turn to analysing the effect of the exponentially small δ in the neighbourhood of the critical layers. We start by analysing v_r in the neighbourhood of $z = z_-$. Writing $y = z - z_-$, and substituting (3.139) into (3.137), we have

$$\sigma = \frac{H_0}{2|z_-|} y \tag{3.142}$$

$$\frac{d^2 v_r}{dy^2} - \left(1 - \frac{4|z_-|e^{-z_-^2/\epsilon^2}}{\epsilon y}\right) v_r = 0. \tag{3.143}$$

Substitution of (3.138) with $z_0 \equiv z_-$ into (3.143) gives

$$\delta = -4|z_-|\epsilon^{-1} e^{-z_-^2/\epsilon^2}. \tag{3.144}$$

Now, if we are constructing an unstable mode, it follows that $\mathrm{Im}\sigma < 0$, and that therefore there is not really a singularity at $\sigma = 0$ at all. If σ has a small negative imaginary part as we pass through $y = 0$, it follows from (3.142) that y must also have a small negative imaginary part ($-i\mu$, say). Since $\ln(z - z_-)$ has branch points at the zeros of σ, the effect of this small negative imaginary part of σ is to displace the branch point of the logarithm from $y = 0$ to $y = i\mu$ for some small positive μ. As y is increased through zero along the real axis, the argument of y must therefore increase by π to be consistent with the branch cut of the logarithm. The situation is depicted in figure 3.29. Since $\ln y = \ln|y| + i\mathrm{Arg}y$, and since v_r takes the value $e^{-|z_-|}$ to leading order at $y = 0$, it follows that the leading order contribution to the phase shift of the solution as we pass through $y = 0$ is given by $i\pi\delta e^{-|z_-|} y + \cdots$. The solution satisfies (3.137), and therefore for $y > 0$, the leading order contribution to the imaginary part of the solution introduced by the branch cut is

$$v_r^i = -4\pi i|z_-|e^{-|z_-|}\epsilon^{-1} e^{-|z_-|^2/\epsilon^2} \sinh y. \tag{3.145}$$

In addition to an imaginary part of the solution due to the presence of critical layers in the flow, an imaginary contribution to v_r can also be introduced by having a small imaginary part of c, which we shall denote as ic_i. Near $z = 0$, in the region where $\zeta = O(1)$, $v_r^{(i)}$ is expanded in powers of ϵ:

$$v_r^i = v_0^i + \epsilon v_1^i + \cdots. \tag{3.146}$$

Then v_0^i is constant, and v_1^i satisfies

$$\frac{d^2 v_1^i}{d\zeta^2} = \frac{H_0 v_0^i}{2c_1}\mathrm{sech}^2\zeta - \frac{iH_0 c_i}{2c_1^2}\mathrm{sech}^2\zeta. \tag{3.147}$$

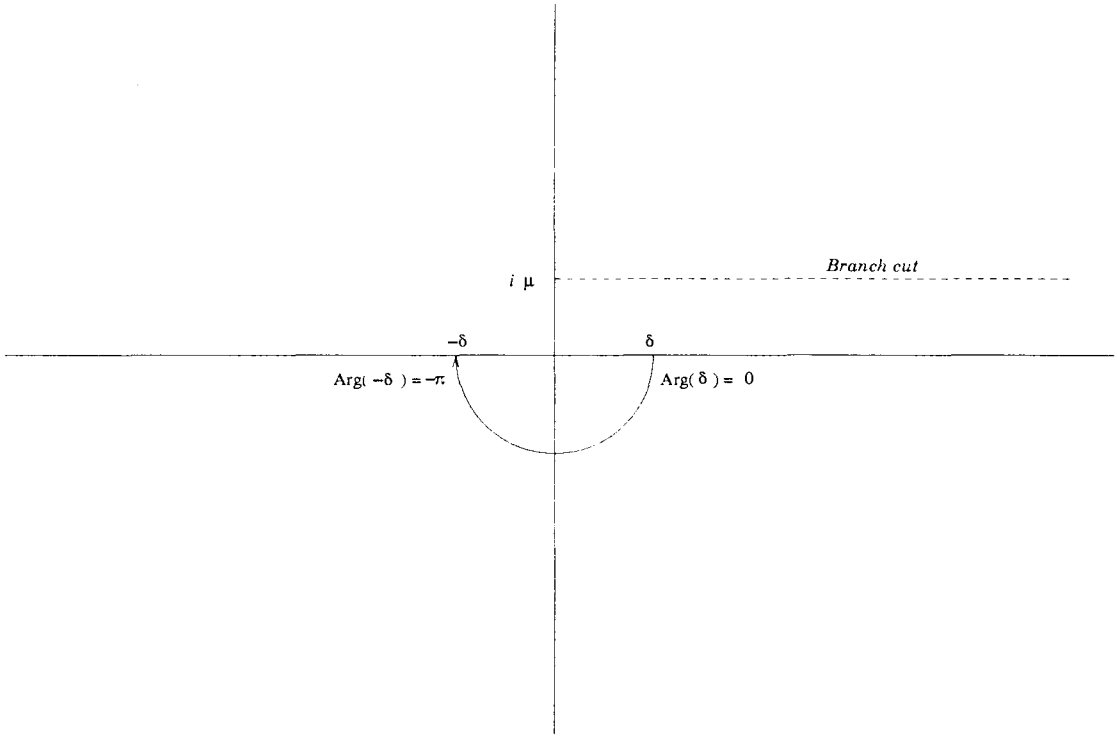

Figure 3.29: Schematic showing how argument changes in the neighbourhood of a branch point displaced slightly from the real axis.

This equation has solution

$$v_1^i = -\left(v_0^i + \frac{2ic_i}{H_0}\right) \ln\cosh\zeta + k_1\zeta + k_2. \tag{3.148}$$

As $\zeta \to -\infty$,

$$v_r^i \sim -4\pi i|z_-|e^{-|z_-|}\epsilon^{-1}e^{-|z_-|^2/\epsilon^2}(\sinh|z_-| + \epsilon\zeta\cosh|z_-| + O(\epsilon^2)). \tag{3.149}$$

Hence

$$v_0^i = -4\pi i|z_-|\epsilon^{-|z_-|}\sinh|z_-|\epsilon^{-1}e^{-|z_-|^2/\epsilon^2} \tag{3.150}$$

$$v_0^i + \frac{2ic_i}{H_0} + k_1 = -4\pi i|z_-|\epsilon^{-|z_-|}\cosh|z_-|\epsilon^{-1}e^{-|z_-|^2/\epsilon^2}. \tag{3.151}$$

Then, as $\zeta \to \infty$, we will have

$$v_r^i \sim v_0^i + \epsilon\left(-v_0^i - \frac{2ic_i}{H_0} + k_1\right)\zeta. \tag{3.152}$$

The solution in the region $z > 0$ is now written as

$$v_r^i = Ae^z + Be^{-z}. \tag{3.153}$$

Matching implies

$$A + B = v_0^i; \quad A - B = -v_0^i - \frac{2ic_i}{H_0} + k_1. \tag{3.154}$$

It is the exponentially growing part of this solution which will match to the exponentially growing (and imaginary) part of the solution in $r > 1$, introduced in the region $1 < r < r_c$ by the matching procedure across the sonic radius $r = r_c$. Of particular interest is therefore the value of A, which is given by

$$A = \frac{k_1}{2} - \frac{ic_i}{H_0} = -\frac{2ic_i}{H_0} - 2\pi i|z_-|\epsilon^{-2|z_-|}. \tag{3.155}$$

Finally, we must attend to the matching conditions across the second critical layer at $z = z_+$. In the same manner as the critical layer at $z = z_-$, this introduces a further small imaginary part to v_r as the leading order solution crosses the critical layer. The existing imaginary part is not changed at leading order. At this second critical layer we use the variable $y = z - z_+$. Then

$$\sigma = -\frac{H_0}{2|z_+|}y \tag{3.156}$$

$$\frac{d^2v_r}{dy^2} - \left(1 + \frac{4|z_+|e^{-|z_+|^2/\epsilon^2}}{\epsilon y}\right)v_r = 0. \tag{3.157}$$

Now recall that the singularity is to be removed by introducing a small negative imaginary part to σ. In the case $z \sim z_+$, we see from (3.156) that y therefore has a small positive imaginary part as we pass through $y = 0$ along the real line. This is the opposite sign to the case $z = z_-$, in which y was required to have a small negative imaginary part. In the present case the branch

point of the logarithm is therefore displaced to $y = -i\mu$, and the argument of y decreases by π as y is increased through $y = 0$. Hence to the imaginary part of the solution we add

$$-4\pi i|z_+|e^{-|z_+|}\epsilon^{-1}e^{-|z_+|^2/\epsilon^2}\sinh y. \tag{3.158}$$

The exponentially growing part of this solution is

$$-2\pi i|z_+|e^{-2|z_+|}\epsilon^{-1}e^{-|z_+|^2/\epsilon^2}e^z. \tag{3.159}$$

Hence the sum of the exponentially growing imaginary terms in the region $z > z_+$ will be

$$\left[-2\pi i\epsilon^{-1}\left(|z_+|\epsilon^{-2|z_+|}e^{-z_+^2/\epsilon^2}+|z_-|e^{-2|z_-|}e^{-z_-^2/\epsilon^2}\right)-\frac{2ic_i}{H_0}\right]e^z. \tag{3.160}$$

Exponentially growing real terms can be removed by a small change to the real part of c.

We now turn to matching this to the region $1 < r < r_c$. In this region, the expansion of the leading order term for $r \to 1^+$ gives an exponential function which is decaying with increasing r. However, as discussed in the analysis for the vortex with discontinuous PV, the radiation condition introduces an exponentially growing term, which is exponentially small (in m), and out of phase with the leading order exponentially decaying term. The ratio of growing to decaying terms in v_r as $r \to 1^+$ is $-(i/2)e^{2m|\Psi(1)|}$, where $\Psi(1)$ is given by (3.84, 3.85, 3.91). Since we took v_r to be one at leading order in this region, matching conditions in the limit $z \to \infty$ for the imaginary component of v_r from (3.160) imply

$$\frac{2\pi}{\epsilon}\left(|z_+|e^{-2|z_+|}\epsilon^{-z_+^2/\epsilon^2}+|z_-|e^{-2|z_-|}e^{-z_-^2/\epsilon^2}\right)+\frac{2ic_i}{H_0}=\frac{1}{2}e^{2m\Psi(1)}. \tag{3.161}$$

Now let $Z = \max(|z_+|, |z_-|)$. Then if

$$\epsilon = Z/(2|\Psi(1)|)^{1/2}m^{-1/2}, \tag{3.162}$$

with small corrections, then (3.161) is solved with $c_i = 0$, and the necessary imaginary part of v_r in the limit $z \to \infty$ exists without introducing an imaginary part to c. If ϵ is smaller than, but of the same order as, the value given by (3.162), then c_i will be of order $e^{2m|\Psi(1)|}$.

If $\epsilon \ll m^{-1/2}$, then the principal phase shift across the PV gradient is due to the imaginary part of c, and

$$c_i = \frac{1}{4}e^{2m\Psi(1)}. \tag{3.163}$$

Again, this is consistent with equation (3.94), derived in the limit of discontinuous potential vorticity.

Finally, if $\epsilon > Z/(2|\Psi(1)|)^{1/2}m^{-1/2}$, the equation (3.161) can only be satisfied with $c_i < 0$. This is a contradiction, since the analytic continuation used at the critical layers assumed $c_i > 0$. Consequently the eigenmode structure of the problem is lost if $\epsilon > Z/(2|\Psi(1)|)^{1/2}m^{-1/2}$.

It is interesting to see how some of these conclusions could have been reached without the detailed analysis presented above. In particular, the equation (3.143) is precisely the equation which would be obtained without any effects of divergence or gravity waves. It is Rayleigh's equation for a monotonic PV profile. The difference is that, without a turning point and gravity waves in the far field, the boundary conditions for (3.143) would normally be that the eigenfunctions should be exponentially decaying for $|z| \to \infty$ at all orders, and in particular there would be no exponentially growing imaginary term. That would force $c_i < 0$, which is a contradiction, since c_i was assumed to be greater than zero.

Now, since it is possible to prove Rayleigh's theorem without recourse to eigenmodes, we should know that any attempt to construct solutions to (3.143), which are exponentially decaying as $|z| \to \infty$, by introducing an infinitessimally small imaginary part to c must ultimately contradict itself, and this is exactly what has happened. Reversing the signs of the imaginary terms in v_r throughout the analysis leads to the same contradiction for any postulated temporally decaying modes with $c_i < 0$. There are no analytic solutions to (3.143) satisfying exponentially decaying boundary conditions, and Rayleigh's theorem holds.

It follows that, if the structure of the instability is to be retained, the Rossby wave critical layers at $\sigma = 0$ must not introduce an imaginary part in the eigenfunction greater than that required for matching to the imaginary part of the radiating solution in $r > 1$. Since the amplitude of the imaginary part introduced by critical layers will depend linearly on the strength of the PV gradient at the critical layers, and since the radiating solution has only an exponentially small (in m) imaginary component as $r \to 1^+$, it follows that the PV gradient must be exponentially weak in m at the locations of the critical layers. Consequently, a rapidly decaying profile for the PV gradient, such as $\mathrm{sech}^2\zeta$, will require only a small enhancement of the peak PV gradient (in this case given by $\epsilon^{-1} = O(m^{1/2})$), whereas a broader function, such as $1/(1+\zeta^2)$ for example, would require PV gradients exponentially large (in m) at $\zeta = 0$ in order that they will decay to exponentially small amplitudes for z of order 1 where the critical

layers occur. The order of the peak PV gradient required to retain the instability is thus very dependent on the profile of the potential vorticity chosen. The common feature is the order of the PV gradient at the critical layers of the flow, which must be exponentially small in m.

3.4 Relevance to the existence or non–existence of a slow manifold

Having shown that an axisymmetric shallow water vortex is unstable for all Froude and Rossby numbers, one may ask how this result relates to the question of existence or non-existence of a slow manifold for the f-plane shallow water equations.

As a preliminary, let us recall two general properteis of the inviscid shallow water equations.

Firstly, suppose we have a solution of the shallow water equations $\{(u_r^{(1)}, u_\theta^{(1)}), h^{(1)}\}$:

$$u_r^{(1)} = \mathcal{U}_r(r,\theta,t;f); \quad u_\theta^{(1)} = \mathcal{U}_\theta(r,\theta,t;f); \quad h^{(1)} = \mathcal{H}(r,\theta,t;f), \tag{3.164}$$

where (u_r, u_θ) are the radial and azimuthal components of the velocity field, and h the height field. Then another solution of the shallow water equations, $\{(u_r^{(2)}, u_\theta^{(2)}, h^{(2)}\}$, is given by

$$u_r^{(2)} = -\mathcal{U}_r(r,\theta,-t;-f); \quad u_\theta^{(2)} = -\mathcal{U}_\theta(r,\theta,-t;-f); \quad h^{(2)} = \mathcal{H}(r,\theta,-t;-f). \tag{3.165}$$

This is a general transformation property of the shallow water equations, which states that if all particle velocities are reversed, including the sense of the background rotation, then the flow evolution is reversed. The effect on the potential vorticity is to transform $Q \to -Q$. This we shall refer to as the particle symmetry of the equations.

Secondly, suppose again that we have a solution of the shallow water equations given by (3.164). Then another solution of the shallow water equations, $\{u_r^{(3)}, u_\theta^{(3)}, h^{(3)}\}$, is given by

$$u_r^{(3)} = \mathcal{U}_r(r,-\theta,t;-f); \quad u_\theta^{(3)} = -\mathcal{U}_\theta(r,-\theta,t;-f); \quad h^{(3)} = \mathcal{H}(r,-\theta,t;-f). \tag{3.166}$$

This is also a general transformation property of the shallow water equations, which states that the motion is unchanged if the system is viewed in a mirror, with the radial coordinate unchanged, but with the sence of the azimuthal coordinate reversed. As in the case of (3.165), the effect on the potential vorticity is to transform $Q \to -Q$. However, unlike (3.165), time is not reversed under this transformation.

Now, in order to discuss the existence or non-existence of a slow manifold, we must say what properties we shall assume a slow manifold to possess. Such a set of properties, consistent with the notion of a slow manifold as it is usually understood, is the following:

(a) The dimension of the slow manifold is one-third the dimension of the phase space of the shallow water equations.

(b) The slow manifold is tangent to the quasigeostrophic manifold at zero Rossby number, so that flow on the slow manifold is identical to quasigeostrophic flow at the leading order in Rossby number.

(c) Steady axisymmetric vortices and steady parallel flows are on the slow manifold.

(d) Viewing the system in a mirror ($f \to -f, u_r \to u_r, u_\theta \to -u_\theta, h \to h$) keeps the system on the same slow manifold as that which it was on when viewed in the original frame.

(e) Reversing the absolute direction of motion of all particles ($f \to -f, u_r \to -u_r, u_\theta \to -u_\theta, h \to h$) keeps the system on a slow manifold.

(f) At any instant in time, the entire velocity field and the entire height field on the slow manifold can be determined uniquely from the potential vorticity distribution $Q(x, y)$ at that instant in time.

Notice that *(c)*, *(d)*, *(e)* and *(f)* all follow from *(a)* and *(b)* in the small Rossby number limit. In particular, for quasigeostrophic flow, the potential vorticity field can be shown to determine all other dynamical fields uniquely. Notice also that *(f)* is a strong form of *(a)*. Furthermore, notice the distinction between property *(d)*, which states that, under the specified transformation, the system must remain on the same slow manifold, and property *(d)*, which states that under a different transformation, the system must simply remain on a slow manifold. It seems reasonable to make this distinction, in that the transformation under consideration in *(d)* can be effected entirely by regarding the system under reflection in a mirror, and its evolution should therefore be identical to the original flow, whereas the transformation under consideration in *(e)* involves a change in the physical state of the system, and is therefore not directly connected to the original flow.

Since, on any slow manifold having property *(f)*, Q and f are sufficient to determine the entire velocity field and the entire height field, it is natural to impose one further condition:

(g) Under the transformation $Q \rightarrow -Q; f \rightarrow -f$, the implied flow on th... $\{\boldsymbol{u}_s, h_s\}$, will remain on the slow manifold, and be transformed acc... $-\boldsymbol{u}_s; h_s \rightarrow h_s$.

This last property was termed "sign consistency" by McIntyre & Norton (19... property of all standard balanced models, such as the quasigeostrophic and ... equations. Property *(g)*, where it applies, is a strong form of property *(e)*, an... to giving the same force to property *(e)* as that which was given to proper... that under the relevant transformation, the slow manifold is not simply mapp... manifold, but it is mapped onto the same slow manifold. If $\mathcal{M}$ were assum... then property *(g)* and property *(e)* would be equivalent.

It will now be shown that, for the shallow water equations at least, a slow ma... properties *(a)* – *(g)* cannot exist. This is done by first supposing that ther... manifold, $\mathcal{M}$, say, and then deriving a contradiction.

Firstly, recall the vortex instability result. In an unbounded domain, it wa... vortex was temporally unstable for all Froude and Rossby numbers. Moreov... unique temporally growing mode for each azimuthal mode number m, provide... large, and the amplitude of the mode is assumed to be finite at infinity. It ... unique temporally decaying mode for each such m, assuming that the amplitu... finite at infinity. We shall fix attention on a single such azimuthal mode numbe... the growing and decaying eigenmodes for that mode number by $\phi_\uparrow(r)$ and ϕ... Here, the functions $\phi_\uparrow(r)$ and $\phi_\downarrow(r)$ are taken to represent the three-vector... case. In the limit $Ro \rightarrow 0$, $\phi_\uparrow$ and $\phi_\downarrow$ coincide, since the growth rate of the... small order in Rossby number.

Now, let us consider the nature of the evolution of the vortex with a pert... under the assumption of linearized perturbations. The boundary of the vortex ... tion on it, of small amplitude, and of fixed mode number m. On the slow manif... from property *(f)* and linearization that, at any instant in time, the amplitu... the vortex boundary undulation are sufficient to determine the perturbation ve... fields everywhere. Since we are considering linearized perturbations, we can repr...

location of the vortex boundary as a function $r(\theta, t)$, in the form

$$r(\theta, t) = \mathrm{Re}\left\{1 + a(t)e^{im\theta}\right\}, \tag{3.167}$$

for some complex function $a(t)$. Moreover, the assumption of linearized perturbations implies that the amplitude of the perturbations of the velocity and height fields depends linearly on the amplitude of the vortex boundary undulations, so we may represent the perturbation fields φ in the form

$$\varphi(r, \theta, t) = \mathrm{Re}\left\{a(t)\Phi(r)e^{im\theta}\right\}, \tag{3.168}$$

where here, as before, φ represents the three-vector (u, v, h). By substitution of (3.168) into the linearized shallow water equations for disturbances to an axisymmetric vortex, it can be shown using elementary techniques from the theory of solution of partial differential equations by separation of variables that

$$\frac{da}{dt} = \lambda a, \tag{3.169}$$

for some possibly complex constant λ, and therefore

$$\varphi(r, \theta, t) = \mathrm{Re}\left\{A\Phi(r)e^{i(m\theta - \lambda t)}\right\} \tag{3.170}$$

for some complex constant A.

Now, we know from the shallow water vortex instability analysis that, in the unbounded domain, only two bounded solutions of form (3.170) exist, and that they are the temporally growing eigenmode, $\phi_\uparrow$, and the temporally decaying eigenmode, $\phi_\downarrow$. Therefore, in the limit of linearized perturbations of fixed mode number to the boundary of an axisymmetric vortex, the flow on the slow manifold $\mathcal{M}$ consists of either the temporally growing mode alone, or the temporally decaying mode alone.

Suppose that the flow on the slow manifold consists of the temporally growing mode alone. Suppose also, without loss of generality, that $f > 0$. Then, under the transformation $Q \to -Q; f \to -f$, it follows, from property *(g)* and the time symmetry of the shallow water equations (3.164 & 3.165), that the temporally growing mode is mapped onto the temporally decaying mode. However, by property *(d)* and the reflectional symmetry of the shallow water equations (3.164 & 3.166), the transformation $Q \to -Q; f \to -f$ must map the temporally growing mode onto the temporally growing mode. This implies that the flow on the slow manifold for

$\{-Q, -f\}$ consists simultaneously of the temporally growing mode alone and the temporally decaying mode alone, which is a contradiction.

Now let us suppose we relax the condition *(g)*, the condition of sign consistency, and ask whether there can exist a slow manifold satisfying only conditions *(a)* – *(f)*. The velocity field on such a slow manifold, which we shall denote by $\boldsymbol{u}_s$, can then be written as the sum of two components, $\boldsymbol{u}_s = \boldsymbol{v} + \boldsymbol{w}$, where, under the transformation $Q \to -Q$; $f \to -f$, the velocity fields $\boldsymbol{v}$ and $\boldsymbol{w}$ transform according to the transformation laws $\boldsymbol{v} \to -\boldsymbol{v}$ and $\boldsymbol{w} \to \boldsymbol{w}$. One can regard $\boldsymbol{v}$ as the sign-consistent part of the slow manifold flow, and $\boldsymbol{w}$ as the sign-inconsistent part of the flow. The sign-inconsistent part, $\boldsymbol{w}$, is in general non-zero, and in particular it is non-zero, at arbitrarily small Froude and Rossby numbers, in the neighbourhood of an axisymmetric vortex. On the other hand, if $\boldsymbol{v} + \boldsymbol{w}$ is the velocity field on a slow manifold for a given $\{Q(x, y), f\}$ then, from the general transformation properties of the shallow water equations (3.164, 3.165), $-\boldsymbol{v} - \boldsymbol{w}$ constitutes a velocity field for $\{-Q(x, y), -f\}$, which must also be on a slow manifold. Then, from the transformation properties assumed for $\boldsymbol{v}$ and $\boldsymbol{w}$, $\boldsymbol{v} - \boldsymbol{w}$ constitutes the flow on a slow manifold for a potential vorticity distribution and Coriolis parameter $\{Q(x, y), f\}$. We have thus now arrived at a situation in which two flows, $\boldsymbol{v} + \boldsymbol{w}$ and $\boldsymbol{v} - \boldsymbol{w}$, are both flows on a slow manifold corresponding to the same potential vorticity distribution $Q(x, y)$ and Coriolis parameter f, and that $\boldsymbol{w}$ is in general non-zero, even at arbitrarily small Rossby numbers. It follows at once that, if condition *(g)*, the condition of sign consistency, is not imposed, then a slow manifold, if one exists, is not uniquely defined by the potential vorticity distribution, $Q(x, y)$, even in the limit of arbitrarily small Rossby number.

We might now attempt to make the definition of the slow manifold unique by insisting that its gravity wave field satisfies a causality condition, and hence, in the case of the shallow water instability problem, that the temporally growing mode is taken for both $f > 0$ and $f < 0$. This is feasible in the case of the vortex instability problem, because we can require that there are no gravity waves in the flow at $t = -\infty$. In this case, the limit $t \to -\infty$ is well defined, and the flow approaches an axisymmetric balanced vortex in that limit. For a general shallow water flow, however, the limit $t \to -\infty$ is not necessarily well defined, and imposing a causality condition will require the specification of an initial instant t_0 (say), at which time the vortex flow was "turned on", and before which time no gravity waves had been radiated. The choice of initial instant is clearly not unique, and yet in general we must expect the details of the

gravity waves generated, and their effect on the vortical flow, to depend on that initial instant. This point was made explicitly in analysis of the effect of gravity wave generation on a localized vortical disturbance at small Froude number, discussed in chapter 2. Each flow corresponding to a different choice of t_0 can be thought of as a "slow manifold", but with t_0 required to select one of the infinite number of possible branches.

There can now be little doubt now that the original concept of the unique slow manifold, as defined by Leith (1980), and clarified by Lorenz (1986), cannot apply to the shallow water equations. The shallow water vortex instability analysis showed that, at sufficiently large mode number, an axisymmetric vortex is unstable at arbitrarily small Rossby number, from which it follows that a slow manifold cannot be sign consistent, and therefore cannot be unique. Furthermore, the eigenfunctions have a gravity wave-like tail, albeit an exponentially weak one. One might argue from a physical viewpoint that the clear appearance of gravity-wave like structures at arbitrarily small Rossby number is sufficient to show that no so-called slow manifold could be truly slow, even if an invariant manifold specified only by potential vorticity distributions did exist, since it would inevitably contain "fast" gravity wave-like structures. From a mathematical viewpoint we have seen that the appearance of these gravity wave-like structures at arbitrarily small Rossby number is indeed inextricably linked to our inability to define a sign-consistent slow manifold, and hence our inability to define a unique slow manifold.

3.5 Instability of a parallel jet

In this section, we consider the linear stability of a parallel jet. The potential vorticity in the jet is taken to be piecewise uniform, with a single discontinuity at $y = 0$. The discontinuity is sometimes referred to as a front.

We choose to work with a nondimensionalization that is different from the one used in the study of the axisymmetric vortex instability. Instead of nondimensionalizing such that the jump in potential vorticity across the interface is unity, we shall set the potential vorticity in the region $y < 0$ to unity. There is no loss of generality here, since if we wish to have a layer of finite depth, with velocity decaying away from $y = 0$, the potential vorticity will have to be positive in both $y < 0$ and $y > 0$. The timescale must then be set by the Coriolis parameter f, and not the potential vorticity jump. We take $f = 1$, and so the layer depth is unity in the

limit $y \to -\infty$. The Rossby deformation radius is effectively $Q^{-1/2}$, where Q is the potential vorticity. A result of these nondimensionalizations is therefore to set the deformation radius to unity in $y < 0$.

3.5.1 The basic state

With the nondimensionalizations introduced above, the equations for the basic state velocity $U(y)$ and height $H(y)$ are

$$U = -\frac{dH}{dy} \tag{3.171}$$

$$1 - \frac{dU}{dy} = QH. \tag{3.172}$$

It follows that

$$\frac{d^2H}{dy^2} - QH = -1. \tag{3.173}$$

Now we let Q take the form

$$Q(y) = \begin{cases} q & \text{for } y > 0 \\ 1 & \text{for } y < 0 \end{cases}, \tag{3.174}$$

then the equations for the basic state can be solved in terms of elementary functions. Imposing continuity of H and U at $y = 0$ gives

$$H(y) = \begin{cases} \frac{1}{q} + \frac{\sqrt{q}-1}{q} e^{-\sqrt{q}y} & y > 0 \\ 1 - \frac{\sqrt{q}-1}{\sqrt{q}} e^{y} & y < 0 \end{cases}; \qquad U(y) = \begin{cases} \frac{\sqrt{q}-1}{\sqrt{q}} e^{-\sqrt{q}y} & y > 0 \\ \frac{\sqrt{q}-1}{\sqrt{q}} e^{y} & y < 0 \end{cases}. \tag{3.175}$$

3.5.2 Ripa's theorem

Before proceeding to the linear instability calculations for the basic state given by (3.175), we shall discuss Ripa's theorems for the stability of parallel and axisymmetric shallow water flows, and show linear stability for the basic state (3.175) in the case $q < 4$.

The basic technique is to consider first and second variations to some linear combination of the conserved quantities of energy and momentum, plus a Casimir. The first variation of the sum is required to be zero, which sets the Casimir, and the second variation is required to be of definite sign. The requirement of sign definiteness gives conditions on the basic flow which are sufficient for linear stability.

For the shallow water equations, the energy is given by

$$E = \frac{1}{2}\int\int (h\boldsymbol{u}^2 + h^2)dxdy, \tag{3.176}$$

while the x-momentum is given by

$$M = \int\int h(u - fy)dxdy. \tag{3.177}$$

General Casimirs are given by

$$C = \int\int hF(Q)dxdy, \tag{3.178}$$

where $F(Q)$ is an arbitrary function of the potential vorticity Q.

It follows that the combination

$$\mathcal{H} \equiv E + \alpha M + C \tag{3.179}$$

is a conserved quantity. Taking the first variation of $\mathcal{H}$ gives

$$\delta\mathcal{H} = \int\int \left[h\left(u + \alpha + \frac{\partial}{\partial y}C'(Q)\right)(\delta u) - \frac{\partial}{\partial x}C'(Q)(\delta v) \right. \tag{3.180}$$

$$\left. + \left(\frac{1}{2}u^2 + h + \alpha(u - fy) + C(Q) - QC'(Q)\right)(\delta h)\right]. \tag{3.181}$$

For stability we require $\delta\mathcal{H} = 0$. This imposes conditions on the Casimir C, such that

$$C''(Q) = -\frac{h(u+\alpha)}{Q'(y)}. \tag{3.182}$$

For linear stability, we now require that the second variation $\delta^2\mathcal{H}$ should be of definite sign. The second variation of $\mathcal{H}$ is given by

$$\delta^2\mathcal{H} = \int\int \left[h(\delta v)^2 + (\delta h + (u+\alpha)\delta u)^2 + \left(h - (u+\alpha)^2\right)(\delta u)^2 - \frac{h^2(u+\alpha)}{Q'(y)}(\delta Q)^2 \right]. \tag{3.183}$$

If we impose the condition $\delta^2\mathcal{H} > 0$, we obtain

$$(u+\alpha)Q'(y) < 0 \quad \text{and} \quad (u+\alpha)^2 < h. \tag{3.184}$$

If we assume that $Q'(y) > 0$ for all y, then the maximum value for α which we may take to obtain stability by the first of these conditions is the peak jet velocity $-u_{max}$. This choice gives us the greatest stability information from the second of the conditions, so we have

$$Q'(y) > 0 \quad \text{and} \quad (u_{max} - u(y))^2 < h(y). \tag{3.185}$$

The condition is just the standard condition of monotonic PV required to ensure that the flow is not unstable to barotropic instability, with the further condition that the flow must be everywhere subsonic with respect to the peak jet velocity, since $h(y)^{1/2}$ is just the nondimensionalized gravity wave phase speed. This condition is analogous to Arnol'd's first theorem.

From (3.175), we see that these conditions are satisfied when $q < 4$.

In passing we note that, by considering the subclass of variations in which $\delta q = 0$ and $\delta u = 0$, the remaining terms are always positive definite, and hence it is not possible to impose the condition $\delta^2 \mathcal{H} < 0$. Consequently there is no analogue of Arnol'd's second theorem for the shallow water equations [1].

3.5.3 The disturbance equations

The disturbance equations for the parallel flow are very similar, except for geometrical factors, to those for axisymmetric flow.

Now we assume that perturbations are of the form $f(y)e^{i(kx-\omega t)}$. The wavenumber k is assumed real, and again the growth rate of any instability is represented by an imaginary part to ω. The disturbance equations then become

$$\frac{du}{dy} = A(y)u + B(y)v \tag{3.186}$$

$$\frac{dv}{dy} = C(y)u + D(y)v, \tag{3.187}$$

where Q is the (piecewise uniform) potential vorticity of the background flow, and

$$A(y) = \frac{Q(-\omega + kU)}{k} \tag{3.188}$$

$$B(y) = i\left(k + \frac{Q^2 H}{k}\right) \tag{3.189}$$

$$C(y) = i\left(\frac{(-\omega + kU)^2}{Hk} - k\right) \tag{3.190}$$

$$D(y) = \left(\frac{U}{H} - \frac{(-\omega + kU)Q}{k}\right) \tag{3.191}$$

Continuity of v and h at $y = 0$ reduce to

$$(-\omega + kU(0))\left[\frac{u}{v}\right] + iH(0)[Q] = 0. \tag{3.192}$$

[1] This observation arose in discussions with Prof. T. G. Shepherd and Dr. T. E. Dowling

3.5.4 Numerical technique

The equations (3.186-3.187) represent an eigenvalue problem for ω. As for the axisymmetric problem, we use a shooting method based on an initial guess for ω. In the far field the disturbances take the form $e^{i(kx+ly-\omega t)}$, where l is given by $\omega^2 - 1 = Q^{-1}(k^2 + l^2)$. Note that l, which takes different values as $y \to \pm\infty$, always has non-zero imaginary part l_i. The disturbance variables are therefore rescaled by $e^{l_i y}$, so that the computed variables remain of order one throughout the domain $-\infty < y < \infty$. Evanescence conditions at $y = \pm\infty$ are used to impose the ratio of u/v to be taken at some large value of $|y|$, as in the axisymmetric vortex calculations. The equations are then integrated in to $y = 0$ using a stiff integrator for ordinary differential equations from the NAG library, and the continuity condition (3.192) at $y = 0$ is imposed.

Initialization for small q

Initial values for the eigenfrequencies supplied to the shooting method were taken, in the case of a small jump in potential vorticity, using a quasi-geostrophic analysis. The magnitude of the potential vorticity jump could then be increased, taking the eigenfrequency for one value of the potential vorticity jump as the initial guess for the eigenfrequency at the next.

The equation for the basic state streamfunction ψ:

$$\left(\frac{d^2}{dy^2} - 1\right)\psi = \begin{cases} q & \text{for } y > 0 \\ 1 & \text{for } y < 0 \end{cases} . \tag{3.193}$$

Continuity of ψ and ψ_y at $y = 0$ lead to

$$\psi = \begin{cases} \frac{1}{2}(q-1)e^{-y} - q & y > 0 \\ -\frac{1}{2}(q-1)e^{y} - 1 & y < 0 \end{cases} . \tag{3.194}$$

If we now introduce a disturbance streamfunction $\tilde{\psi}(y)e^{i(kx-\omega t)}$, the equation for $\tilde{\psi}$ is

$$\left(\frac{d^2}{dy^2} - k^2 - 1\right)\tilde{\psi} = 0. \tag{3.195}$$

At this point it is convenient to introduce

$$\gamma \equiv \left(1 + k^2\right)^{1/2}, \tag{3.196}$$

so that

$$\tilde{\psi} = \begin{cases} \tilde{a}e^{-\gamma y} & \text{for } y > 0 \\ \tilde{b}e^{+\gamma y} & \text{for } y < 0 \end{cases} . \tag{3.197}$$

We must also introduce a disturbance to the position of the interface between the two uniform potential vorticity regions, such that

$$y = \tilde{\eta}e^{i(kx-\omega t)}. \tag{3.198}$$

Imposing continuity of ψ and ψ_y leads to a kinematic condition on $\tilde{\eta}$, which can then be solved for ω:

$$\omega = \frac{1}{2}\left(1 - \frac{1}{\gamma}\right)(q-1)k. \tag{3.199}$$

Note that this eigenfrequency is real, regardless of the magnitude of $q-1$. It is valid in the low Rossby number limit $q - 1 \ll 1$, and is not valid for $q - 1$ of order one. It therefore gives no information in the regime $q > 4$, in which we might expect instability to occur.

3.5.5 Results of the eigenvalue calculations

In the present study, the growth rate of any instability depends on two parameters: the potential vorticity q in the region $y > 0$; and the wavenumber k of the instability.

In figure 3.30, the growth rate of the instability is shown as a function of wavenumber for $q = 6, 10, 20$ and 30. One can see that, at low wavenumbers, the flow is stable, whereas at higher wavenumbers the instability occurs. This is to be expected when we consider the nature of the instability mechanism. Far from the jet, the disturbances satisfy the linear gravity wave dispersion relation

$$\omega^2 - f^2 = c^2(k^2 + l^2). \tag{3.200}$$

Now, the instability exists due to coupling between the vortical wave on the potential vorticity jump, and a gravity wave at infinity. This implies that, in one of $y < 0$ or $y > 0$, we will need l to be real at leading order in the wavenumber k. If we suppose that $\omega \sim Uk$, then the condition $l^2 > 0$ is $k^2(U^2 - c^2) - f^2 > 0$. Thus, the larger the value of k, the less the disturbances are influenced by the Coriolis parameter, and the remaining condition is that the jet speed must exceed the gravity wave phase speed at infinity – exactly Ripa's condition. Hence, we should expect to see Rossby wave – gravity wave instabilities at large wavenumber.

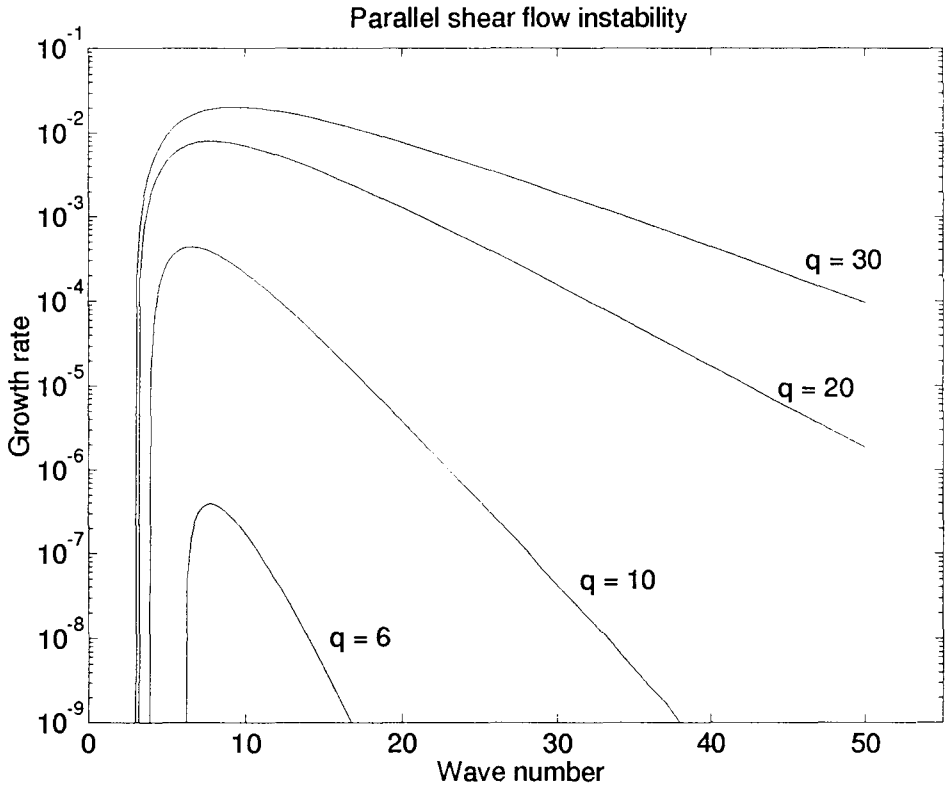

Figure 3.30: Growth rates of linear eigenmodes on a parallel shear flow with a single discontinuity in potential vorticity. Potential vorticity ratios of $6, 10, 20, 30$ are show, with growth rates of eigenmode wavenumbers $k = 0$ to 50.

We shall therefore proceed to analyse the instability in the high wavenumber limit, as we did for the axisymmetric vortex at large mode number.

3.5.6 The limit of large wavenumber

The results of the eigenvalue calculations have shown that there is a tendency towards instability at high wavenumbers. Motivated by the success of the WKBJ analysis for the axisymmetric vortex instability, we shall now perform a WKBJ analysis for the parallel flows discussed in this section. In particular, we shall show that the range of stability found by Ripa's theorem is complete - all flows that do not satisfy Ripa's theorem are unstable.

The details of the parallel flow and axisymmetric vortex analyses are very similar, and only a summary will be given here. The principal difference is that we now impose an evanescence/radiation condition as $y \to \pm\infty$, and this will lead to zero, one or two turning points in the flow.

As in the analysis for the axisymmetric flow, we choose to work with a single second order ordinary differential equation with a single variable. In the interests of consistency with the axisymmetric analysis, we choose to work with the along-stream variable u.

Again, one works with a frequency $c = \omega/k$. After rearranging the disturbance equations (3.186, 3.187) one obtains

$$\frac{d^2u}{dy^2} + F(y)\frac{du}{dy} + G(y)u = 0. \tag{3.201}$$

The function $F(y)$ is everywhere of order unity, and the function $G(y)$ is given by

$$G(y) = \left[\frac{(-c + U(y))^2}{H(y)} - 1\right] k^2 + O(1). \tag{3.202}$$

Again, it is straightforward to see that the jump condition at $y = 0$ can only be satisfied if $c_0 = U(0)$. This gives a condition for a turning point to occur:

$$(u(0) - U(y))^2/H(y) = 1, \tag{3.203}$$

which is precisely the same as the stability boundary predicted by Ripa's theorem.

Now $U(0) = 1 - 1/\sqrt{q}$, and $U \to 0$ as $y \to \pm\infty$. If we consider first $y > 0$, then there will be a turning point if and only if

$$(U(0) - U(y))^2 > H(y). \tag{3.204}$$

Now $H(y) > 1/q$, and $U(0) - U(y) < U(0)$, and therefore a necessary condition for a turning point to exist is

$$U(0)^2 > 1/q; \quad \text{i.e. } q > 4. \tag{3.205}$$

Taking $y = \infty$ in (3.203) ensures that (3.205) is also a sufficient condition.

If we now consider $y < 0$, then $H(y) < H(0)$. There

$$U(0) - U(y) = \frac{\sqrt{q} - 1}{\sqrt{q}}(1 - e^y) < 1, \tag{3.206}$$

and therefore $H(y) - (U(0) - U(y)) = 1/\sqrt{q}$, and hence

$$1 > H(y) > U(0) - U(y) > ((U(0) - U(y))^2, \tag{3.207}$$

and so there is no turning point in $y < 0$.

The situation is now very similar to that of the axisymmetric vortex, in which there is a single turning point and a single potential vorticity discontinuity.

The turning point at $y = y_c$ means that the domain is split into four regions, and the analysis is given below. The four regions and the character of the solutions in them are:

$y < 0$ Exponential decay of solution away from $y = 0$.

$0 < y < y_c$ Exponential decay of real part of solution away from $y = 0$, with exponentially growing imaginary part, such that real and imaginary parts are of the same order of magnitude at $y = y_c$.

$y - y_c = O(k^{-2/3})$ Combination of Airy functions, appropriate for matching onto radiating wave solution in $y > y_c$.

$y > y_c$ Oscillatory functions, satisfying radiating boundary conditions as $t \to \infty$. Small imaginary part of eigenfrequency ensures exponential decay of eigenfunction at very large range.

Continuity conditions at $y = 0$ are then used to obtain the eigenvalue. If we let the eigenvalue ω be written as $\omega = k(c_0 + k^{-1}c_1 + \cdots)$, then

$$c_0 = 1 - 1/\sqrt{q}; \quad c_1 = -\frac{q-1}{2\sqrt{q}}. \tag{3.208}$$

Then if we define

$$\Psi_0 = -\int_0^{y_c} \left(1 - \frac{(\sqrt{q}-1)^2(1-e^{-y\sqrt{q}})}{1+(\sqrt{q}-1)e^{-y\sqrt{q}}}\right)^{1/2} dy \tag{3.209}$$

and

$$\Psi_1 = -\frac{q-1}{2\sqrt{q}} \int_0^{y_c} \frac{U(0)-U(y)}{\Psi_0' H(y)} dy \tag{3.210}$$

then the growth rate c_i is given by

$$c_i = \frac{q-1}{4\sqrt{q}} e^{2(k\Psi_0+\Psi_1)}. \tag{3.211}$$

Comparison with numerical eigenvalue calculations

In figure 3.31, t he growth rate curves shown in figure 3.30 are reproduced, together with their predictions from the WKBJ analysis, valid in the limit $k \gg 1$. On average, there seems to be reasonable agreement at large k, though at moderate k the agreement is not generally as good as it was for the WKBJ analysis of the axisymmetric vortex instability at moderate m.

3.5.7 The limit $q \to \infty$

As discussed in the section 1, the instability of a potential vorticity jump has already been analysed in the limit $q - \infty$ by Paldor (1983), who showed that all eigenmodes are stable in that limit. However, one can show that, in the limit $q \to \infty$,

$$\Psi_0 \sim -\frac{\pi}{4} q^{-3/4}; \quad \Psi_1 \sim -\frac{1}{2}, \tag{3.212}$$

and hence

$$c_i \sim \frac{1}{4} q^{1/2} e^{-\left(\frac{1}{2}k\pi q^{-3/4}+1\right)}, \tag{3.213}$$

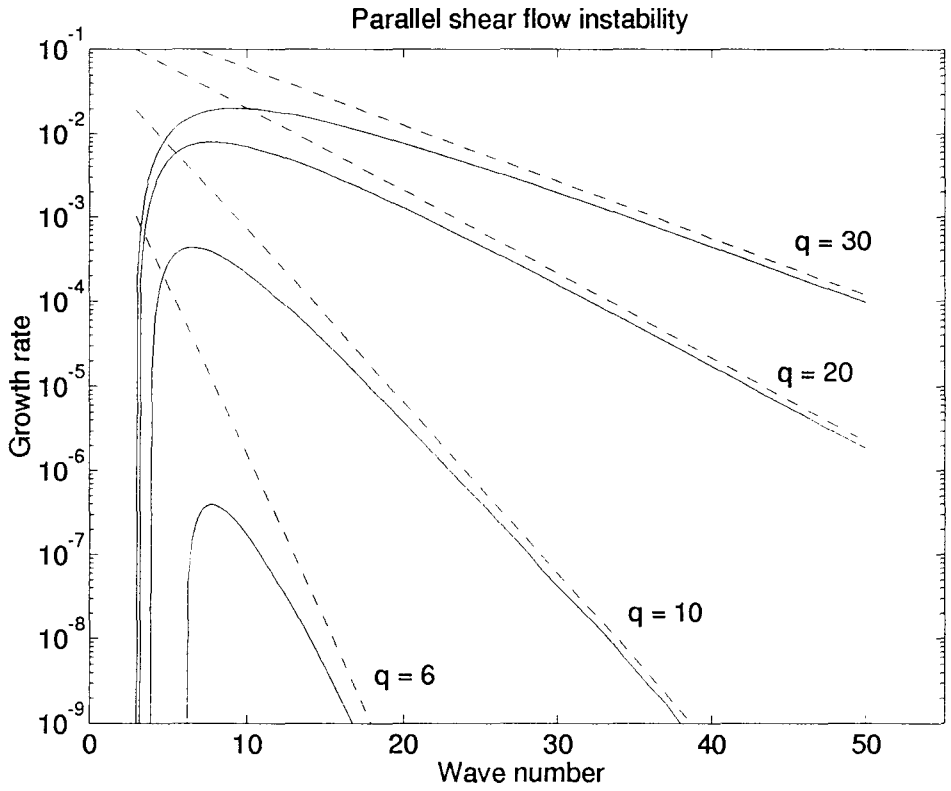

Figure 3.31: Solid lines as figure 3.30, and dashed lines are corresponding growth rate predictions obtained by the WKBJ analysis.

which becomes unbounded in the limit $q \to \infty$. The purpose of this section is to show that the limit $q \to \infty$ is a singular limit. The point is that, at large fixed k, as q is increased, we will approach a limit in which the potential vorticity interface falls within the turning point region. The region $0 < y < y_c$ effectively disappears, and we will be left with only three regions. The appropriate scaling in this limit is to take $q = O(k^{4/3})$.

The scaling $q = O(k^{4/3})$

The aim here is to appreciate the origins of the scaling $q = O(k^{4/3})$. We are seeking to eliminate the inner region $0 < y < y_c$, and therefore we impose that the region including the turning point $y = y_c$ should also include the potential vorticity interface $y = 0$. In the limit $q \to \infty$, the turning point and the interface coincide.

To derive the necessary scaling, we first note that

$$U(0) - U(y) = \left(1 - \frac{1}{\sqrt{q}}\right)\left(1 - \epsilon^{-\sqrt{q}y}\right). \tag{3.214}$$

Notice that $1/\sqrt{q}$ is the natural length scale in the region $y > 0$, and in this analysis we seek to place the turning point at some $y \ll 1/\sqrt{q}$. Therefore,

$$U(0) - U(y) \sim -y\sqrt{q}. \tag{3.215}$$

At the turning point $y = y_c$, we will have $(U(0) - U(y_c))^2 = H(y_c)$. Now $H(y) \sim 1/\sqrt{q}$ for small $\sqrt{q}y$, and therefore the turning point occurs at

$$y^2 q \sim 1/\sqrt{q}; \quad \text{i.e.} \quad y \sim q^{-3/4}. \tag{3.216}$$

On the other hand, the natural length scale for disturbances is k^{-1}, and hence the turning point will lie in the same asymptotic region as the interface if

$$\frac{1}{k} \sim y \sim q^{-3/4} \quad \text{i.e.} \quad q \sim k^{4/3}. \tag{3.217}$$

This scaling could have been predicted with reference to (3.213). The asymptotic analysis of the previous section assumed $k\Psi_0 \gg \Psi_1$, and it can clearly be seen that this assumption breaks down when $q = O(k^{4/3})$. Throughout the remainder of this chapter, we shall therefore replace q with $k^{4/3}\mathsf{q}$, where q is to be taken to be of order unity.

Equations in the region $y = O(k^{-1})$

With the scaling for the potential vorticity jump now fixed, we are able to write down an equation governing disturbances in the region $y = O(k^{-1})$. We introduce an inner length coordinate $Y = ky$, for which the interface is to be found at $Y = 0$, and the turning point at $Y = \mathsf{q}^{-3/4}$.

We express the eigenfrequency ω as

$$\omega = k(c_0 + k^{-1/3}\mathsf{q}^{1/2}c_1 + \cdots). \tag{3.218}$$

The leading order is satisfied by taking $c_0 = U(0)$. The factor of $\mathsf{q}^{1/2}$ is introduced to scale c_1, which is convenient for analysing the limits $\mathsf{q} \to 0$ and $\mathsf{q} \to \infty$.

Then, after some routine algebra, we obtain an equation for u at leading order in k:

$$\frac{d^2u}{dY^2} + (\mathsf{q}^{3/2}(Y + c_1)^2 - 1)u = 0. \tag{3.219}$$

The solution to (3.219) may be represented in terms of parabolic cylinder functions (see Abramowitz & Stegun, 1965, chapter 19).

In the limit $Y \to \infty$, we shall seek to match the solution of (3.219) onto a radiating wave form. We therefore take the solution

$$u(Y) = E(a, 2^{1/2}\mathsf{q}^{3/8}(Y + c_1)), \tag{3.220}$$

where

$$a = \frac{1}{2}\mathsf{q}^{-3/4}. \tag{3.221}$$

The function $E(a, x)$ is related to the real parabolic cylinder function $W(a, x)$ via

$$E(a, x) = \lambda^{-1/2}W(a, x) + i\lambda^{1/2}W(a, -x), \tag{3.222}$$

where

$$\lambda = \sqrt{1 + e^{2\pi a}} - e^{\pi a}; \quad \lambda^{-1} = \sqrt{1 + e^{2\pi a}} + e^{\pi a}. \tag{3.223}$$

In the limit $Y \to \infty$, $u(Y)$ then takes the form

$$u(Y) \sim \sqrt{2/Y}\exp\{i(\mu^2(Y + c_1)^2/4 - a\ln\mu Y + \arg(\Gamma(ia + 1/2)) + \pi/4)\}, \tag{3.224}$$

where

$$\mu = \sqrt{2}\mathsf{q}^{3/8}. \tag{3.225}$$

If c_1 has an imaginary part, one can see from (3.224) that $u(Y)$ is exponentially decaying in the limit $Y \to \infty$.

The continuity equation at $Y = 0$ becomes

$$c_1 \left(\frac{1}{(1 - c_1^2 \mathsf{q}^{3/2})^{1/2}} - \frac{(1 + \mathsf{q}^{3/2}) E(a, \sqrt{2}\mathsf{q}^{3/8} c_1)}{\sqrt{2}\mathsf{q}^{3/8} E'(a, \sqrt{2}\mathsf{q}^{3/8} c_1) + \mathsf{q}^{3/2} c_1 E(a, \sqrt{2}\mathsf{q}^{3/8} c_1)} \right) = -1, \tag{3.226}$$

where the prime denotes differentiation with respect to the second argument. The second term in the bracket is the ratio of u/v at $Y = 0^+$. Recalling that $du/dy = A(y)u + B(y)v$, the complicated form of the denominator comes from the fact that, in this scaling, du/dy, $A(y)u$ and $B(y)v$ are all of the same order of magnitude, whereas in the limit of large k and order one potential vorticity jumps, $A(y)u$ may be neglected. The first term is the ratio of u/v at $Y = 0^-$. Notice that, unlike the previous analysis, it is not unity at leading order. Although there is no turning point in $Y < 0$, the expression

$$\Psi' = \left(1 - \frac{(c - U(y))^2}{H(y)} \right)^{1/2} \tag{3.227}$$

becomes

$$\Psi' = (1 - c_1^2 \mathsf{q}^{3/2}) \tag{3.228}$$

This explains the modification in the first term in (3.226).

The equation (3.226) is a nonlinear equation for the eigenvalue c_1, and it is in general difficult to prove results about the existence or uniqueness of its solutions. For the present analysis, we shall be concerned only with the development of the Rossby wave – gravity wave mode, already discussed in this section, in the limit as the potential vorticity jump is made very large.

The limit $\mathsf{q} \to 0$

We consider first the limit $\mathsf{q} \to 0$. In this limit, we introduce a new variable $z = \mathsf{q}^{3/4} Y$. In this variable, (3.219) becomes

$$\mathsf{q}^{3/2} \frac{d^2 u}{dz^2} + \left(z^2 - 1 + 2c_1 \mathsf{q}^{3/4} z + c_1^2 \mathsf{q}^{3/2} \right) = 0. \tag{3.229}$$

Moreover, c_1 is also expanded in powers of $\mathsf{q}^{3/4}$:

$$c_1 = c_1^0 + \mathsf{q}^{3/4} c_1^1 + \cdots. \tag{3.230}$$

For the present purposes, only c_1^0 will be required to obtain the leading order expression for the growth rate of the instability.

The solution to (3.229) is then written in the form

$$u(z) = A(z) e^{\mathsf{q}^{-3/4}\psi_0(z) + \psi_1(z)} + O(\mathsf{q}^{3/4}). \tag{3.231}$$

Substituting (3.231) into (3.229), one obtains

$$\frac{d\psi_0}{dz} = (1 - z^2)^{1/2} \tag{3.232}$$

$$\frac{d\psi_1}{dz} = -\frac{c_1^0 z}{(1 - z^2)^{1/2}}. \tag{3.233}$$

The analysis from this point is very similar to the WKBJ analyses in the limit of large k. The turning point in the WKBJ analysis occurs at $z = 1$, and so we set $\psi_0(1) = 0$ and $\psi_1(1) = 0$. Then the continuity equation (3.192) becomes

$$c_1^0 \left[1 + 1 + i e^{2(\mathsf{q}^{-3/4}\psi_0(0) + \psi_1(0))} \right] = -1. \tag{3.234}$$

From this it follows that $c_1^0 = -1/2$, and hence

$$\psi_0(0) = -\frac{\pi}{4}; \quad \psi_1(0) = -\frac{1}{2}. \tag{3.235}$$

The growth rate of the instability is then given by

$$\mathrm{Im}(c) \sim \frac{1}{4} e^{-(\mathsf{q}^{-3/4}\pi/2 + 1)}. \tag{3.236}$$

This expression is in agreement with the expression (3.213) for the growth rate of the instability obtained by assuming $q = O(1)$, and then taking the limit $q \to \infty$.

The limit $\mathsf{q} \to \infty$

In the limit $\mathsf{q} \to \infty$, the equation (3.226) is rather difficult to analyse. The principal difficulty comes from the fact that there may be roots with $c_1 = O(\mathsf{q}^{-3/8})$, for which the second argument

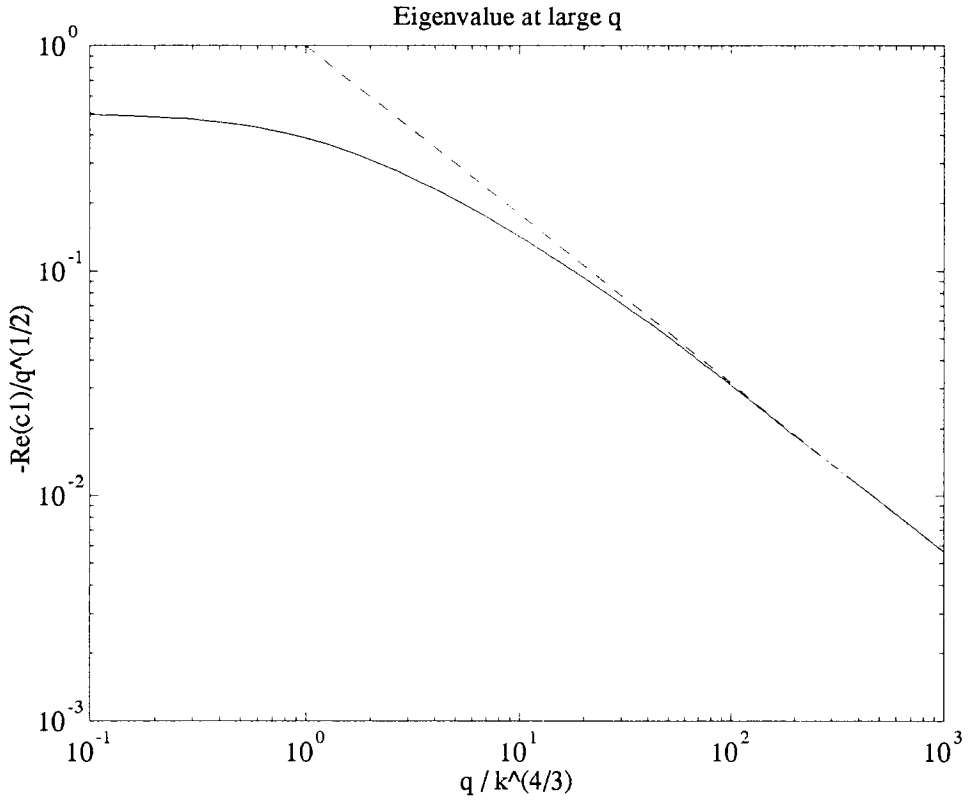

Figure 3.32: Real part of c_1, as a function of q (solid line), with $\mathrm{Re}c_1 = -\mathsf{q}^{-3/4}$ (dashed line).

of the parabolic cylinder function is of order unity. However, we are concerned in this thesis with the character of the Rossby – gravity wave instability as q is varied, and we shall therefore concentrate on the eigenmode which reduces to the above in the limit $\mathsf{q} \to 0$. In the limit $\mathsf{q} \to \infty$, it will be seen that the appropriate root of (3.226) comes by taking

$$c_1 = \mathsf{q}^{-3/4} c_1^1 + \mathsf{q}^{-3/2} c_1^2 + \cdots. \tag{3.237}$$

There is a unique root under this scaling. It shall further turn out that c_1^1 is real, whereas c_1^2 is complex, and the growth rate of the eigenmode, which is $k^{2/3}\mathsf{q}^{1/2}c_1$, thus tends to zero in the limit $\mathsf{q} \to \infty$.

To see this first examine figure 3.32, which shows the real part of c_1, computed numerically by solution of (3.219). At large q, on the log-log scale, one can see that $\mathrm{Re}c \to -\mathsf{q}^{-3/4}$ as $\mathsf{q} \to \infty$. The point about this is that then $1 - c_1^2\mathsf{q}^{3/2}$ is of small order, and hence the balance of terms in (3.226) may change. Expanding

$$c_1 = -\mathsf{q}^{-3/4} + C\mathsf{q}^{-3/2} \tag{3.238}$$

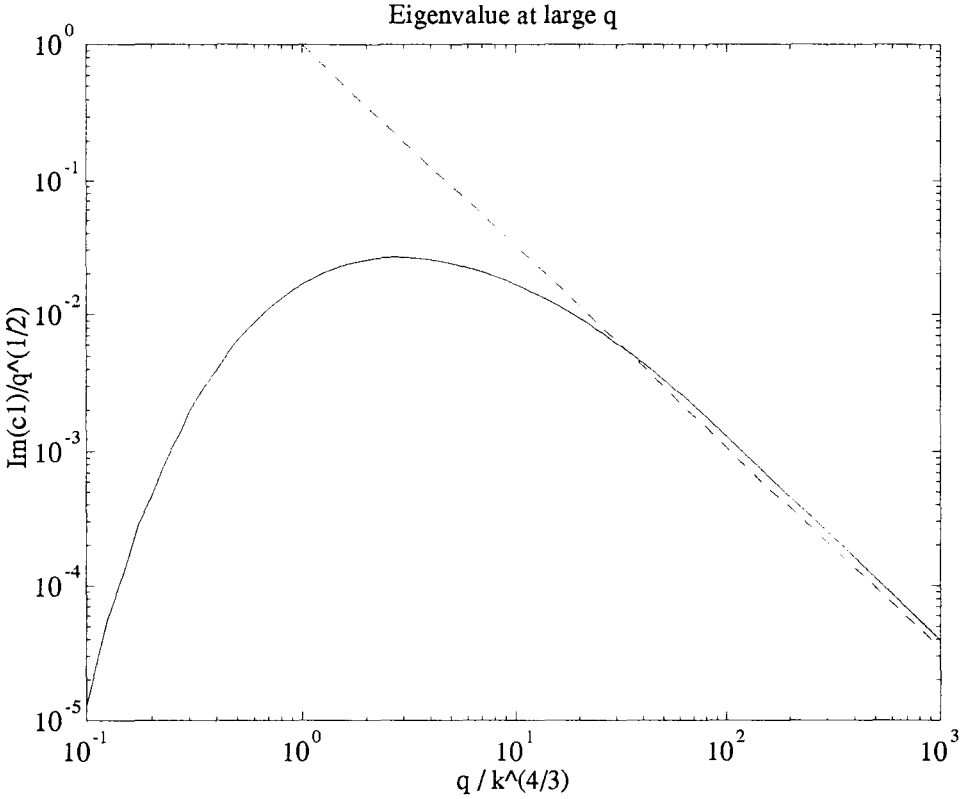

Figure 3.33: Imaginary part of c_1, as a function of q (solid line), with $\mathrm{Im}c_1 = \frac{1}{8}(\Gamma(1/4)/\Gamma(3/4))^2\mathsf{q}^{-3/2}$ (dashed line)

we obtain

$$\frac{1}{(2C)^{1/2}} + \sqrt{2}\frac{E'(0,0)}{E(0,0)} = 0 \tag{3.239}$$

for which the solution is

$$C = \frac{i}{8}\left(\frac{\Gamma(1/4)}{\Gamma(3/4)}\right)^2 \approx 1.09i. \tag{3.240}$$

The imaginary part of c_1 is shown in figure 3.33, with the value given by (3.240) for comparison. In this case, quite large values of q seem to be required for the validity of (3.240).

Thus, c_1 is imaginary at order $\mathsf{q}^{-3/2}$, and hence $\mathrm{Im}(\omega) = O(\mathsf{q}^{-1})$. Therefore, this mode is stable in the limit $\mathsf{q} \to \infty$, consistent with the analysis of Paldor (1983).

3.5.8 Eigenvalue calculations for large q

In figure 3.34, the growth rates of the instabilities are shown for potential vorticity jumps of 10^2, 10^3 and 10^6. The ordinate is $\mathsf{q}^{-3/4}$, or $k/q^{3/4}$ in terms of the original problem. On the

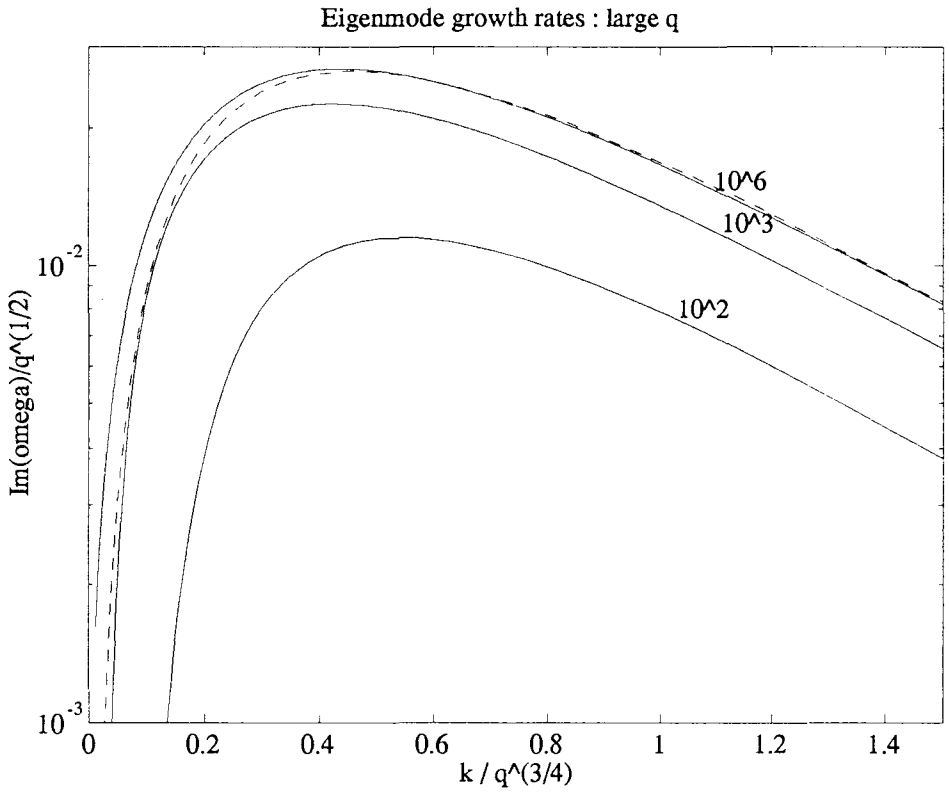

Figure 3.34: Solid lines are growth rates of linear eigenmodes for parallel flows with single potential vorticity jumps of 10^2, 10^3 and 10^6. Dashed line is the growth rate predicted in the limit $q \gg 1$, $k \gg 1$, $\mathsf{q} \equiv q/k^{4/3} = O(1)$

abscissa is $\mathrm{Im}(\omega)/\sqrt{q}$. In the limit of large q, with q of order unity, all the curves should fall on the dashed curve, which is obtained from the eigenvalue equation (3.226).

Comparison of the computed with the predicted growth rates shows that quite large values of q are required to obtain good agreement between computed growth rates and the large q limit. With $q = 10^6$, there is very good agreement for $k/q^{3/4}$ between 0.5 and 1.0. Outside this range, agreement is less good. It would improve with a larger value of q. However, the differential equations that must be integrated to obtain the eigenvalue become very stiff, and there is some doubt as to whether the numerical eigenvalue finder is sufficiently accurate to proceed to values of q in excess of about 10^6. However, calculation with $q = 2 \times 10^7$ (not shown) did appear to show some improvement over $q = 10^6$ for $k/q^{3/4}$ down to around 0.2, apparently confirming that we can ultimately expect to see agreement between the computed and theoretical curves for all but the smallest values of $k/q^{3/4}$, for which the analysis, which assumes $k \gg 1$, can never be valid.

3.5.9 Remarks

The instability of a parallel shear flow with a single discontinuity of potential vorticity has been investigated numerically, and analytically in the limit of short wavelength instabilities. The instability at short wavelength is present whenever the stability criteria of Ripa (1983) fail.

In the limit of a large potential vorticity jump, the instability becomes very strong, with a growth rate of order $k^{2/3}$ if the potential vorticity jump is of order $k^{4/3}$. However, as the jump is made large compared with $k^{4/3}$, the growth rate decays algebraically, and the limiting case of a surfacing front, investigated by Paldor (1983), is stable, as Paldor found.

3.6 Discussion

This chapter has furthered the study of vortex – gravity wave interactions in the shallow water equations by investigating instabilities which owe their existence to a coupling between Rossby waves and gravity waves.

First we investigated the stability of an axisymmetric vortex with a single radial discontinuity in potential vorticity. Numerical results showed that the presence of background rotation had a significant effect on the growth rates of any instabilities. This appeared to be due mainly

to differences in the character of the basic states. The sonic radius tended to be closer to the vortex boundary for values of the Coriolis parameter between 0 and -1. Asymptotic analysis for large azimuthal mode number showed that the vortex was always unstable, provided some rather weak assumptions were made about the basic state – assumptions which were always found to hold in practice. The growth rates are predicted to be exponentially small in the mode number for large mode number. There was good agreement between analysis and numerical eigenvalue calculations for quite moderate values of the mode number. The analysis was generalized to a limited class of flows with smooth potential vorticity profiles, and the connections between the current work and the study of Sozou (1987) were clarified.

The implications for the nature of a slow manifold for the shallow water equations were then discussed. Although there is no absolute proof that an invariant manifold of dimension 1/3 the dimension of the full phase space cannot be found, two things are clear. One is that any such invariant manifold is not unique. Another is that it is not truly slow, in that gravity wave - like features are bound to be present on it, albeit exponentially weakly at small Rossby number.

Finally, the stability of a parallel flow with a single discontinuity of potential vorticity was analysed. The numerical eigenvalue problem and large wavenumber limits are similar to those for the axisymmetric vortex. The problem was nondimensionalized somewhat differently from the axisymmetric vortex problem, and it allows a limit in which the potential vorticity on one side of the discontinuity becomes unbounded, corresponding to a vanishing layer depth. This limit has already been shown to be stable, and it turns out that a further asymptotic regime, in which the potential vorticity q in the shallow layer scales as $k^{4/3}$, where k is the wavenumber of the disturbance, is required to capture this limiting behaviour. Thus, although the maximum growth rate of the instability becomes unbounded as $q \to \infty$, it occurs at a wavenumber with a fixed value of $k/q^{3/4}$, with the growth rate tending to zero as $k/q^{3/4}$ tends to infinity.

In conclusion, a number of Rossby wave – gravity wave instabilities have been investigated in this chapter. They are generally short wave instabilities, and are therefore ideally suited to analysis by the WKBJ technique. In all cases investigated, the growth rates of the instabilities tended to be rather small, with the possible exception of an axisymmetric vortex at fairly large Froude number, with potential vorticity of opposite sign to the background. Nonetheless, it was shown that the instability persists, albeit exponentially weakly, for arbitrarily small

Rossby number, and this has significant implications for the slow manifold hypothesis. It seems increasingly unlikely that a slow manifold exists for the shallow water equations. In this chapter, it has been shown that if one does exist it is not unique, and must contain structures on it which are definitely gravity wave - like. It is unlikely that the concept of a truly slow manifold is therefore a useful one.

Chapter 4

Nonlinear simulation of gravity wave generation

4.1 Introduction

Since the development of the theory of aerodynamic sound by Lighthill (1952), several attempts have been made to verify it, and to investigate the range of Mach numbers over which it is valid (see, for example, Lighthill, 1954; Lush, 1971; Bridges & Hussain, 1992). In this chapter, we shall be concerned with two questions:

1 Over what range of Froude and Rossby numbers does the Lighthill theory of aerodynamic sound generation, appropriately modified to incorporate the effects of background rotation, give a quantitatively accurate description of the gravity wave field radiated by vortical motions in the shallow water equations?

2 How does the gravity wave radiation depend on the Froude and Rossby numbers as the Froude number is increased beyond the regime in which the Lighthill theory is valid, and, specifically, what conditions must exist in the vortical flow to enable gravity waves with order-one fluxes to be generated?

A comparison of the theory with early experimental data was made by Lighthill (1954). In general, there was reasonable agreement between theory and experimental data. In accordance with equation (2.10), the power of the acoustic waves radiated from the jet scaled approximately as the eighth power of the jet speed, providing some support for the validity of the theory when applied to actual turbulent jet flows.

Subsequent experiments by Lush (1971) confirmed the U^8 scaling law for the radiated power, where U is the speed of the jet, in somewhat more convincing detail than the earlier experiments discussed by Lighthill (1954), but also observed that when the acoustic waves passed through the jet for several wavelengths, they do not obey Lighthill's scaling law. This raises doubts about the claim, implicit in Lighthill's original formulation of his theory, that eddies in compressible jets will tend to be incoherent over a typical acoustic wavelength, and will not interfere with the radiated acoustic waves. Much of the literature on the aeroacoustics of jets over the last 20 years has been concerned with this point (see, for example, Moore, 1977; Mankbadi & Liu, 1984).

Recently, Bridges & Hussain (1992) have returned to the issue of the detailed verification of the Lighthill theory in a jet undergoing shear instability, in which the entire sound generation

region is acoustically compact with respect to all but the shortest wavelengths of the radiated acoustic wave field. They present a detailed analysis of the jet flow, identifying vorticity as the most robust measurable quantity from which to reconstruct velocities in the jet, under the assumption that the Mach number in the jet is sufficiently low that the velocity field can be approximated by the incompressible velocity field due to a given vorticity distribution, and hence to effective quadrupole source term for the radiated sound field. Comparisons between measurements of the acoustic field and its reconstruction from the Lighthill theory of aerodynamic sound generation are exceptionally good, thus verifying that the compact source assumption can be applied successfully to actual jet flows. If the vortical source of the radiated sound field is well modelled by a compact source approximation, one can show that for axisymmetric vortical flows, an extinction angle occurs at 54^o to the axis of symmetry. In the experiments of Bridges & Hussain, the jet axis serves as the axis of symmetry, and the extinction angle is well captured in the experimental data. However, agreement between theory and observations is not perfect, since the theory also predicts a second extinction angle which is not observed in their experimental data. Bridges & Hussain suggest that noise associated with the nozzle from which the jet issues is the most likely cause of the discrepancy.

A set of experiments even more idealized than those of Bridges & Hussain, also designed to test the validity of the Lighthill aeroacoustic theory, has been carried out by Kambe & Minota (1983), and Minota & Kambe (1986), who investigate experimentally the sound generated by a pair of colliding vortex rings. These experiments allow an especially detailed investigation of the validity of the theory of sound generation, since the flows may be made localized and compact for sufficiently small Mach number, and there is somewhat more detailed knowledge of the velocity field than in the experiments of Bridges & Hussain (1992). Moreover, since the sound generation is most intense when the vortex rings are interacting, and the point of interaction is well separated from the position of the generation of the vortex rings, there is no difficulty equivalent to the "nozzle noise" problems encountered by Bridges & Hussain (1992). The radiated sound field is compared with that predicted by the analytical work of Kambe & Minota (1981). They find that there is good agreement between experiments and theory, provided viscosity is taken into account. This is clear from their plots of directivity, which are initially consistent with a compact quadrupolar source, but develop a strong isotropic component from an effective monopole, which is due to viscosity, as the experiments proceed

in time.

Although there has been much experimental work with three dimensional jet flows, there appears to have been comparatively little experimental study of gravity wave generation in two dimensional flows. The only study to have been reported in the literature was undertaken by Webster (1970), who verified that a jet in shallow water excites surface waves whose intensity scales with the seventh power of the jet speed for Froude numbers up to approximately 1.0, consistent with (2.11). The Froude number must also be large enough that the jet noise exceeds the noise generated by interaction between the fluid and the nozzle from which the jet is issued. This confirms that the Lighthill theory appears to work well for quite large Froude numbers in two dimensional flows, just as it works well for quite large Mach numbers in three dimensional flows – a fact which could not have been assumed *a priori*, since there is no reason to expect the domain of validity of a small Froude number approximation in two dimensions to be the same as the domain of validity of a small Mach number approximation in three dimensions

Recently, Lele & Ho (1993) have presented a numerical study of a compressible mixing layer in a two dimensional numerical model. The mixing layer is unstable, and the waves which grow on the edges of the mixing layer eventually develop into a train of coherent vortices. The simulations are performed in a domain which is periodic in the the direction of the initial flow, and has absorbing regions placed near the boundaries which are parallel to the initial flow. Since it can be shown that the Lighthill theory is formally valid in the limit of low Mach number, it might be asked whether the source term to be taken in the Lighthill theory should come directly from the velocity and density fields in the numerical simulation, or whether it should be constructed from the vorticity field, under the assumption of incompressible flow, as Bridges & Hussain did in their experimental study. Lele & Ho found that the agreement between the simulated radiated wave field and its reconstruction using the Lighthill theory was significantly better when actual velocity and density fields were used to compute the Lighthill source term than when the incompressible fields were used, and that the Lighthill reconstruction could work quite well at Mach numbers of up to about 0.6, at which they found errors in the acoustic pressure field predicted by the Lighthill theory of only about 10%. For Mach numbers up to 0.2, the errors were only about 1–2%. It seems that the the low Mach number approximation is violated in the source region at quite small Mach numbers, whereas the assumption that the source region is small compared with the scale of the acoustic waves generated, although

formally a low Mach number approximation itself, is valid over a much wider range of Mach numbers.

The basic conclusion from the studies discussed above is that, leaving aside subtleties associated with extensive jets and directivity of the radiated sound, all experiments to date have demonstrated good agreement with the Lighthill theory up to quite large values of the Mach number, with the intensity of the 'sound' scaling with the eighth power of the Mach number in three dimensions, and the seventh power in two dimensions. This implies that the sound radiated, although weak at low Mach numbers, will rise very sharply in intensity as the Mach number is increased. Moreover, when a complete knowledge of the source flow is available, as in the numerical experiments of Lele & Ho (1993), the acoustic sound field can be reconstructed with excellent accuracy for Mach numbers up to 0.6 from the Lighthill source term. They also found that the momentum flux in the acoustic wave region scaled as the sixth power of the Mach number, consistent with scaling arguments which can be derived for one dimensional wave radiation from a vortical source (see Ffowcs-Williams, 1969).

Although the Lighthill theory of aerodynamic sound generation is therefore apparently well established for simple flows and turbulent jet flows over a range of Mach numbers, there remains no numerical or experimental study of the corresponding gravity wave generation problem, for cases where the rotation of the reference frame should be taken into account.

Recently, McIntyre & Norton (1993) presented simulations of a forced polar vortex in a hemispherical shallow water model. The forcing is applied over a long time scale, so it does not generate gravity waves directly, but acts to disrupt the polar vortex, thereby generating gravity waves as a result of the subsequent vortical motions. They compared the shallow water simulations with simulations using balanced models of varying accuracy, and found that the amplitude of gravity waves generated appeared to be very low, even when the Froude number in the flow reached 0.7. Without further investigation, their results might appear to contradict the established body of literature on aerodynamic sound generation and the validity of the Lighthill (1952) theory, which predicts that the amplitude of gravity waves generated by vortical motions will increase rapidly with increasing Froude number.

The complexity of the flows simulated by McIntyre & Norton (1993) makes it difficult to analyse nature of the gravity wave generation process in detail for their simulations. In this chapter, we shall investigate only simple flows, in which the vortical field is comparatively well

understood. We shall use the shallow water equations on an f-plane. This way, large scale Rossby waves are avoided, and the potential vorticity will be non-uniform only in some finite region. A modified version of the Lighthill theory of aerodynamic sound generation can then be used to investigate the validity of the compact source approximation as the Froude number is increased.

The nature of gravity waves generated by vortical motions, and the domain of validity of the modified Lighthill theory, are not only of theoretical interest. Frequently, the passage of a jet streak at the level of the tropopause can give rise to a significant amount of gravity wave activity. Usually, the gravity waves generated will propagate vertically upwards into the stratosphere. Occasionally the tropospheric conditions can act as a wave guide, and a significant amount of the waves generated by the passage of the jet streak remain trapped in the troposphere.

Such an event was observed and analysed by Koch & Dorian (1988) using a mesoscale observing network. In addition to presenting an analysis of the gravity wave field, they investigated possible source mechanisms. After ruling out convection as a possible source, they concluded that the gravity waves were generated either as a result of stratified-shear-flow instability, or through nonlinear interaction with the unsteady vortical motions associated with the jet streak itself. They were unable to demonstrate conclusively which of these two possible mechanisms was responsible for the observed waves. However, if we can gain some more insight into how to apply and interpret the modified Lighthill theory, and have some knowledge of its domain of validity as the Froude number is increased, we may lay the foundations for the development of a test to determine whether the amplitude and form of the observed waves is consistent with their being generated by coupling with the vortex dynamics. Gravity waves of long wavelength and period, apparently generated by vortical motions, have also been observed in simulations of baroclinic lifecycles by D. J. O'Sullivan (personal communication).

Although we may bear in mind these applications as a motivation for the present study, I have chosen not to concentrate on any particular flow which might be observed in the atmosphere, but rather to concentrate on flows which can be analysed and interpreted readily. I have therefore required three things of the idealized experiments to be discussed in this chapter:

1 Any gravity waves present in the simulation must be unequivocally due to vortical motions, and should not be due to any forcing or initialization procedure.

2 The simulations should depend on the minimum number of adjustable parameters, which should be related to the Froude number and the Rossby number.

3 Whatever mechanism is used to generate the vortical flow should apply in the limit of low Froude number, so that in this limit the modified Lighthill theory of gravity wave generation may be tested.

Of these requirements, it is undoubtedly the first requirement which places the most severe restrictions on the nature of the initial flow whose subsequent evolution we may study. Suppose we wish to initialize our simulation with an arbitrary potential vorticity field. A small amount of gravity wave activity is inevitable, due to the non-existence of a true slow manifold for the shallow water equations, established in the previous chapter. How much gravity wave activity there is depends inevitably on which balanced model we choose. In any case, even if the very minimum of gravity waves are introduced by the initialization procedure, we will be in the position of having gravity waves present from the initial instant in our simulation, but no knowledge of the flow which is supposed to have generated them. This is a totally unsuitable situation for testing the validity of a modified Lighthill theory.

The only flows from which we can unambiguously eliminate gravity waves are the steady solutions of the shallow water equations – parallel flow and axisymmetric flow. Since these are steady flows, they will never develop gravity waves. However, if they are unstable, then an arbitrarily small disturbance may develop into a vigorous vortical motion from which gravity waves may be radiated. From the viewpoint of numerical simulation, it is simpler to work with initially parallel flow than initially axisymmetric flow, and that is the sole focus of the study presented here.

The most familiar form of parallel flow instability is the so-called "barotropic" shear flow instability, described, for example, in Hoskins *et al.* (1985). This instability can occur when there is a reversal in the sign of the potential vorticity gradient across the flow. This means that there are potential vorticity gradients of both signs in the flow. Physically, the direction of the potential vorticity gradient sets the direction of Rossby wave propagation, and therefore we can have counter-propagating Rossby waves in the flow, propagating on potential vorticity gradients of opposite sign. For some critical values of wavelength, these two counter-propagating waves can lock onto each other, and thereby cause each other to grow. For this reason, the instability

is sometimes referred to as "Rossby wave – Rossby wave" instability.

An extensive review of shear flow instability, including barotropic shear flow instability, was given by Ho & Huerre (1984). As the instability develops, the potential vorticity rolls up into a train of vortices, spatially periodic in the streamwise direction. Many previous studies have addressed the subsequent merging of adjacent vortices as subharmonics of the fundamental wavelength of the instability develop (see Ho & Huerre (*op. cit.*) and refs. therein). In this study, we are concerned with the degree to which the vortex motions, following the roll up of the primary instability, will excite gravity waves which radiate away from the shear layer. To enable a thorough investigation of the Froude and Rossby number parameter space, I have chosen to concentrate resources on simulating just one wavelength of the primary instability. It follows that subharmonics do not develop, and so the extent to which the vortex merging process excites gravity waves has not been investigated.

An alternative mechanism for parallel flow instability in the shallow water equations was presented in chapter 3, and can be regarded as a "Rossby wave – gravity wave" instability. However, there are three reasons for preferring to use barotropic instability for generating the vortical motions which will excite gravity waves in our experiments.

1 Typical growth rates of Rossby wave – gravity wave instability are very small, so the instability will take a long time to develop, and might saturate at low amplitude.

2 The Rossby number and Froude number are not independent parameters for an initial flow with a single discontinuity of or sharp jump in potential vorticity, so it is not possible to vary them independently in simulations initialized in this way

3 The Rossby wave – gravity wave instability is not present at arbitrarily small Froude number, so rendering a comparison with the modified Lighthill theory impossible in the small Froude number limit in which the theory is formally valid.

For these reasons, all the numerical simulations presented in this chapter are simulations of barotropically unstable parallel flows. Initially, the potential vorticity is everywhere uniform, equal to Q_0, say, except in some strip of finite width. The velocity tends to zero far from the strip, and the height tends to a uniform value. Inside the strip, the potential vorticity takes a different uniform value, Q_1. The potential vorticity jump is smoothed over at least 5 grid

points in the numerical model. The ratio of the difference between the strip and background potential vorticities, $Q_1 - Q_0$, to the background value, Q_0, defines an effective Rossby number $Ro = Q_1/Q_0 - 1$ for the flow. As the strip width is increased, so the velocities in the strip increase, and hence the Froude number is governed by the width of the strip.

The rest of this chapter is organized as follows.

In §4.2 the Lighthill analysis for the shallow water equations is developed, as appropriate for periodic jets.

In §4.3 the pseudomomentum and pseudoenergy are introduced as possible diagnostic quantities for quantifying the intensity of gravity wave radiation, and it is shown that the pseudoenergy flux is the natural wave quantity to choose in this study.

In §4.4 the numerical model to be used for the nonlinear simulations is described, and an overview of the simulations performed with the model is presented in §4.5.

In §4.6, the gravity wave radiation from a train of vortices generated by the roll up of a cyclonic strip of potential vorticity is discussed. The strip has potential vorticity equal to six times the background value.

In §4.7, the effect of increasing the potential vorticity in the strip is investigated.

In §4.8, anticyclonic strips are investigated, with potential vorticity in the strips equal to 0.1 and 0.0 times the background value.

In §4.9, the effects of negative potential vorticity is investigated, with potential vorticities in the strip of -0.1, -1.0 and -19.0 times the background value.

Some conclusions are offered in §4.10.

4.2 A "Lighthill" theory of gravity wave generation for a periodic parallel flow

In this section the analysis necessary to investigate the quantitative accuracy of the Lighthill theory, applied to periodic flows in a rotating frame, is developed. In further sections the analysis will be used to investigate the degree to which the theory remains useful as the Froude number is increased and the compact source assumption becomes less valid.

Returning to equation (2.4), we recall that manipulation of the shallow water equations gives

$$\left(\frac{\partial^2}{\partial t^2} + f^2 - c_0^2\nabla^2\right)\frac{\partial h}{\partial t} = \frac{\partial^2}{\partial x_i \partial x_j}T_{ij}, \tag{4.1}$$

where

$$T_{ij} = \frac{\partial}{\partial t}(hu_iu_j) + f\varepsilon_{ik}hu_ju_k + \frac{1}{2}g\frac{\partial}{\partial t}(h-h_0)^2\delta_{ij}, \tag{4.2}$$

h_0 is the layer depth far from the region of vortical motion, and $c_0 = (gh_0)^{1/2}$ is the gravity wave phase speed far from the region of vortical motion. These equations have formal solution

$$\frac{\partial h}{\partial t} = \frac{1}{4\pi c_0}\frac{\partial^2}{\partial x_i \partial x_j}\int_{t-t'>|\boldsymbol{x}-\boldsymbol{x}'|/c_0} \frac{T_{ij}(\boldsymbol{x}',t')\cos(f((t-t')^2 - |\boldsymbol{x}-\boldsymbol{x}'|^2/c_0^2)^{1/2})}{((t-t')^2 - |\boldsymbol{x}-\boldsymbol{x}'|^2/c_0^2)^{1/2}} d^2\boldsymbol{x}'dt'. \tag{4.3}$$

The key point in Lighthill's theory is now to assume that the source term T_{ij} is only non-zero over a small enough region that it may be approximated by a quadrupole point source, so that we may write the solution as

$$\frac{\partial h}{\partial t} = \frac{1}{4\pi c_0}\frac{\partial^2}{\partial x_i \partial x_j}\int_{t-t'>|\boldsymbol{x}|/c_0} \frac{S_{ij}(t')\cos(f((t-t')^2 - |\boldsymbol{x}|^2/c_0^2)^{1/2})}{((t-t')^2 - |\boldsymbol{x}|/c_0^2)^{1/2}} dt', \tag{4.4}$$

where

$$S_{ij}(t') = \int_{\mathbb{R}^2} T_{ij}(\boldsymbol{x}',t')d^2\boldsymbol{x}'. \tag{4.5}$$

In the classical problem of aerodynamic sound generation, this is the compact source approximation – that the length-scale of the source is small compared with the length-scale of the waves. Here we are imposing an additional condition – that the length-scale of the source is also small compared with a Rossby deformation radius.

If we now assume that we know the way in which the source term scales as the flow parameters are varied, then we may estimate how the amplitude of the wave field depends on parameters such as the Froude number and the Rossby number. Lighthill (1954) proposed that the theory could be applied to an extensive body of turbulence by assuming that each turbulent eddy was itself compact, and not correlated with other eddies.

It is clearly not possible to apply this analysis directly to a radiating vortex train, since the eddies in the train are highly correlated with each other. We must therefore develop a version of the theory specifically for the case where the source, and therefore the waves, are periodic in the x direction.

In comparing the gravity wave radiation with that which is predicted by the Lighthill theory, we shall concentrate on that component of the wave field which is independent of the streamwise coordinate x. In the asymptotic limit of small Froude number, it can be shown by the method of matched asymptotic expansions that all other components of the radiated wave field are exponentially small compared with the x–independent component, and so this seems the natural component on which to focus the analysis.

Now, let the x–average of a quantity a be denoted by $\overline{a}^x$. To derive the effective source for the x–independent component of the wave field, we must take the x–average of equation (4.1). The x derivatives, in both the wave operator and the quadrupole term, then vanish, and we are left with a one-dimensional Klein-Gordon equation, with a one-dimensional quadrupole source term:

$$\left(\frac{\partial^2}{\partial t^2} + f^2 - \frac{1}{c_0^2}\frac{\partial^2}{\partial y^2}\right)\overline{\frac{\partial h}{\partial t}}^x = \frac{\partial^2}{\partial y^2}\overline{T_{22}}^x. \tag{4.6}$$

To proceed, we need only assume that the source term $\overline{T_{22}}^x$ is compact with respect to the cross stream direction y. Making that assumption, we obtain

$$\overline{\frac{\partial h}{\partial t}}^x(y,t) = \frac{1}{2c_0}\frac{d^2}{dy^2}\int_{-\infty}^{t-|y|/c_0} S(t')\mathrm{J}_0(\sqrt{((t-t')^2 - y^2/c_0^2)})dt', \tag{4.7}$$

where

$$S(t') = \int_{-\infty}^{\infty} \overline{T_{22}}^x(y',t')dy', \tag{4.8}$$

and J_0 is the regular Bessel function of order zero (see Morse & Feshbach, 1953). The factor $\frac{1}{2}$ arises from the fact that waves propagate in both positive and negative y directions away from the source at $y = 0$.

To reconstruct the wave field from a numerical simulation using equation (4.7), we now need only know the function $S(t)$, a single function of time, which is obtained for each time t during the simulation by evaluating the integral (4.8) over the entire flow.

We may readily proceed from here to show how $\partial h/\partial t$ in the wave region scales with properties of the vortical flow in the vortex train. Taking the Fourier transform of (4.6) with respect to t, we have, making the compact source approximation,

$$i\omega\tilde{h} \sim \frac{\sqrt{\omega^2 - f^2}}{2c_0}e^{i\sqrt{\omega^2-f^2}y/c_0}\int \tilde{\overline{T_{22}}}^x(y',\omega)dy', \tag{4.9}$$

where, as usual, ω is the transform variable. Now, scale analysis of (4.2) gives a scaling for T_{22}: $\widetilde{\overline{T_{22}}^x}(y',\omega) \sim \omega u^2 \lambda \tilde{h_0}$, where λ is the length scale of the vortical region, and hence, for $\omega^2 > f^2$,

$$h' \sim h_0 \left(\frac{u}{c_0}\right)^2 \left(\frac{\left(\sqrt{\omega^2 - f^2}\right)\lambda}{c_0}\right). \tag{4.10}$$

4.3 Pseudoenergy and pseudomomentum for the shallow water equations

Since we are interested in the amplitude of gravity wave radiation over a wide range of Froude and Rossby numbers, it is desirable to take the flux of an appropriate wave quantity, such as pseudoenergy or pseudomomentum, as a measure of the strength of gravity wave radiation by the vortical flow.

In general, a wave activity density A is a field, second order in disturbance amplitude in the limit of small disturbances, for which there exists an associated wave flux $\boldsymbol{F}$, such that

$$\frac{\partial A}{\partial t} + \nabla.\boldsymbol{F} = 0. \tag{4.11}$$

Definition of wave activities and their corresponding fluxes must be made with respect to some reference state. In this chapter, we shall take the initial parallel flow as the reference state for the definition of wave activities and their fluxes. Throughout this section, $\boldsymbol{u}_0$, h_0 and Q_0 represent the velocity, height and potential vorticity of the basic state respectively, and $\boldsymbol{u}'$ and h' represent departures of velocity and height from the basic state values. The basic state possesses symmetries with respect to x-translation and time translation, and therefore it is possible to define both pseudoenergy and x–pseudomomentum fluxes. For the present study, we are interested in developing a wave quantity which can be used to characterise the strength of gravity wave radiation. If we are to take a single quantity, such as a wave flux strength, to characterise gravity wave radiation, then that quantity should satisfy a monotonic radiation property – that is, all radiating waves should give rise to fluxes of the same sign, at least in the limit of linear waves. It turns out that this "monotonic radiation property" is not satisfied by the pseudomomentum, but is satisfied by the pseudoenergy.

The technique for obtaining wave activities and fluxes is now quite well established (McIntyre & Shepherd, 1987; Haynes, 1988), and the details of the calculations of the pseudoenergy and

pseudomomentum for the shallow water equations will not be reproduced here.

The pseudomomentum density for the shallow water equations is given by

$$A_m = h'u' + h\int_{y_0}^{y} (Q - Q_0(y'))\, h_0(y')dy' \tag{4.12}$$

and its flux is given by

$$\boldsymbol{F}_m = \boldsymbol{u}A_m + \left(\frac{1}{2}h_0\left(u'^2 - v'^2\right) + \frac{1}{2}gh'^2, u'v'h_0\right), \tag{4.13}$$

so that

$$\frac{\partial A_m}{\partial t} + \nabla.\boldsymbol{F}_m = 0. \tag{4.14}$$

The pseudoenergy density is

$$A_e = \frac{1}{2}h\left(u'^2 + v'^2\right) + u_0u'h' + \frac{1}{2}gh'^2 + h\int_{y_0}^{y} (Q - Q_0(y'))\, h_0(y')u_0(y')dy' \tag{4.15}$$

and its flux is

$$\boldsymbol{F}_e = \boldsymbol{u}A_e + h_0\boldsymbol{u}_0.\boldsymbol{u}'\boldsymbol{u}' - \frac{1}{2}h_0\boldsymbol{u}'^2\boldsymbol{u}_0 + \frac{1}{2}gh'^2\boldsymbol{u} + gh_0h'\boldsymbol{u}'. \tag{4.16}$$

In (4.12) and (4.15), y_0 is the initial y location of the fluid in the reference state which is at location (x, y) at time t at which the wave activity or flux is to be evaluated. The integrals in (4.12) and (4.15) represent "Lagrangian information" about the motion of fluid particles. Notice, however, that they will be non-zero only if the potential vorticity in the basic state is non-uniform between y and y_0, implying that Rossby waves exist at the location y. In this chapter, we shall be concerned with gravity wave fluxes in a region of uniform potential vorticity. In computing the fluxes far from the vortical region, therefore, the contribution to (4.12) and (4.15) from the potential vorticity integrals will be identically zero.

To investigate the properties of the pseudoenergy and pseudomomentum fluxes in the far field, we consider the linearized shallow water momentum equations about a state of no motion. We assume that disturbances are wavelike, of the form $e^{i(kx+ly-\omega t)}$. The equations are

$$-i\omega u' - fv' + ikgh' = 0 \tag{4.17}$$

$$-i\omega v' + fu' + ilgh' = 0. \tag{4.18}$$

Considering the quadratic terms in the pseudoenergy flux in the limit where $u_0 = 0$, we see that the y-component of the pseudoenergy flux is dominated by the term $h_0h'v'$. To evaluate

$h'v'$ we eliminate u from (4.17-4.18). This gives

$$gh' = \frac{\omega^2 - f^2}{\omega^2 l^2 + f^2 k^2}(\omega l + ikf)v'. \tag{4.19}$$

Averaging over wave periods gives

$$g\overline{h'v'} = \frac{\omega^2 - f^2}{\omega^2 l^2 + f^2 k^2}\frac{\omega l}{2}|v'|^2. \tag{4.20}$$

For the pseudomomentum, we see that in the far field the y-component of the pseudomomentum flux is dominated by $h_0 u'v'$. So, to analyse the pseudomomentum flux in the far field, we eliminate h' from (4.17-4.18). This leads to

$$u' = \frac{(\omega^2 - f^2)kl + i\omega f(k^2 + l^2)}{\omega^2 l^2 + f^2 k^2}v'. \tag{4.21}$$

Averaging over wave periods here gives

$$\overline{u'v'} = \frac{\omega^2 - f^2}{\omega^2 l^2 + f^2 k^2}\frac{kl}{2}|v'|^2. \tag{4.22}$$

To check for radiation properties, we consider the dispersion relation for gravity waves

$$\omega^2 - f^2 = c_0^2(k^2 + l^2), \tag{4.23}$$

where $c_0 = \sqrt{gh_0}$.

We wish to impose a radiation condition with respect to the propagation in the y direction, so that

$$\frac{\partial \omega}{\partial l} \equiv c_0^2 \frac{l}{\omega}\begin{cases} > 0 & \text{for } y > 0 \\ < 0 & \text{for } y < 0 \end{cases}. \tag{4.24}$$

It follows that l and ω should be of the same sign as $y \to +\infty$, but should be of opposite sign as $y \to -\infty$.

Now we want to select the wave flux such that $\boldsymbol{F}.\boldsymbol{n}$ is the same sign on the upper and lower y–boundaries, recalling that the normal is in the positive y direction for $y > 0$, and is in the negative y direction for $y < 0$. This forces us to choose the pseudoenergy flux, since $h_0\overline{h'v'}$ takes the same sign as ωl provided $\omega^2 > f^2$, so that the waves are radiating. If $\omega^2 < f^2$ then l is imaginary, the waves are evanescent, and there is no wave flux.

It follows that, with the present sign convention for pseudoenergy, there should be a net flux of pseudoenergy in time away from the jet due to gravity wave radiation, whereas there is no corresponding monotonic radiation property for the flux of pseudomomentum.

To see how the intensity of the pseudoenergy flux scales with the Froude number, we note that

$$F_e = h_0 g h' v' = \frac{g^2 h_0 \omega l}{\omega^2 - f^2} h'^2. \tag{4.25}$$

From (4.10), this implies

$$F_e \sim h_0 c_0^2 \left(\frac{u}{c_0}\right)^4 \lambda^2 \omega l. \tag{4.26}$$

From the dispersion relation (4.23), with $k = 0$, we therefore obtain

$$F_e \sim \begin{cases} h_0 c_0 \left(\frac{u}{c_0}\right)^4 \lambda^2 \omega \sqrt{\omega^2 - f^2} & \omega^2 > f^2 \\ 0 & \omega^2 < f^2 \end{cases} . \tag{4.27}$$

Thus if, at low Froude numbers, we assume that the velocity u scales as $u \sim \omega\lambda$, and the Froude number $F \sim \omega\lambda/c_0$, it follws that

$$F_e \sim \begin{cases} h_0 c_0^3 F^6 \sqrt{1 - f^2/\omega^2} & \omega^2 > f^2 \\ 0 & \omega^2 < f^2 \end{cases} . \tag{4.28}$$

Thus, if ω, c_0 and h_0 are held fixed, and the Froude number is increased by increasing λ, the scale of the vortical motions, the intensity of the pseudoenergy flux will increase as the sixth power of the Froude number, in agreement with the analysis of one-dimensional sound radiation by vortical motions presented by Ffowcs-Williams (1969). However, if the Froude number is increased by increasing the magnitude of the vorticity in the vortical region, and therefore increasing $|\omega|$, no such simple scaling law applies. In general, for a given Froude number, the intensity of wave fluxes will be greatest when $\omega^2 \gg f^2$, and the f^2/ω^2 term in (4.28) becomes insignificant.

4.4 The numerical model

The numerical model used in this chapter integrates the nonlinear f-plane shallow water equations in a channel geometry. The channel is periodic in the x-direction, and has solid boundaries at $y = \pm Y$, for some (usually large) Y. The shallow water equations are integrated in nondimensional form, viz:

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u}.\nabla\boldsymbol{u} + \boldsymbol{k} \times \boldsymbol{u} + \nabla h = 0 \tag{4.29}$$

$$\frac{\partial h}{\partial t} + \nabla.(h\boldsymbol{u}) = 0, \tag{4.30}$$

where $\boldsymbol{u}$ is the two-dimensional velocity field, h is the layer depth, and $\boldsymbol{k}$ is the unit vector normal to the plane. The nondimensionalization sets the length scales and time scales for the flow, such that the unit timescale is the inertial period f^{-1}, and the unit length scale is the Rossby deformation radius where the fluid is at rest $\sqrt{gh_0}/f$. In (4.29) and (4.30), h has been rescaled so that g may be set to unity. The potential vorticity away from the region of vortical motions will therefore be unity. In subsequent sections, all results of model integrations will be presented using this nondimensionalization of length and time scales.

Several numerical schemes for integrating the shallow water equations have been presented in the literature, of which the best known is that of Arakawa & Lamb (1981). A possible advantage of the Arakawa & Lamb scheme is that it can be shown to conserve energy and enstrophy exactly. The proof relies on an assumption that a regularly-spaced grid is used to discretize the equations. In this chapter, however, we are interested in flows which will generally consist of a highly nonlinear but highly localized region of vortical motion, from which low amplitude gravity waves are radiated, with a wavelength much longer than the scale of the vortical region. In the interests of computational efficiency, the model used in this chapter will therefore allow variable resolution in both the streamwise and cross-stream directions. There is therefore no particular reason to favour a scheme such as that of Arakawa & Lamb, and the model used here was developed so as to allow the fields with variable resolution to be represented in a convenient way, but not to possess any particular conservation properties.

The geometry is periodic in x, but of finite extent in y. Therefore, the equations were discretized using finite differences in the y direction, with fields at each value of y being represented as a sum of Fourier modes in x. The y-discretization is performed on a staggered grid, with u, v on physical grid levels, and h at intermediate levels. The model is a pseudo-spectral model, with streamwise derivatives being computed in spectral space, and nonlinear products computed in physical space.

The variable cross stream resolution was implemented using a coordinate transformation. The numerical model is written in terms of a cross-stream variable η. The grid positions are equally spaced in the model coordinate η, and the physical coordinate transformation is implemented by specifying a relationship between the model coordinate η and the physical

coordinate y. Cross-stream differencing is performed on the η grid, where centred differencing can be used. By a simple application of the chain rule, the centred differences are then multiplied by $d\eta/dy$ to give the value of the derivative with respect to y. In the vortical region the value of $d\eta/dy$ is unity, whereas in the wave region its value is generally less than unity. In the region of variable resolution, a self-similar transformation is employed, in which $d\eta/dy = e^{-a(\eta-\eta_1)}$, where η_1 is the outer limit of the region of high resolution, and a is a constant which sets the size of the region of variable cross-stream resolution.

The variable streamwise resolution is implemented in a very simple way. The streamwise resolution is specified in the vortical region by specifying a maximum number of Fourier components which are to be used to represent the flow there. A full set of Fourier harmonics is retained throughout the vortical region, and in the region of varying cross-stream resolution. Beginning at the start of the region of low resolution, the number of Fourier components used to represent the solution is then reduced by a factor of two at every fifth cross-stream grid point, until a specified minimum number of streamwise components are left. This number of components is then used to represent the solution in the region of low resolution. In all simulations presented in this chapter, 64 Fourier coefficients in the x direction were used to resolve the vortical region.

Several shallow water models have been presented which use vorticity, divergence and height as prognostic variables (e.g. Bourke, 1972). They have the advantage of a flux formulation with only quadratic nonlinearity, ensuring that quadratic quantities are conserved (but not energy, which is cubic in the shallow water system) when integrated using the leapfrog timestepping scheme. However, these models require inversion of the Laplacian operator at each time step, and the velocity field at one location depends on the vorticity, divergence and height at all locations in the model. This seems an undesirable property for a model when a large domain, with regions of greatly differing character, is to be integrated. The present model uses the two components of velocity and height as the prognostic variables. Therefore, the model does not require inversion of elliptical operators to obtain the velocity and height fields and, although it is not a conservative scheme, there is no reason to expect it to be less accurate locally than a model which uses a flux formulation.

Some diffusion is required to remove fine scales, especially in the vortical region. This was implemented by applying a small amount of hyperdiffusion to the Fourier components in each

of the fields u, v and h. The hyperdiffusion is proportional to k^6, where k is the wave number. Since the hyperdiffusion acts only in the x-direction, its anisotropic nature may make it appear to be a particularly unphysical type of hyperdiffusion. However, the rotational nature of vortical flow means that it should be sufficient to apply a diffusion in the x-direction only. Any fine scale structure which builds up in the cross-stream direction in the vortical flow will rotate into a streamwise orientation, where it will be removed by the hyperdiffusion. This type of hyperdiffusion was used in a model with streamwise spectral representation and cross stream grid-point representation in a numerical study of nonlinear critical layer evolution by Haynes (1989), and appears to control fine scale structure adequately for the present purposes. One advantage is that it is quite simple to implement, and in particular may be implemented in an implicit diffusion scheme using only division, and not tridiagonal matrix inversion, as would be required for an isotropic diffusion with a grid point discretization in the cross stream direction.

At the lateral boundaries, sponge layers may be placed over a variable number of grid levels. Rayleigh friction is applied there, which relaxes the flow back to the initial state. The value of the Rayleigh friction is small at the point where it is first encountered by waves propagating towards the boundary, and increases linearly towards the boundary. In the model, the number of grid levels over which the Rayleigh friction is applied, and its amplitude, are arbitrary. However, for all simulations presented here, it was found that applying Rayleigh friction over 30 grid levels, with a maximum value of 1.0 at the boundary, corresponding to an e-folding decay time of 1.0 for disturbances at the boundary, generally prevented any significant reflection from the boundary, and these values were used throughout.

The equations are integrated forward in time using an explicit leapfrog time step, but with the hyperdiffusion and Rayleigh friction being performed implicitly. The basic leapfrog method is unstable, however, and a time filter must be used to prevent the growth of a rapidly oscillating computational mode. In the present simulations, a Robert-Asselin time filter (Robert, 1966; Asselin, 1972) was used with a value of 0.02.

4.5 Overview of numerical simulations

Using the numerical model described in §4.4, gravity wave generation by vortical motions in the shallow water equations is now studied by numerical simulation of the nonlinear evolution

of a barotropically unstable strip of potential vorticity. The potential vorticity in the strip is Q_1, and the background value of the potential vorticity is unity. The Rossby number Ro can then be defined as $Ro = Q_1 - 1$. The only other significant parameter in the initial flow is the width of the strip, Δ, which determines the Froude number of the flow.

In the following sections, simulations with a range of values of Q_1 and Δ are discussed. The simulations are labelled by letters **A** – **H**, with each letter corresponding to a different value of Q_1. Simulations with the same value of Q_1 are distinguished by Roman numerals (e.g. **A**i–vi), with the Roman numeral increasing with increasing initial strip width. Table 4.1a shows the values of Q_1 and Δ investigated, with their corresponding labels.

In all cases, the initial conditions for the numerical simulation consist of a strip of potential vorticity Q_1 centred on $y = 0$. The model domain in the cross-stream direction extends from $y = -Y$ to $y = +Y$, for some large Y, to accomodate several wavelengths of the radiating gravity waves within the computational domain. Only one wavelength of the fastest growing unstable linear eigenmode is simulated in all cases. The wavenumber of the fastest growing eigenmode is shown in table 4.1b, and a matrix method is used to obtain the eigenmode. In all cases except simulations **C**i–iv and **H**i–iv, a small amplitude disturbance of the form of the fastest growing eigenmode is added to the initial parallel flow at $t = 0$. If a large amplitude of the fastest growing eigenmode is added, then the flow will adjust, radiating gravity waves. The amplitude of the eigenmode added was therefore controlled such that any gravity waves generated by this initial adjustment had an amplitude of no more than 1–2% of the gravity waves subsequently generated by the vortical motions, when viewed in the $\partial h/\partial t$ field. In cases **C**i–iv and **H**i–iv, the strips are very narrow compared with a deformation radius. Consequently, the eigenmode decays very slowly with distance away from the strip, when compared with the width of the strip. This presents very large memory requirements for the matrix method used to find the eigenmode, and in these cases the flow was disturbed by the addition of random noise. Again, the amplitude of the random noise added was chosen to be sufficiently small that any gravity wave radiation associated with it was of small amplitude compared with the gravity waves subsequently generated by the vortical motions.

In the nonlinear evolution of the flow, the strip of potential vorticity rolls up into a train of vortices, which then nutate, radiating gravity waves as they do so. In general, it was found that the maximum value of the Froude number, found in the vortical region, can increase by

Table 4.1: Initial strip widths, fastest growing wave numbers and Froude numbers for all simulations.

as much as 50% during the initial development of the instability, and then tends to fluctuate as the vortices nutate. In subsequent sections, we shall consider how the amplitude of the flux of the radiated gravity waves scales with the Froude number, with reference to the predictions made in §4.2, and in particular equation (4.28). Therefore, as a measure of the Froude number of the flow, we shall require a Froude number associated with the gravity wave generation phase of the flow, rather than the initial roll-up phase. For this reason, the maximum value of the Froude number over all times was taken to characterize the Froude number of the flow, and for each simulation this value is shown in table 4.1c.

With the values of Q_1 and Δ selected, the remaining parameter which must be adjusted is the hyperviscosity. Since it has no physical meaning, it was selected by experimentation with the simulation **A**iii, with the aim of finding the minimum value which prevented an unacceptable build-up of noise on small scales in the potential vorticity field. On the other hand, it was important to ensure that the vortices did not become axisymmetric too quickly as a result of excessive hyperdiffusion, and thereby lose their ability to radiate gravity waves. It was found that 64 Fourier coefficients were required to represent the fields at each cross stream grid level if the required level of hyperdiffusion was not to be so great as to cause the vortices to become axisymmetric after one or two nutations. With the value of the hyperviscosity ν selected, it was then adjusted between simulations so as keep $\nu k_{\max}^6 \times (\delta Q)$ constant, where $k_{\max}$ is the maximum wavenumber in the simulation, and (δQ) is the magnitude of the potential vorticity difference between the vortices and the surroundings, meaning that in all simulations it takes the same amount of time to damp out noise in the highest wave numbers on typical vortex dynamical timescales, set by the magnitude of the potential vorticity variations. For $k = 1.0$ and $(\delta Q) = 1.0$, the value of ν used is $\nu = 6.4 \times 10^{-9}$.

To accommodate the wide range of strip widths (see table 4.1a), the grid-point spacing in the cross-stream direction had to be changed between simulations. In all cases, the region of uniform potential vorticity in the strip was distributed over at least seven grid intervals, and the potential vorticity was adjusted to the background value over five grid intervals. Details of the cross-stream resolution for all simulations are given in table 4.2. For the streamwise resolution, the 64 Fourier coefficients which were used in the vortical region were frequently more than sufficient to resolve the flow in the wave region. Therefore, in addition to varying the cross-stream resolution, the streamwise resolution was also varied, as described in §4.4. The

Table 4.2: Details of numerical resolution used in all experiments. $(\Delta y)^i$ is the cross-stream grid spacing in the vortical region; Ny^i is the number of cross-stream gridpoints in the vortical region; $(\Delta y)^e$ is the cross-stream grid spacing in the wave region; Ny^t is the total number of cross-stream gridpoints; Nx^e is the number of Fourier coefficients in the streamwise direction used to resolve the wave region; Δt is the timestep.

number of Fourier coefficients used in the wave region are given in table 4.2.

4.6 Jets with moderate Rossby number and variable Froude number

In the first set of numerical experiments, to be described in this section, the Rossby number is fixed, and the effect of varying the Froude number is investigated. In all cases to be described in this section, therefore, the model is initialized with a strip in which the potential vorticity is equal to six times the background value. This can be regarded as fixing the Rossby number at 5. The Froude number then is varied by varying the width of the strip.

Six simulations were performed with the potential vorticity in the strip equal to six times the background value. Initial strip widths of 0.018, 0.035, 0.07, 0.14, 0.21, and 0.28 were used. The corresponding Froude numbers found in the subsequent evolution varied from 0.11 to 0.67, increasing monotonically as the initial strip width increased.

Figure 4.1 shows the potential vorticity field during the initial development and saturation of the instability in the simulation **A**i. All potential vorticity plots are shown with an aspect ratio of unity, and consequently they show only a small portion of the domain in the cross-stream direction. While the model domain accomodates only one wavelength of the primary instability in the streamwise direction, in figure 4.1, and in all subsequent figures shown, two periods of the model domain are displayed.

In figure 4.1, one can see that, as the instability develops, waves develop on the edges of the potential vorticity strip, which can be seen clearly in figures 4.1b and 4.1c. Nonlinear saturation of the instability is shown in figure 4.1d, where the strip has rolled up into a train of coherent vortices, connected by thin filaments.

Figure 4.2 shows the potential vorticity field at four subsequent equally spaced time intervals until the end of the simulation. Although a small amount of hyperdiffusion is applied in the x–direction to prevent an accumulation of noise on the grid scale of the numerical model, it seems that the inviscid character of the vortical flow has been well simulated in this experiment. The vortices appear to nutate between almost axisymmetric and substantially elliptical shapes, whereas if the hyperviscosity is increased significantly they become axisymmetric after only two or three rotations. It is possible that the presence of background shear in the experiment is

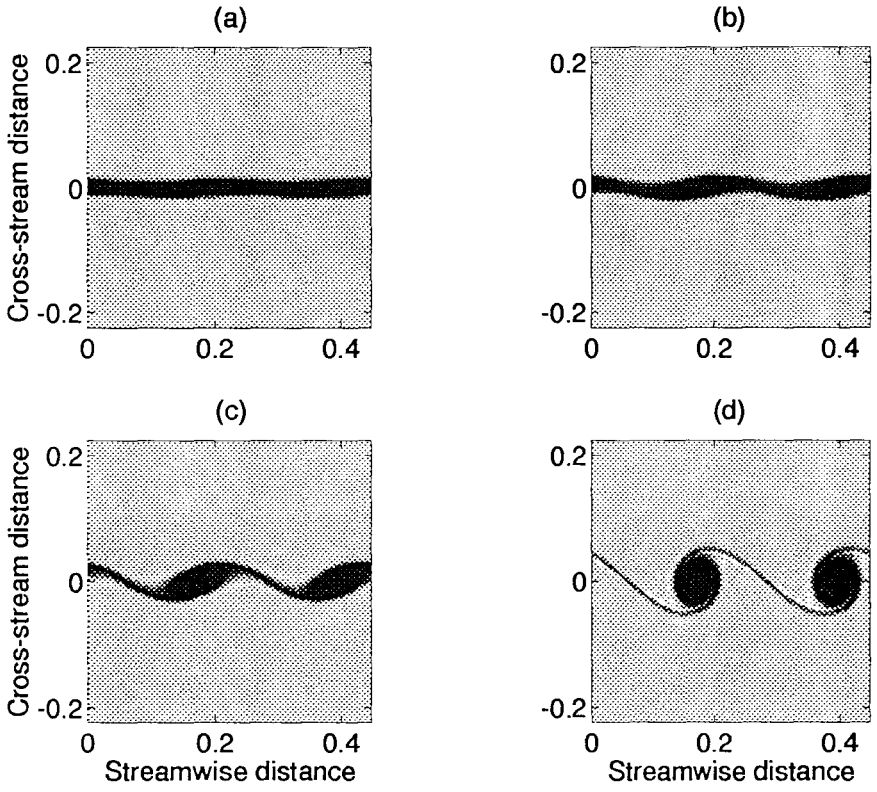

Figure 4.1: Early stages of potential vorticity evolution, simulation Ai. Figures a,b,c,d correspond to times 1.56, 2.81, 4.06 and 5.31 respectively. Two periods of the model domain are shown.

responsible for this nutating behaviour, as proposed by Kida (1981). The filamentary structure appears to have been almost completely smeared out after one rotation of the vortices.

Linear gravity waves have zero potential vorticity perturbation, and so they are not observed in the potential vorticity plots shown in figures 4.1 and 4.2. However, we recall from (4.6) that, in the absence of nonlinearity, the Eulerian time derivative of the height field, $\partial h/\partial t$, satisfies the linear wave equation for gravity waves, i.e.

$$\left(\frac{\partial^2}{\partial t^2} + f^2 - c_0^2\nabla^2\right)\frac{\partial h}{\partial t} = \text{nonlinear terms.} \tag{4.31}$$

It is therefore natural to use $\partial h/\partial t$ to investigate gravity waves radiated by the shear instability. For each of the times shown in figure 4.2, the corresponding $\partial h/\partial t$ field is shown in figure 4.3. Only the region $y > 0$ is shown, since all simulations are symmetric about $y = 0$. The entire computational domain for $y > 0$ is shown in all plots of $\partial h/\partial t$. In figure 4.3, to show the entire computational domain requires that the cross-stream direction be compressed compared with the streamwise direction. As in the case of the potential vorticity field, two periods of the model domain in the streamwise direction are shown in all plots of $\partial h/\partial t$. The colourmap is chosen to saturate at the peak amplitudes in the wave region, even though typical values of $\partial h/\partial t$ in the vortical region may be more than 10 times greater than those found in the wave region. No quantitative information should be inferred from the the greyscale plots of $\partial h/\partial t$ shown in this chapter. We shall address the quantitative aspects of the gravity wave radiation when we compare the waves generated with those predicted by the Lighthill theory, and discuss the way in which the amplitude of the radiating wave fluxes depend on the Froude and Rossby numbers of the vortical flow.

In the greyscale figure 4.3, however, two features of the radiated gravity wave field are nonetheless particularly striking. Firstly, the wavelength of the gravity waves is much longer than the cross-stream scale of the vortical motions. Secondly, the radiated gravity wave field is almost independent of the streamwise coordinate x. This means that we should expect the reconstruction of the gravity wave field from the Lighthill source term to be quite good for this simulation.

Figure 4.4 shows the source function $S(t)$ for simulation **Ai**, computed from (4.8). During the growth phase of the instability, $S(t)$ remains almost zero, and only becomes significant during the subsequent rotation of the vortices in the train.

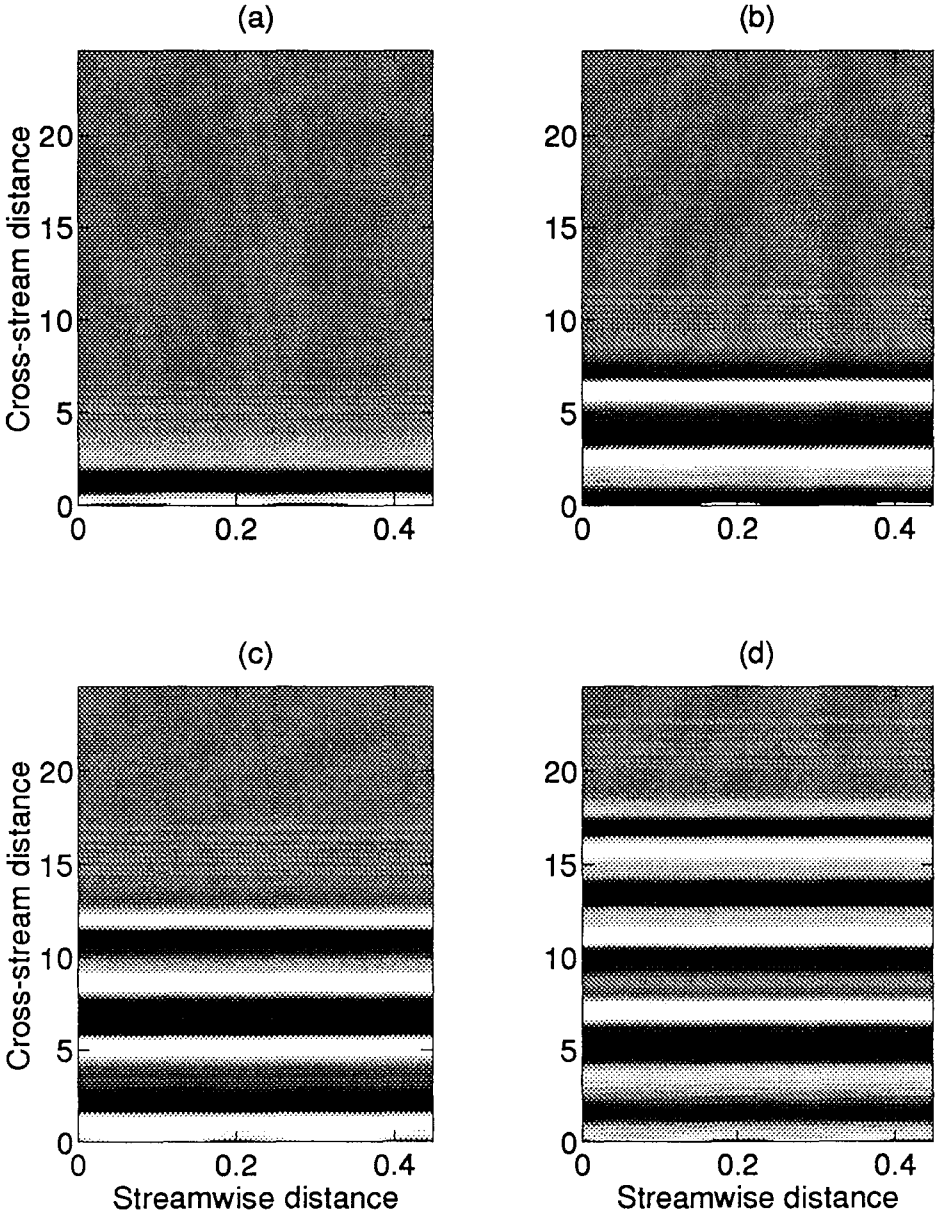

Figure 4.3: Development of gravity wave radiation, simulation Ai. Figures a,b,c,d correspond to times 6.56, 12.2, 17.8 and 23.4 respectively. Two periods of the model domain are shown.

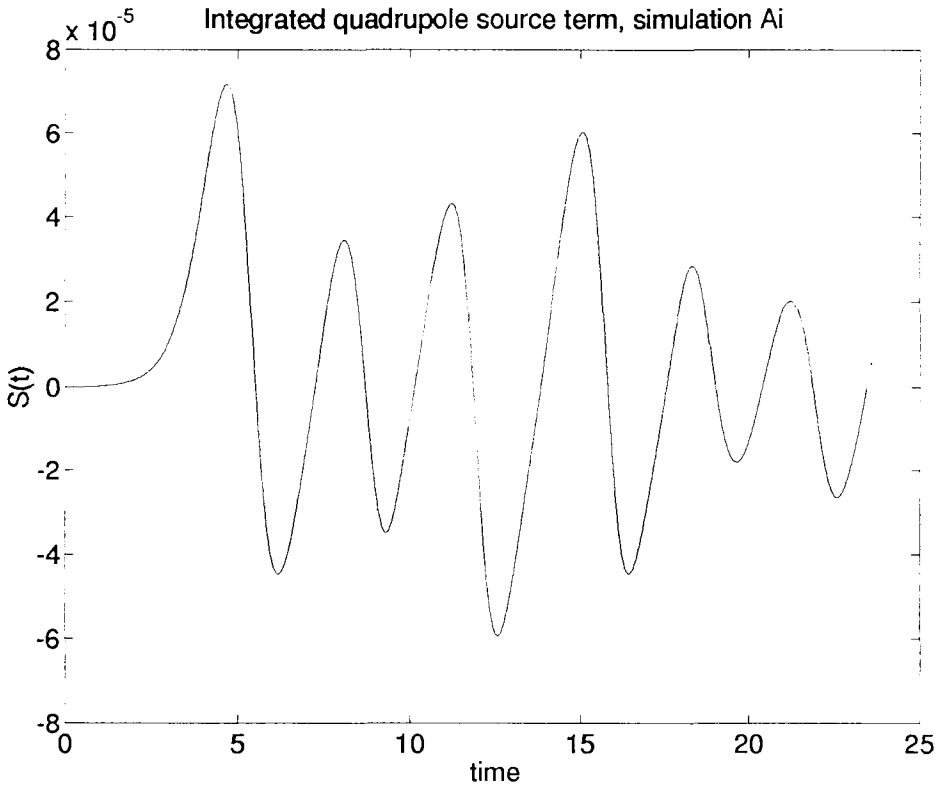

Figure 4.4: Integrated quadrupole source term, $S(t)$, for simulation **Ai**

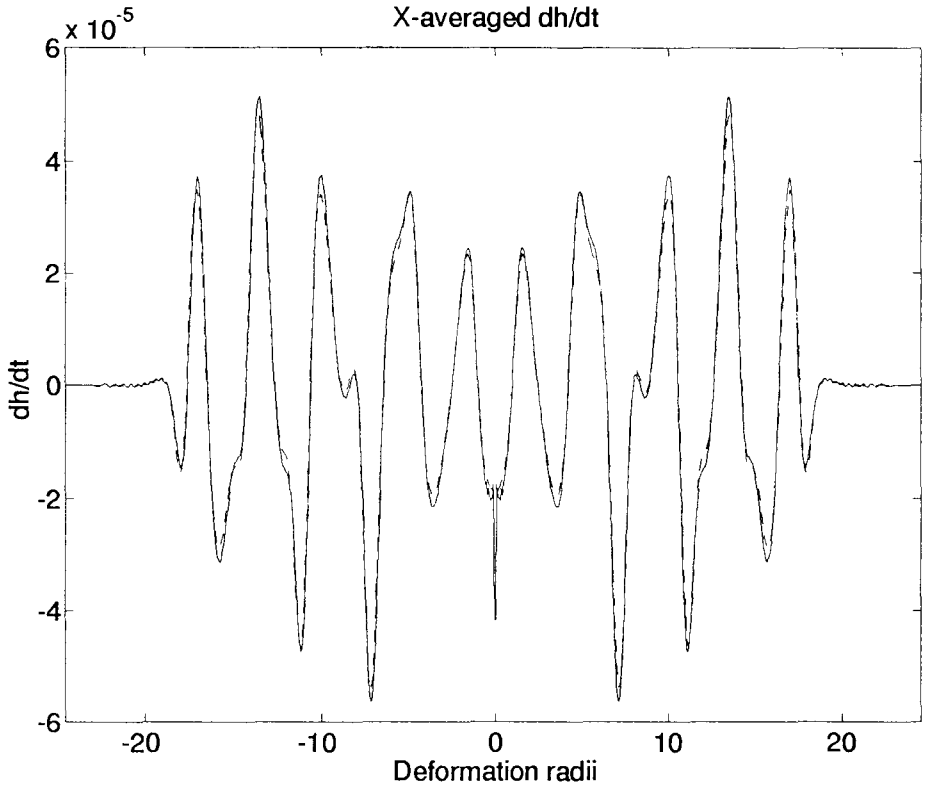

Figure 4.5: Comparison of x–averaged $\partial h/\partial t$ field at termination of simulation **Ai**: solid line is from nonlinear simulation, dashed line is reconstruction from Lighthill convolution integral

In figure 4.5, the x–averaged $\partial h/\partial t$ field is shown at the termination of simulation **Ai**. The solid line in figure 4.5 is the x–average of the height field obtained directly from the nonlinear simulation. The dashed line in figure 4.5 is the result of using the source term $S(t)$, shown in figure 4.4, in (4.7), and is therefore the wave field predicted by this modified form of the Lighthill theory, using the actual velocity and height fields from the simulation to evaluate the source term. For this simulation, the agreement between the full simulation and the Lighthill reconstruction seems very good. This is reassuring, partly because the Froude number is quite small, and the compact source approximation should be reasonably accurate for this flow; and partly because it means that the numerical model is performing sufficiently well to capture the Lighthill mechanism, and that the resolution employed is adequate to reconstruct the Lighthill source term for the convolution integral (4.7).

Figures 4.6 and 4.7 show the potential vorticity and $\partial h/\partial t$ respectively from simulation **Aii** at four equally spaced time intervals during the simulation, and figures 4.8 and 4.9 show the

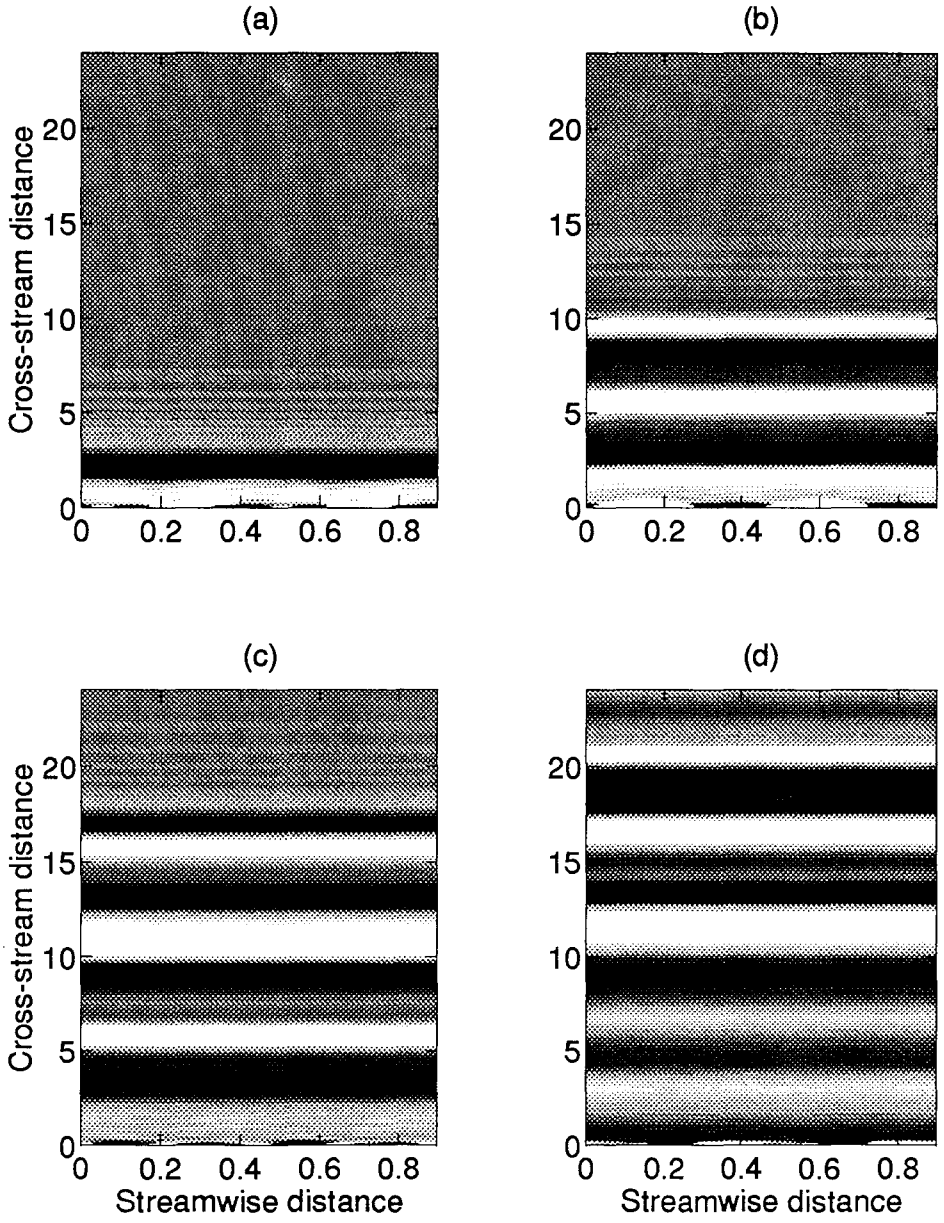

Figure 4.7: Development of gravity wave radiation, simulation Aii. Figures a,b,c,d correspond to times 6.9, 15.0, 23.1 and 31.2 respectively. Two periods of the model domain are shown.

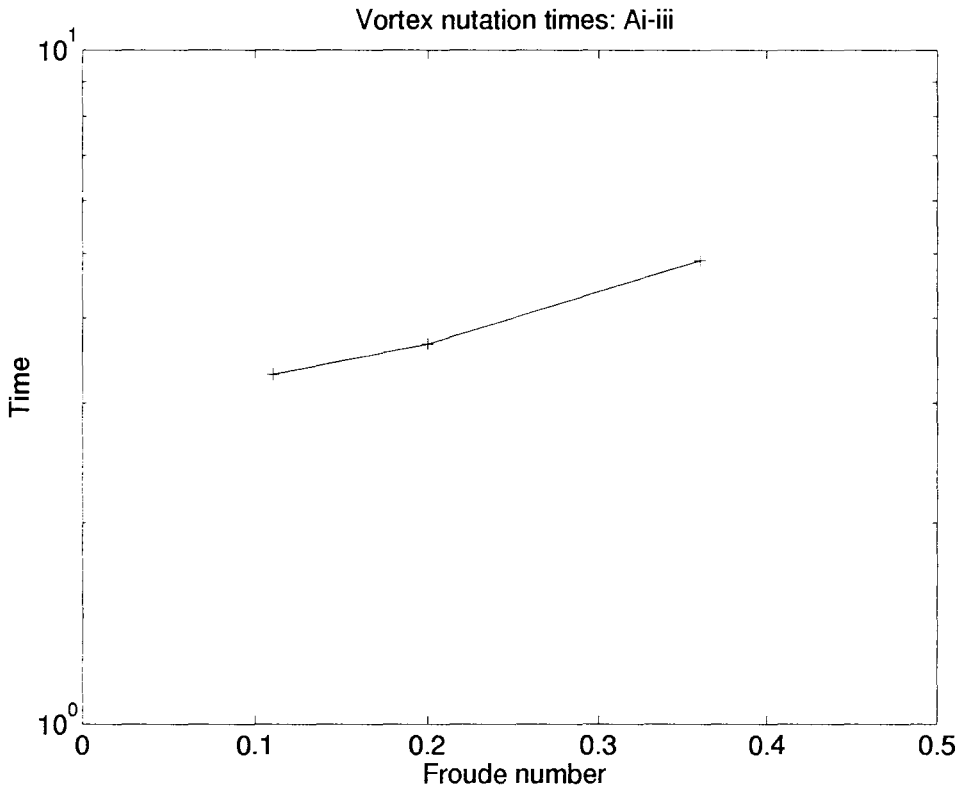

Figure 4.10: Vortex nutation times: simulations Ai-iii

same fields respectively for simulation Aiii.

On visual inspection, there appears to be little difference in the vortical aspects of the dynamics between each of the three simulations Ai–iii. In each case, the strip of high potential vorticity rolls up into a periodic train of vortices, which subsequently nutate. The only perceptible difference is in the nutation time, shown in figure 4.10, which increases from 3.44 inertial periods (simulation Ai) to 4.88 inertial periods (simulation Aiii). The vortex nutation times are a significant feature of the flow, in that they are a broad measure of the degree of unsteadiness of the vortical flow compared with the unit inertial period.

Considering now the gravity wave aspects of the flows Aii and Aiii, we see from figures (4.7) and (4.9) that the form of the radiated gravity waves remains similar in these two cases to those observed in simulation Ai. In figure 4.11, the x-averaged $\partial h/\partial t$ field at the end point of each of the numerical simulation is represented by the solid lines, and its reconstruction using the compact source approximations is shown by the dotted lines. The agreement seems to be

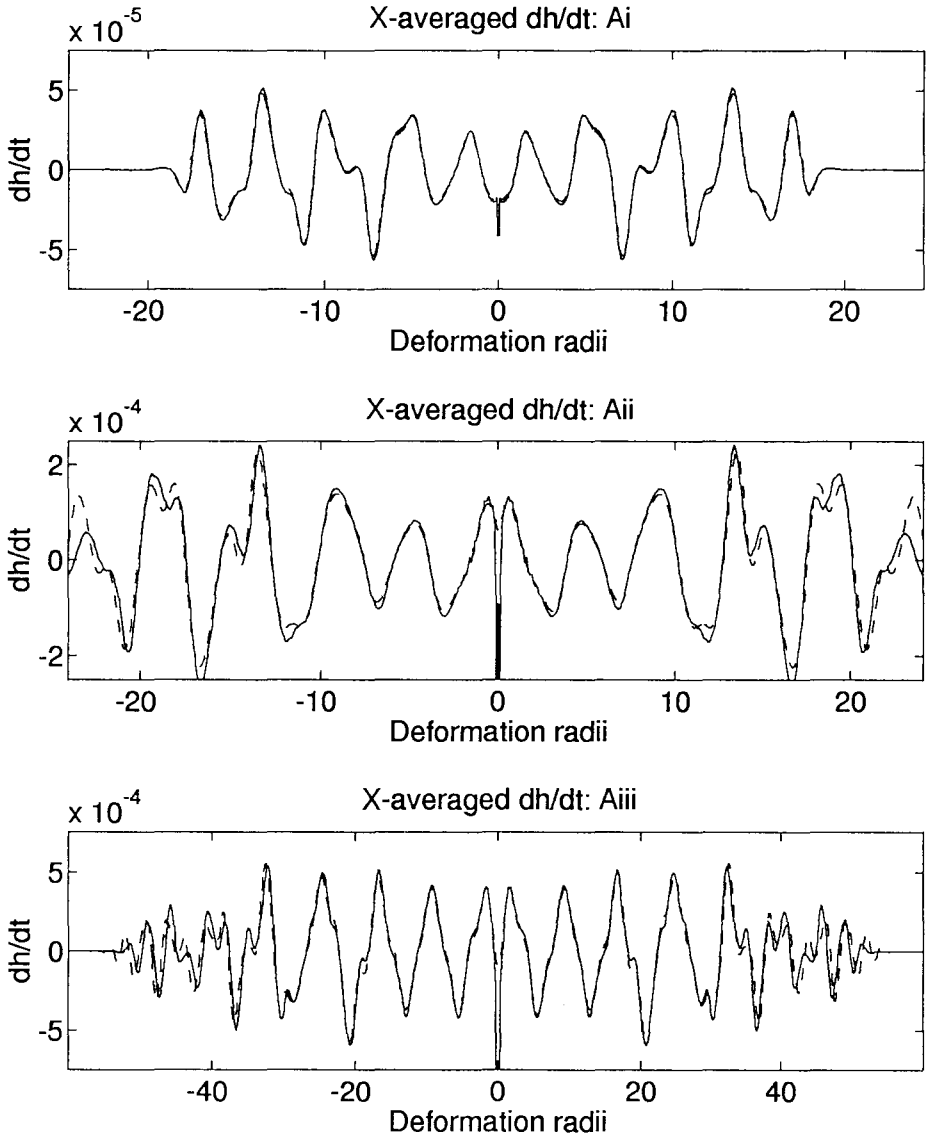

Figure 4.11: The x–averaged $\partial h/\partial t$ field at the termination of simulations Ai-iii. Solid lines are from the nonlinear simulation, and dashed lines are from the Lighthill convolution integral

quite good in each case.

From figure 4.11, we can also see that the amplitude of the radiated gravity waves increases by a factor of about 12 between **A**i and **A**iii. The maximum Froude number found in the evolution increases from 0.11 (**A**i) to 0.36 (**A**iii) (see table 4.1c). However, we should recall from (4.10) that, as the Froude number is increased, we expect the amplitude of the radiated gravity waves to increase as the third power of the Froude number. Thus, on the basis of the low Froude number asymptotic analysis, we should expect the gravity wave amplitude to change by a factor of 35. Evidently, the increase in gravity wave amplitude as a function of Froude number over this range is not as large as one might expect on the basis of the Lighthill theory. Two assumptions were made to predict that the amplitude of the radiated waves would scale with the third power of the Froude number – the point source assumption, and the scaling assumption $u \sim \omega l$. The fact that the wave amplitudes do not increase as rapidly as the theory predicts is thus not necessarily an indication that the point source approximation will fail for these simulations.

Three further simulations (**A**iv – **A**vi) were then performed, with strip widths of 0.14, 0.21, and 0.28. The vortical aspects of the flow remained qualitatively unchanged as the width of the strip, and hence the Froude number, was increased. In each case, the strip initially rolled up into a periodic train of vortices, which were allowed to rotate several times before the simulation was terminated. The most significant quantitative difference in the vortical aspects of the flow between these three cases is in the nutation rate of the vortices in the train, shown in figure 4.12, which increase super-exponentially with increasing Froude number.

Figure 4.13 shows the $\partial h/\partial t$ field at the termination of the simulations **A**iii–**A**vi. The main point is that, as the Froude number is increased, the radiated gravity waves develop more x–dependent structure. The gravity wave field is expected to be x–independent at low Froude numbers, and it is reasonable to expect more x–dependence in the field as the Froude number is increased, as the lengthscale separation between the vortices and the gravity waves diminishes.

Figure 4.14 shows the x–averaged $\partial h/\partial t$ field at the termination of simulations **A**iii-vi, and its reconstruction from the Lighthill source term. The most striking feature of the sequence of figures is that, in contrast to the rapid increase in wave amplitude with Froude number predicted by Lighthill's scaling argument, the radiated wave amplitudes actually decrease. This clearly differs from the scaling arguments presented by numerous authors on aeroacoustics, which were

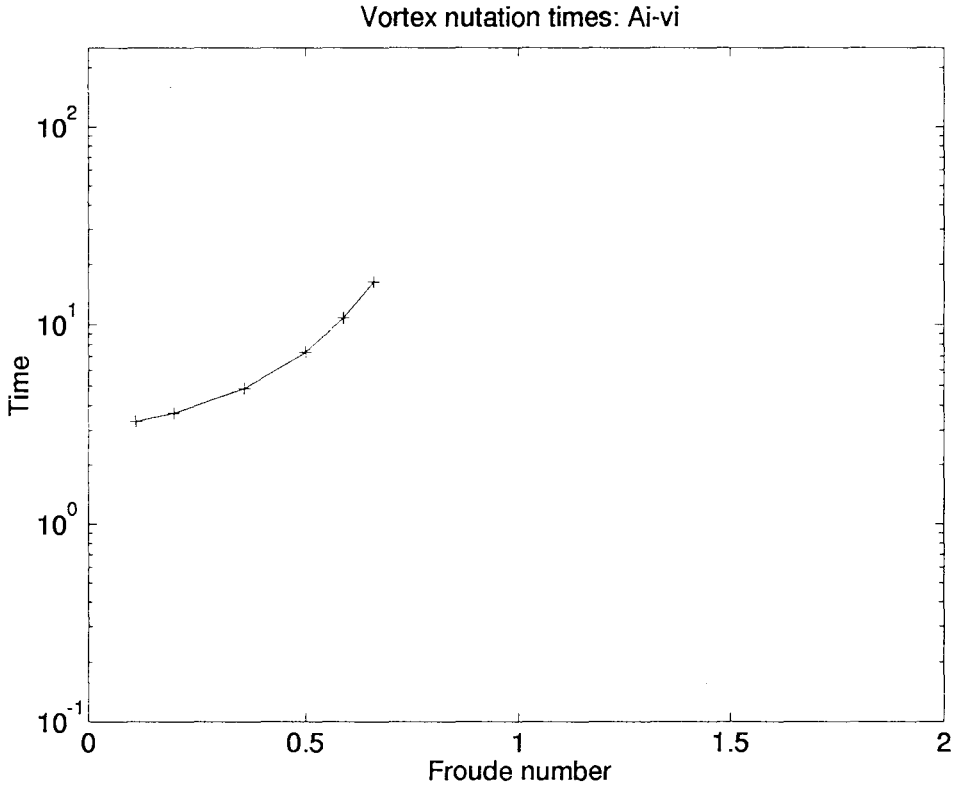

Figure 4.12: Vortex nutation times: simulations Ai-vi

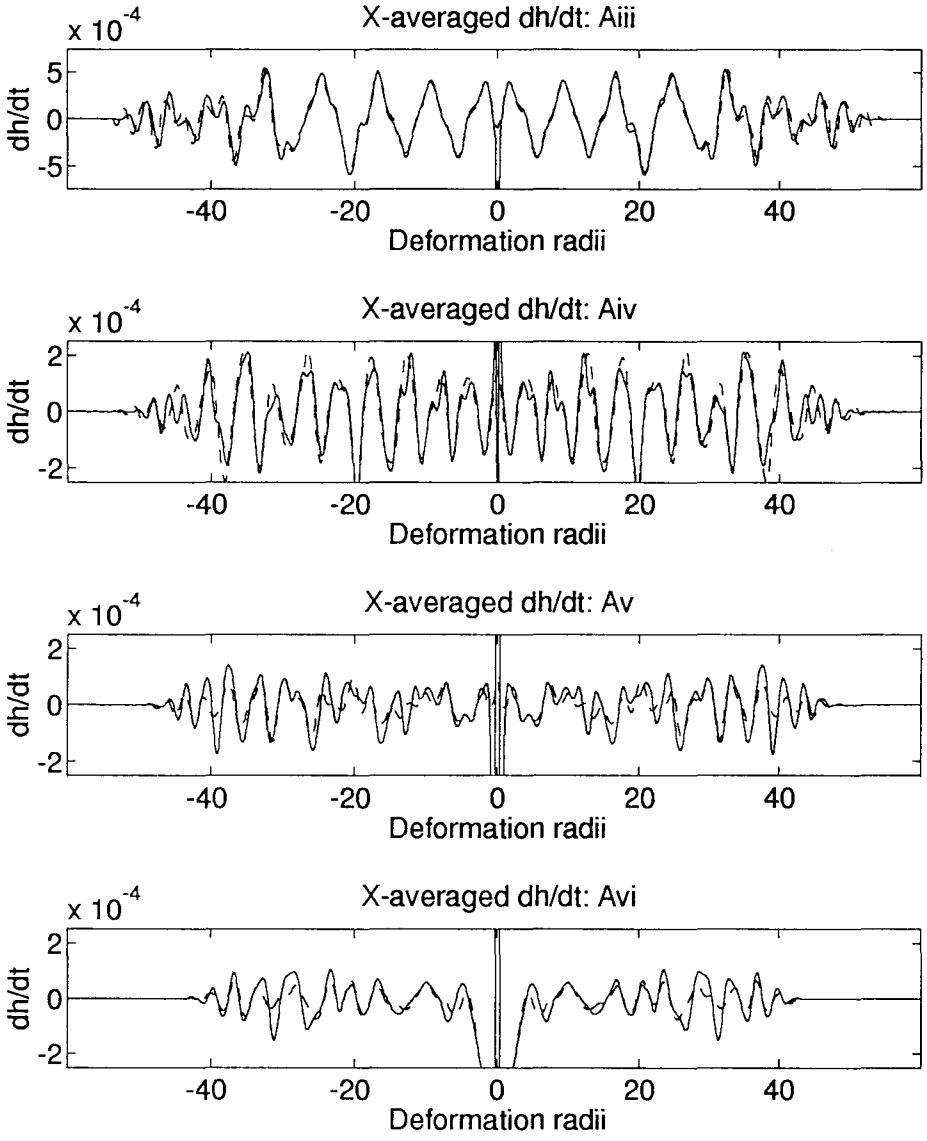

Figure 4.14: The x–averaged $\partial h/\partial t$ field at the end of simulations **A**iii-vi

discussed at the beginning of this section, and from the mass of experimental data that confirm the Lighthill scaling in practice.

Since the only new effect in the present study is the inclusion of background rotation, it follows that background rotation must be responsible for decreasing the wave amplitude as the Froude number is increased. Moreover, since the reconstruction of the wave field from the Lighthill source term effectively captures the decrease in wave amplitude, it must be explicable within the framework of the Lighthill theory.

There are two possibilities. One is that the quadrupole source strength decreases, rather than increases, as the Froude number is increased. However, we should bear in mind that in order for the quadrupole source to excite propagating waves, it must have a significant component of its frequency above the inertial frequency. Therefore, it is possible that, although the magnitude of the source terms might actually increase as the Froude number is increased, their frequency component above the inertial frequency might decrease.

Figure 4.15 shows the integrated source term for each of the simulations **A**i–vi. In general, the amplitude of the source term increases with increasing Froude number, but with frequency decreasing very rapidly with increasing Froude number. It seems, therefore, that the effect of the inertial cut-off, inhibiting gravity wave radiation at frequencies below the inertial frequency, is now dominant over the increased magnitude of the source term, leading to reduced wave amplitudes as the Froude number is further increased.

We may conclude that, although the potential vorticity in the strip was chosen to be six times the background value, both the vortical flow and the wave generation process are significantly affected by the presence of background rotation. For very small Froude numbers (between 0.11 and 0.35), the amplitude of the radiated gravity waves increases with Froude number, although not quite as rapidly as F^3, as found in the asymptotic limit $F \ll 1$. When the Froude number exceeds 0.35, however, the radiated gravity wave amplitudes are found to decrease with increasing Froude number, even though the typical amplitudes of $S(t)$ are generally increasing. This behaviour has never been found in numerical or laboratory experiments in a non-rotating frame. The presence of background rotation thus severely inhibits gravity wave radiation at moderate Rossby numbers, and there seems little doubt that the present study has investigated a case in which the effect of background rotation is quite strong, despite a notional Rossby number of 5. Therefore, in the next section, we investigate the effect of increasing the potential

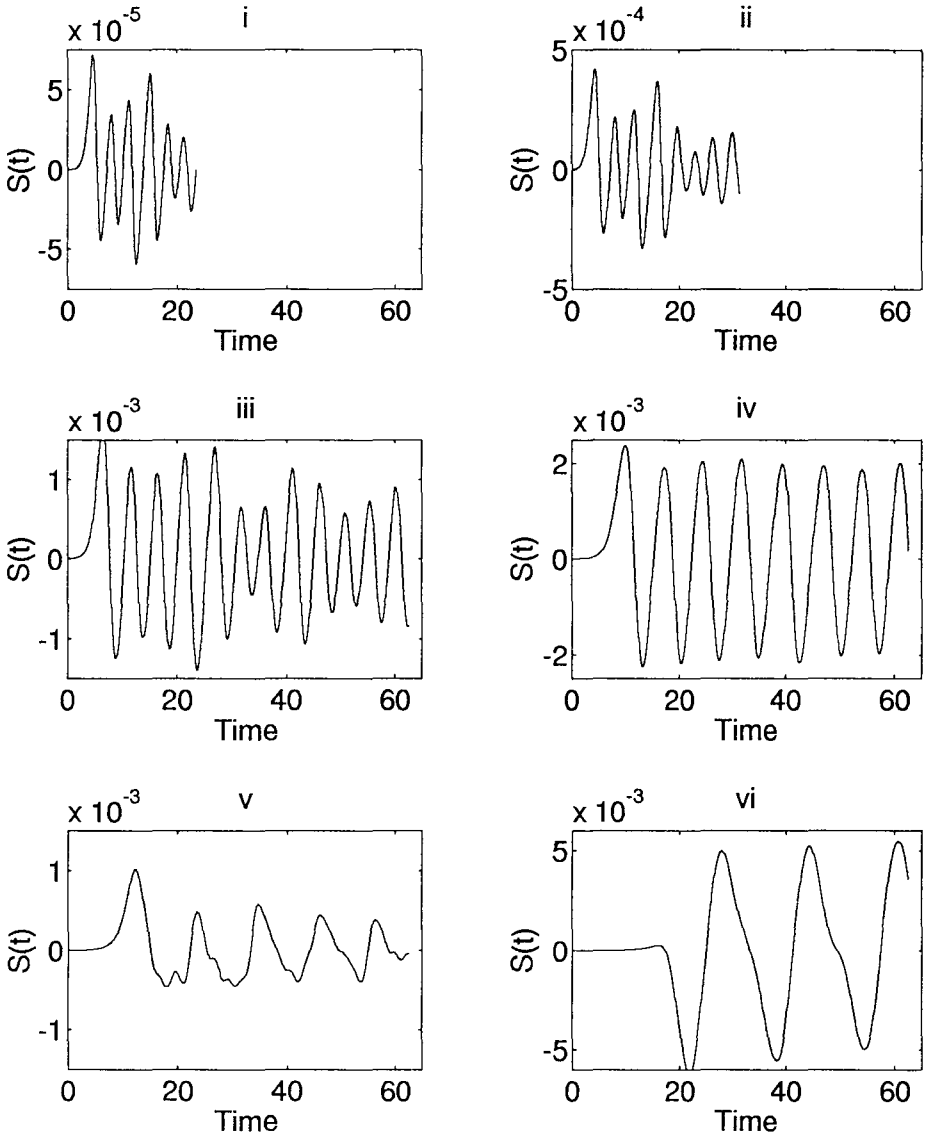

Figure 4.15: The source term $S(t)$ for simulation **A**i-vi. Note the differing scales on the $S(t)$ axes.

vorticity in the strip. The strip remains cyclonic, but the effect of background rotation should decrease as the potential vorticity in the strip increases.

4.7 Cyclonic strips at large Rossby number

In this section the results of simulations with strip potential vorticities of 9 and 21 are presented. There are four simulations with strip potential vorticity of 9, and four with strip potential vorticity of 21. The simulations with strip potential vorticity of 9 are labelled **B**i–iv, and those with strip potential vorticity of 21 are labelled **C**i–iv. In neither set of simulations should we expect to observe any qualitative difference from the simulations with potential vorticity of 6 in the strip. Quantitatively, we should expect to see more rapid vortical motions, and consequently a larger pseudoenergy flux in the radiated wave field.

In simulations **B**i–iv, the initial strip widths are 0.018, 0.035, 0.07 and 0.21, resulting in Froude numbers of 0.17, 0.32, 0.53 and 0.84 respectively. In each case, the strip rolled up into a periodic train of vortices, which then nutated, radiating gravity waves. The vortical flow appeared very similar to that observed in experiments **A**i–vi, and potential vorticity plots are not shown here. The nutation periods for these vortices are shorter than for the corresponding simulations in sequence **A**, but still appear to increase super-exponentially with Froude number (figure 4.16), in common with sequence **A**.

In figure 4.17, the $\partial h/\partial t$ field is shown for the end of each simulation **B**i–iv. The wave field follows broadly the same pattern as in the lower Rossby number simulations **A**i-vi. At small Froude numbers, the wave field is almost independent of x, and as the Froude number is increased, amplitudes of the x–dependent modes increase.

In figure 4.18, the x–independent wave field is shown at the end of each simulation (solid line), and compared with its reconstruction from the Lighthill theory (dashed line). Overall, there is good agreement between the Lighthill theory and the numerical simulations, as there was in the lower Rossby number simulations **A**i–vi. As before, the agreement is best when the Froude numbers are lowest. The radiated wave amplitudes are seen to increase with increasing Froude number for simulations **B**i–iii, but then decrease between **B**iii and **B**iv. The corresponding pseudoenergy fluxes are shown in figure 4.19, and the maximum pseudoenergy flux in the radiated wave field for simulations **A** and **B** is shown in figure 4.20. Notice in figure 4.19 that

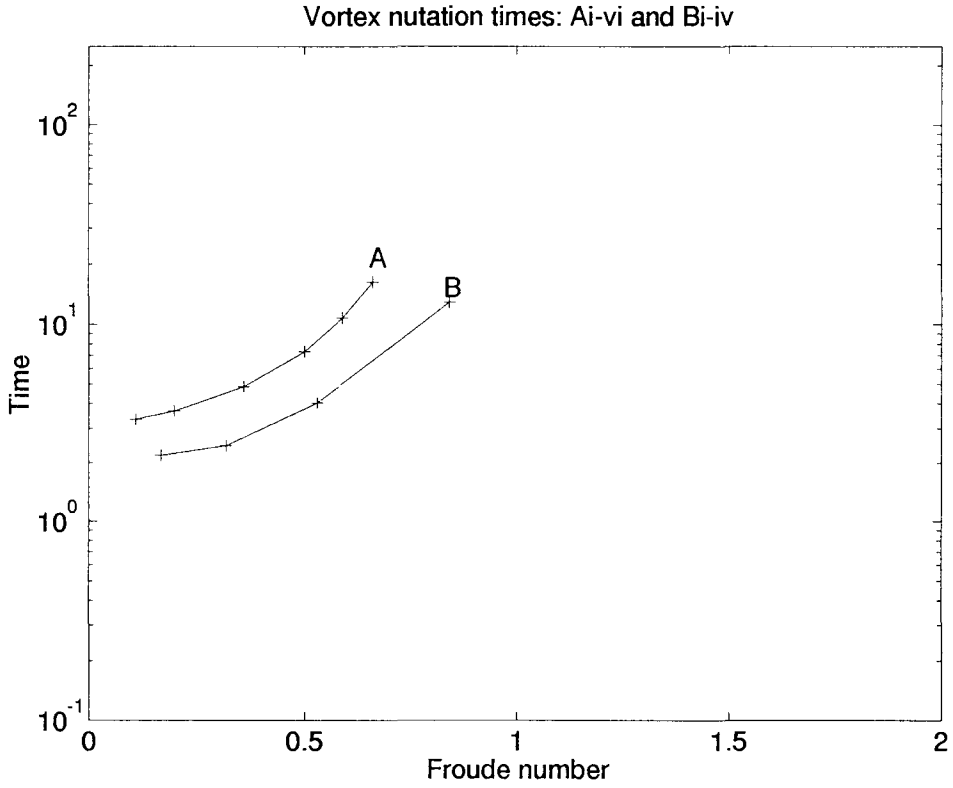

Figure 4.16: Vortex nutation times: simulations Bi-iv

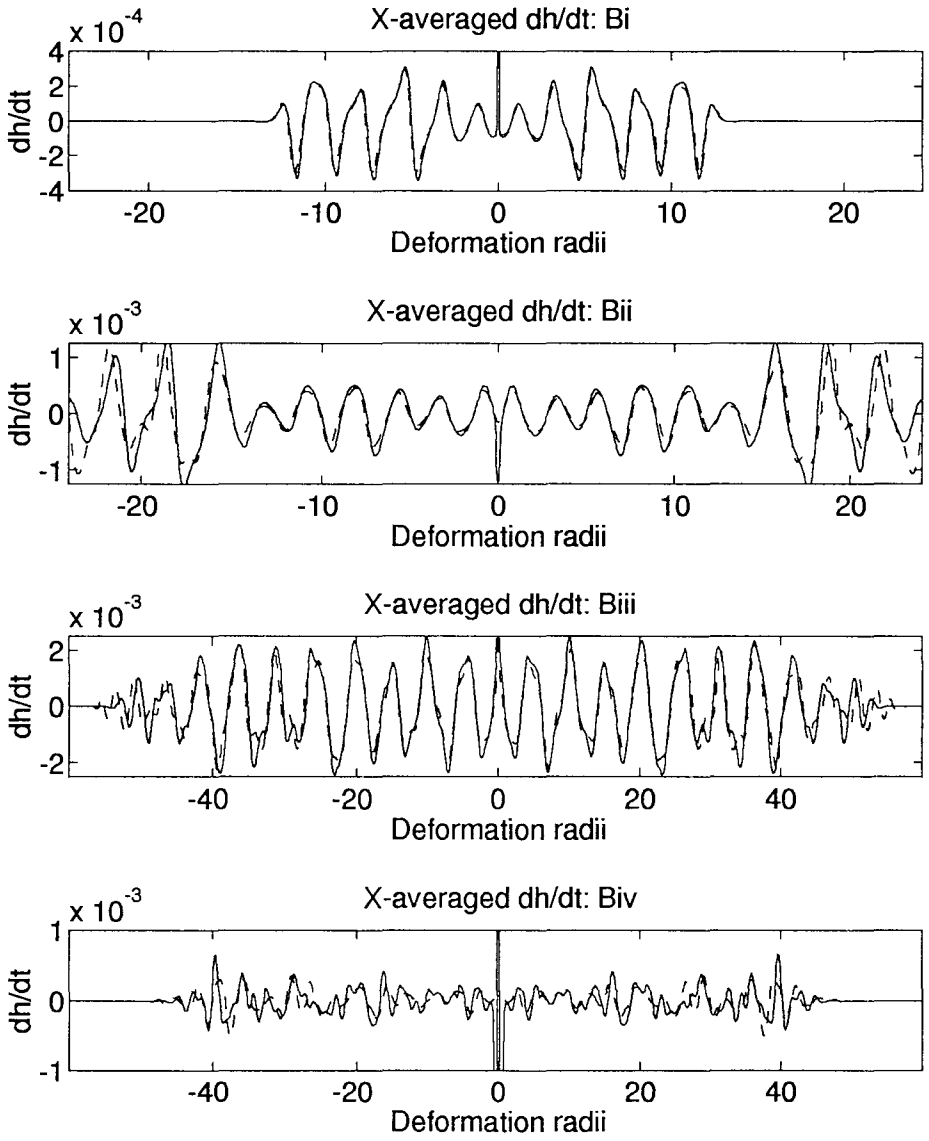

Figure 4.18: The x–averaged $\partial h/\partial t$ field at the termination of simulations **B**i-iv. Solid lines are from the nonlinear simulation, and dashed lines are from the Lighthill convolution integral

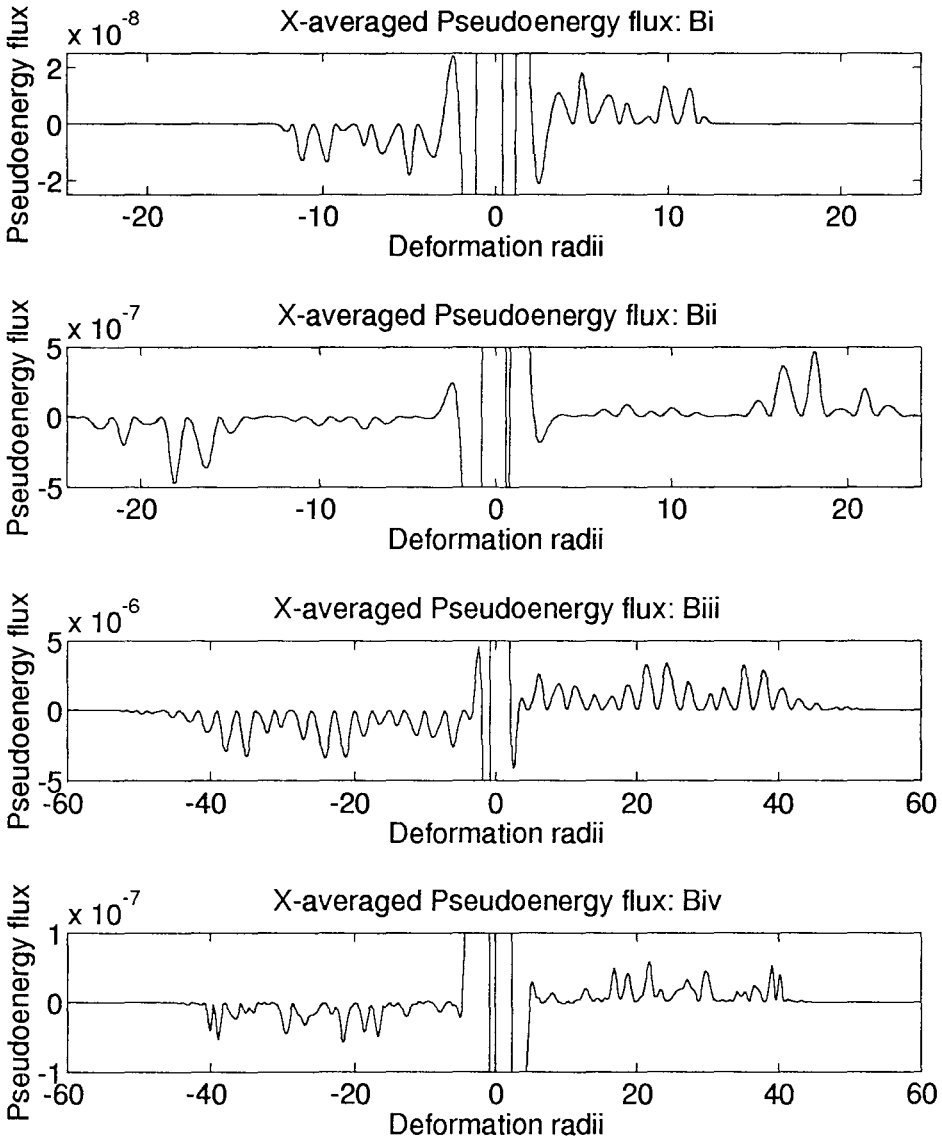

Figure 4.19: The x–averaged pseudoenergy flux at termination of simulations Bi-iv

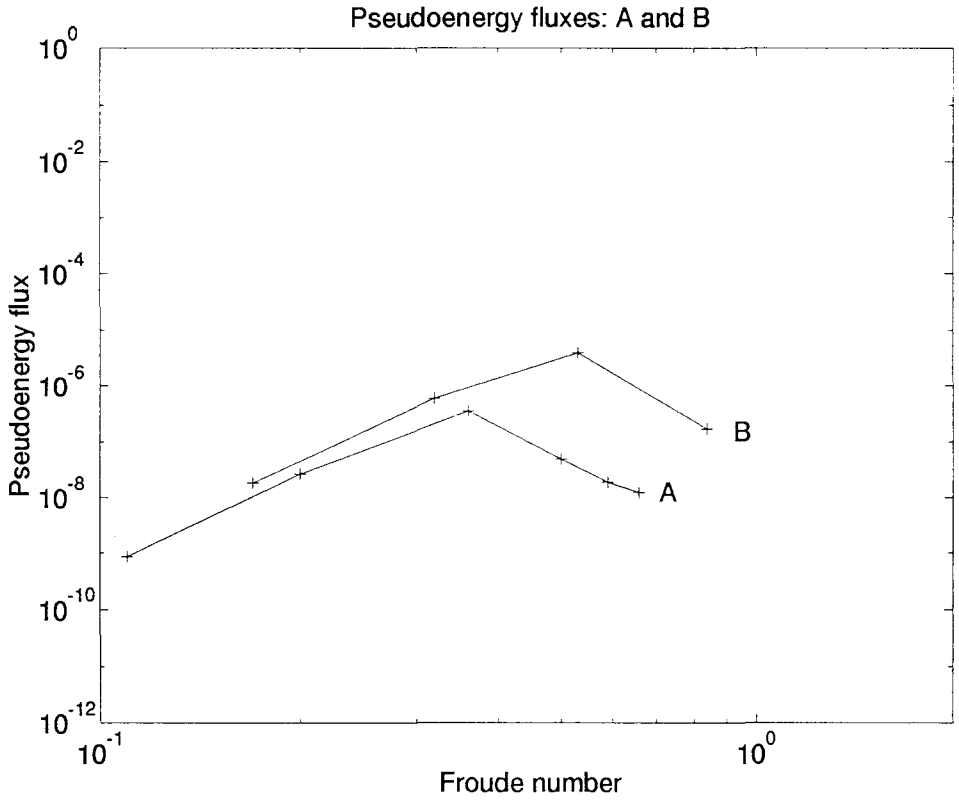

Figure 4.20: The peak pseudoenergy flux due to gravity wave radiation throughout simulations **A** and **B**

the pseudoenergy fluxes are negative for $y < 0$, and positive for $y > 0$, confirming that the flux of pseudoenergy away from the vortical flow at $y = 0$ is single-signed, as demonstrated by the analysis of §4.3.

The Froude number at which the maximum pseudoenergy flux occurs is greater in case **B** than in case **A**, but the strip width at which the transition from increasing to decreasing pseudoenergy fluxes appears to be about the same, at around 0.1.

Overall, increasing the potential vorticity in the strip from 6 to 9 has the effect of increasing the amplitude of radiated gravity waves. However, in both cases, there exists a Froude number (or equivalently a strip width) which is in some sense optimal for gravity wave radiation. The amplitude of the x–averaged flux of radiated gravity waves increases with increasing Froude number up to this critical Froude number, but then decreases as the Froude number is increased further. This property appears to be specific to flows in a rotating frame, and is due to the reduced unsteadiness of the vortical flow at larger Froude numbers, manifested in the rapidly increasing nutation times at larger Froude numbers, combined with the inhibiting effect of the inertial cut-off frequency on gravity wave radiation. It has not been observed in non-rotating aeroacoustic experiments or simulations.

Four further experiments were then performed with a strip potential vorticity of 21. The experiments are labelled **C**i–iv. These correspond to initial strip widths of 0.011, 0.021, 0.041 and 0.081 respectively. Once again, in each case the strip rolls up into a periodic train of vortices, which then nutate several times before the simulation is terminated. The dependence of the nutation time upon the Froude number is shown in figure 4.21, and is consistent with the behaviour found in experiments **A** and **B** – i.e., it appears to be increasing super-exponentially with Froude number.

The $\partial h/\partial t$ field at the end of each simulation is shown in figure 4.22, and again has similar properties to those for simulations **A** and **B**, although at the largest Froude number simulated smaller scale features seem to appear in the $\partial h/\partial t$ field. The comparison of the x–averaged $\partial h/\partial t$ field with its reconstruction by the Lighthill theory is shown in figure 4.23, and again good agreement is generally obtained. Indeed, it seems that the agreement improves as the Rossby number is increased, when compared with simulations **A**i-vi and **B**i-iv. Even in simulation **C**iv, in which the Froude number exceeds unity in the vortical region, the general form of the radiated wave field is captured by the Lighthill theory, although the fine details are not captured

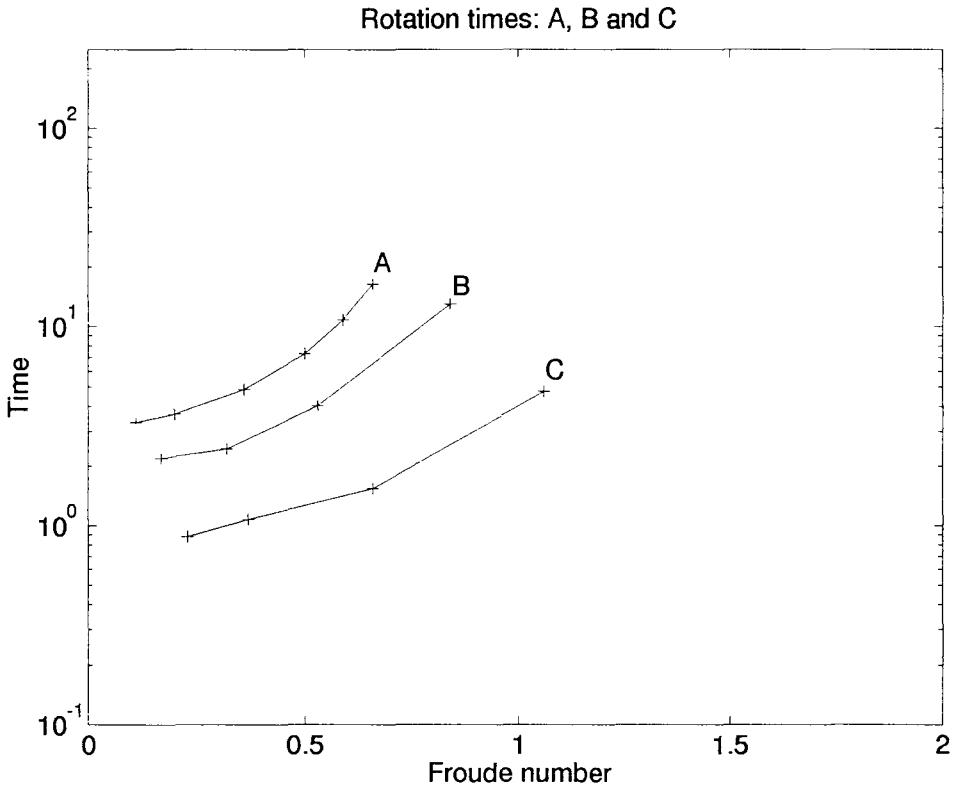

Figure 4.21: Vortex nutation times for simulations Ci-iv

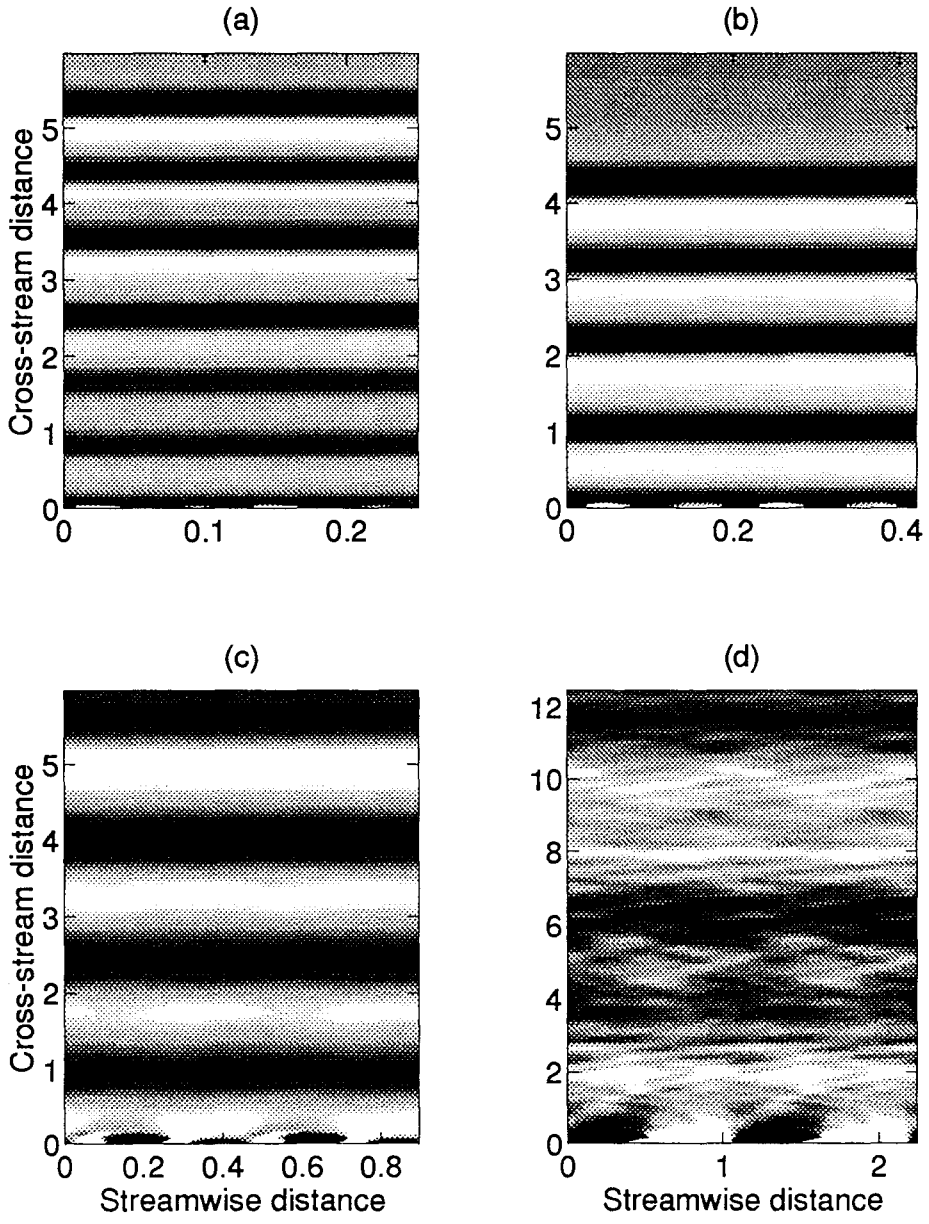

Figure 4.22: The field $\partial h/\partial t$ at the termination of the simulations Ci-iv. Two periods of the model domain are shown.

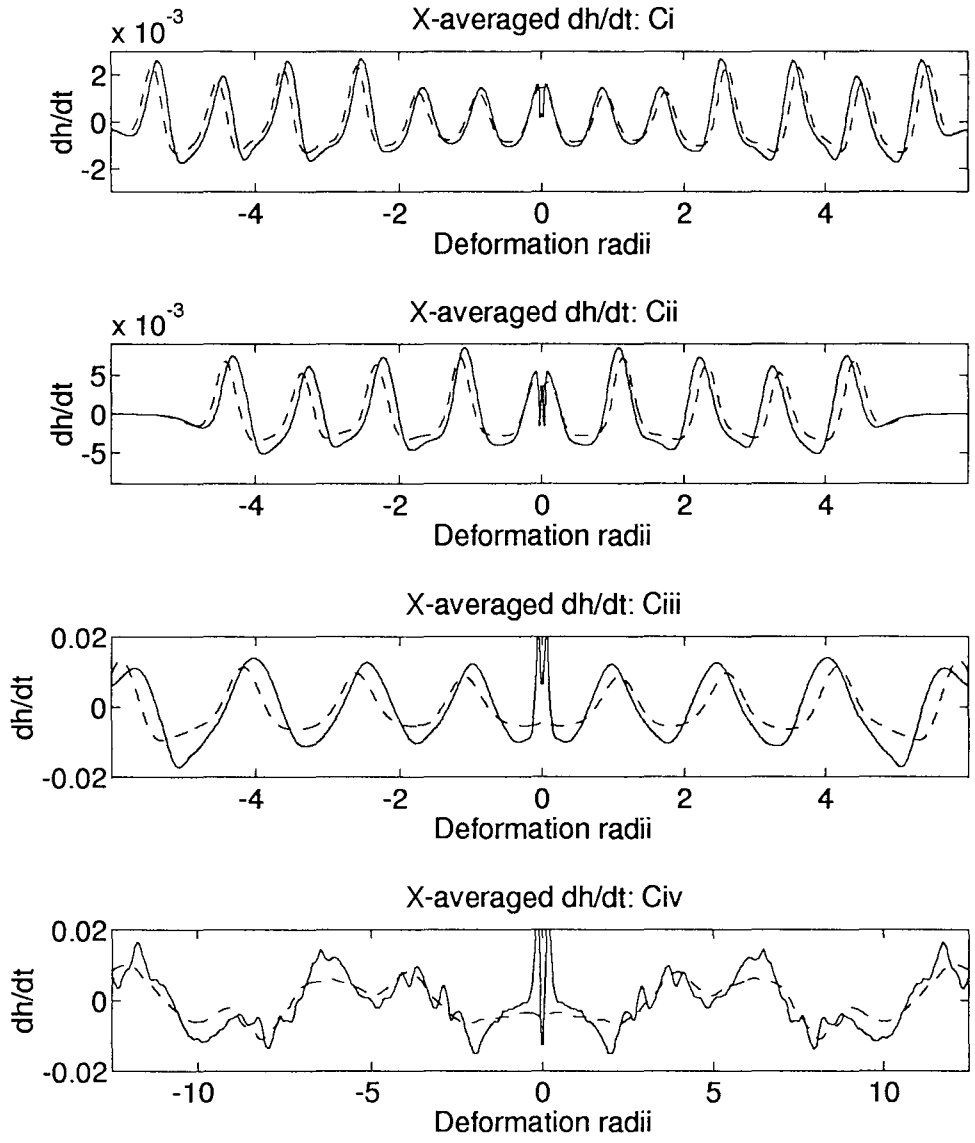

Figure 4.23: The x-averaged $\partial h/\partial t$ field at the termination of simulations Ci-iv (solid lines), and its reconstruction from the Lighthill convolution integral (dashed lines)

by the Lighthill theory.

The pseudoenergy flux at the end of each simulation is shown in figure 4.24. In this case, the pseudoenergy flux appears to be increasing as the Froude number is increased, unlike simulations **A** and **B**, where it decreased as the Froude number was increased beyond a certain critical value. It is interesting to note that in simulation **C**iv the x–averaged pseudoenergy flux appears to be a smoother measure of wave radiation than the x–averaged $\partial h/\partial t$ field, shown in figure 4.23.

In figure 4.25 the maximum x–average pseudoenergy flux over all time in the wave region for each simulation is plotted against Froude number, for the sequences of simulations **A**i–vi, **B**i–iv and **C**i–iv. The dashed line is a line of gradient 6 on the log-log scale, which would be predicted by the compact source asymptotics (equation 4.28). In all cases the pseudoenergy flux increases as the sixth power of the Froude number at small Froude number but, as the Froude number is increased, the pseudoenergy flux increases less rapidly with increasing Froude number. It seems plausible from figure 4.25 that the very large Rossby number simulations **C** will exhibit an optimal Froude number for gravity wave radiation, in the same manner as simulations **A** and **B**, but that it exceeds the values of Froude number investigated by the nonlinear simulations.

From this section, we may conclude that several of the features exhibited by the strips with a potential vorticity of 6 are robust features of cyclonic strip roll-up, subsequent nutation and gravity wave radiation. In particular, the nutation time increases super-exponentially with increasing Froude number. In general the pseudoenergy flux associated with the radiating gravity waves increases with the sixth power of the Froude number at small Froude number, but ultimately decreases as the Froude number is made very large, due to the increased nutation times, and consequently reduced fraction of the effective gravity wave source spectrum lying above the inertial frequency.

It is important to realize at this point that thus far only cyclonic strips have been investigated in this study. All cyclonic strips appear to exhibit similar behaviour, in respect of their vortex nutation times and pseudoenergy flux dependences upon the Froude number. In the remainder of this chapter, we shall investigate gravity wave generation by anticyclonic vortex trains, and compare it with that found for the cyclonic cases. The anticyclonic parameter space is divided into three parts: strips with positive potential vorticity, strips with negative potential vorticity, and the single case of a strip with a potential vorticity of zero. In the next section, §4.8, we

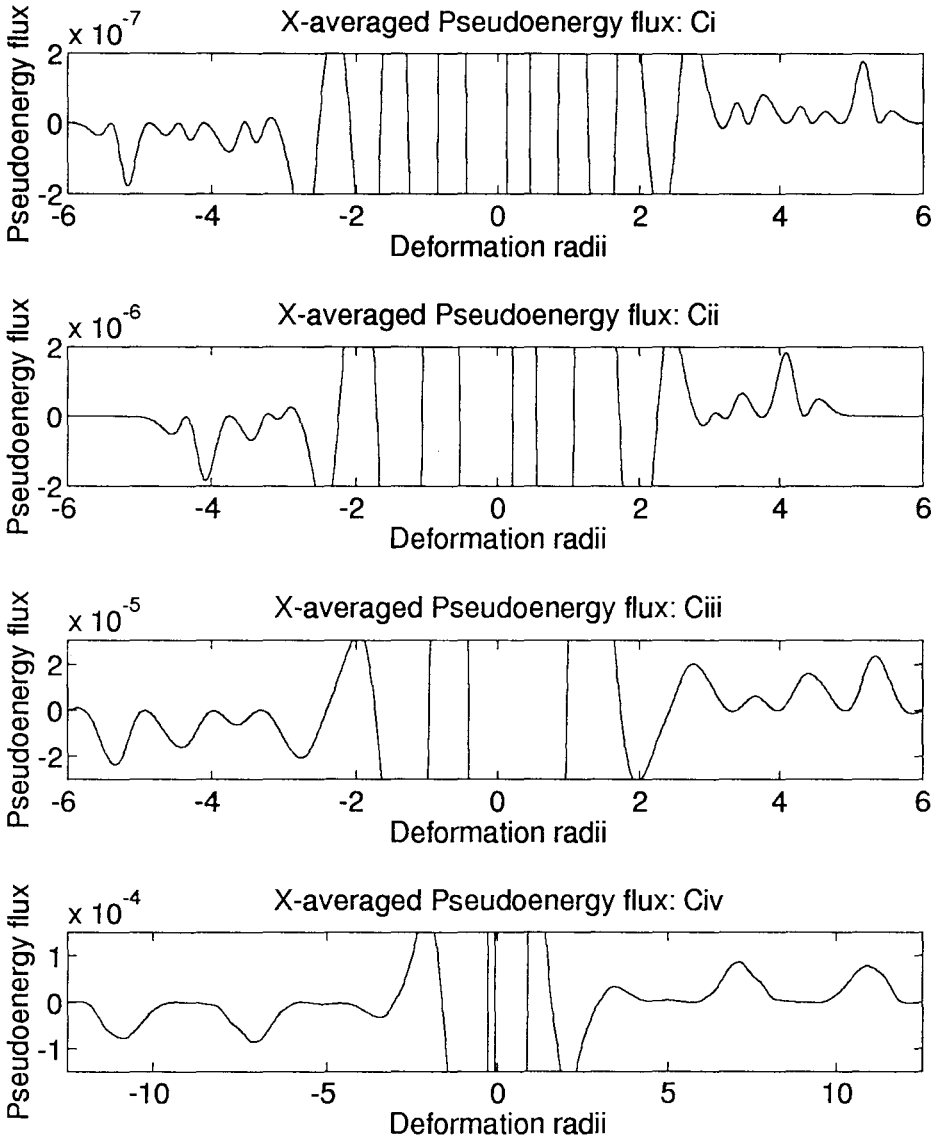

Figure 4.24: The pseudoenergy fulx at the termination of simulations Ci-iv

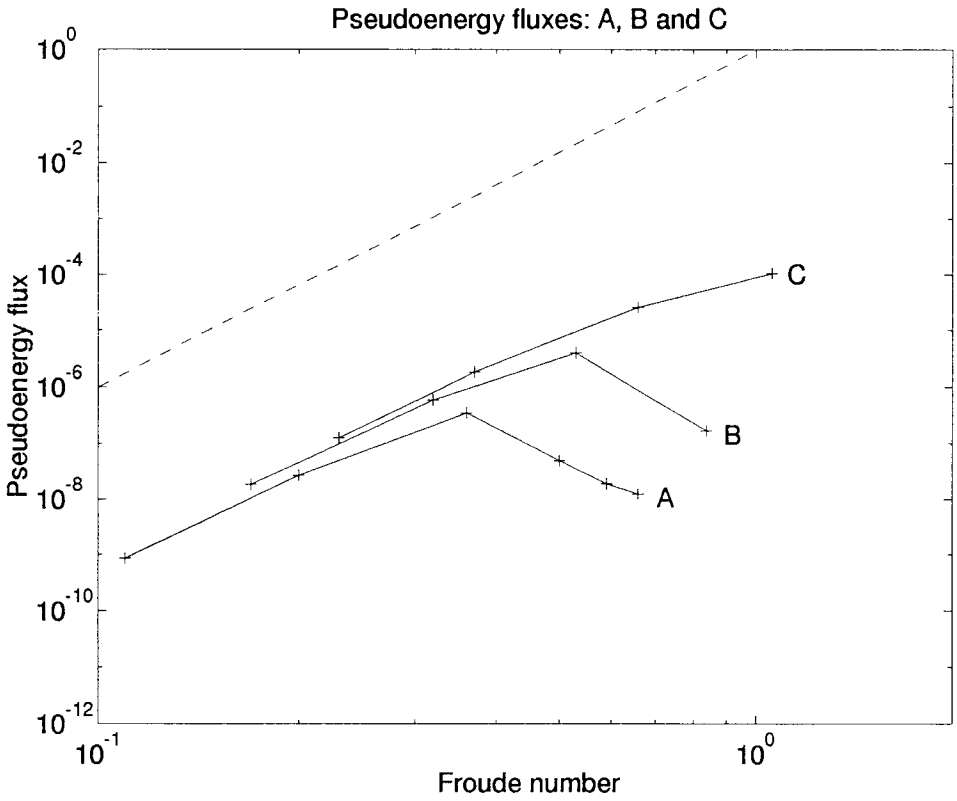

Figure 4.25: The peak pseudoenergy flux due to gravity wave radiation throughout simulations **A**, **B** and **C**

consider strips with non-negative potential vorticity, and then proceed in the following section, §4.9, to consider strips with negative potential vorticity.

4.8 Anticyclonic strips with non-negative potential vorticity

In this section, two sets of simulations are presented, with strip potential vorticity values of 0.1 and 0.0, to be labelled **D** and **E** respectively.

Now, at low Froude number, the vortical flow is identical for all Rossby numbers, except that the timescale is set by the magnitude of the potential vorticity jump, with strips with small jumps evolving more slowly than those with larger jumps. However, we know from simulations **A** – **C** that a potential vorticity jump of at least 5 is required if the pseudoenergy flux is to exceed 10^{-6} at a Froude number of 0.1. In this section we are concerned with anticyclonic but positive potential vorticity in the strip. We are therefore restricted to strip potential vorticity values between 1 and 0, and hence potential vorticity jumps between 0 and 1. It follows that we must expect very weak gravity wave radiation at low Froude numbers when the potential vorticity in the strip is between 0 and 1. Consequently, it was decided to concentrate on a strip potential vorticity value of 0.1, which is quite small (i.e. δQ is quite large for anticyclonic potential vorticity of the same sign as the background), and hence the flow will give rise to reasonably large radiated gravity wave amplitudes, without the strip potential vorticity being so close to zero that very large Froude numbers would be required to establish any significant differences between the two cases **D** and **E**.

Six simulations were performed with a strip potential vorticity of 0.1, with initial strip widths of 0.42, 0.84, 1.68. 3.36, 6.00 and 9.00, labelled **D**i–vi respectively. The vortical aspects of the dynamics in these simulations are similar to those found for simulations **A** – **C**. Figure 4.26 shows the dependence of the nutation time on the Froude number for experiments **A**, **B**, **C** and **D**. In common with the strips with cyclonic potential vorticity, the nutation times for experiments **D**i-vi increase super-exponentially with increasing Froude number.

However, agreement with the Lighthill theory is not found to be very good, even in the case **D**i, with a Froude number of only 0.2. Figure 4.27 shown the x–averaged $\partial h/\partial t$ field during simulations **D**i and **D**ii. Although the Lighthill reconstruction is capturing the essential features, on the whole it is performing rather poorly, when compared with cyclonic experiments

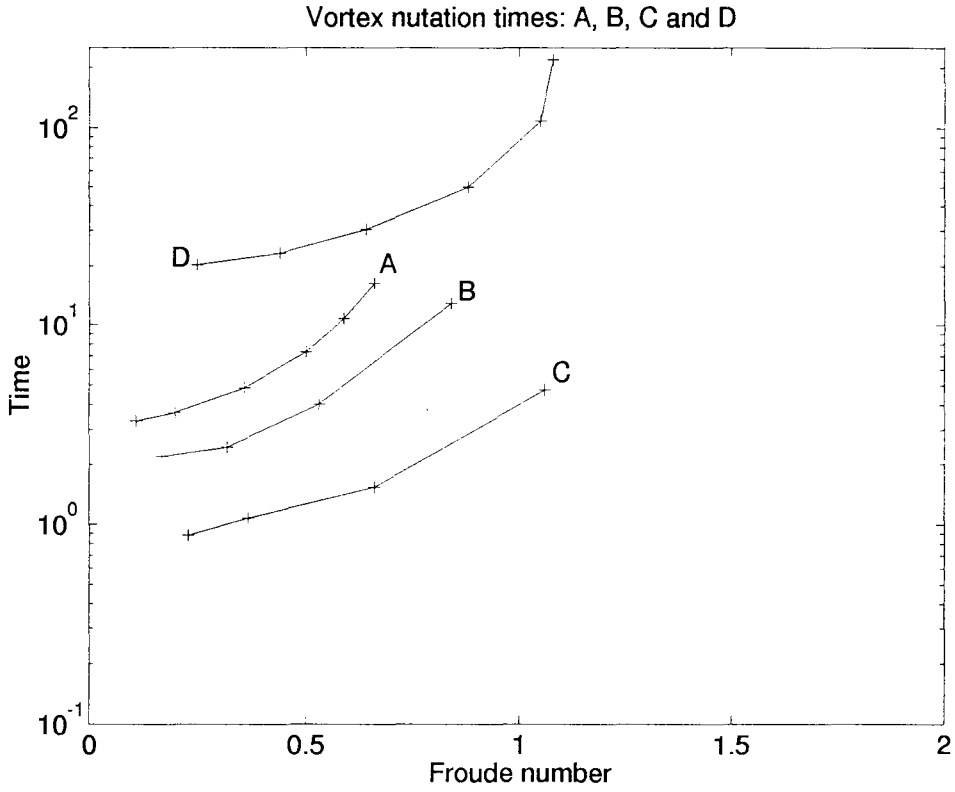

Figure 4.26: Vortex nutation times for simulations Di-vi

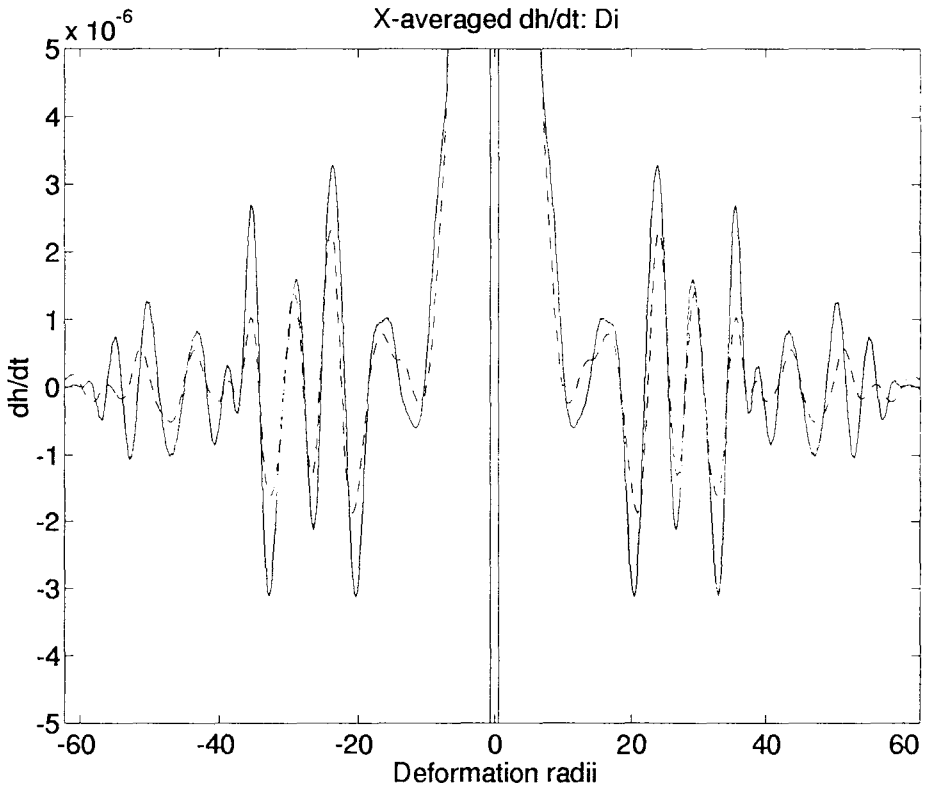

Figure 4.27: The x–averaged $\partial h/\partial t$ field at the termination of simulation **Di** (solid line), and its reconstruction using the Lighthill convolution integral (dashed line)

at similar Froude numbers.

Now, in classical aeroacoustics, only two length scales are present in the flow: the scale of the vortical motions, and the scale of the aeroacoustic waves which they generate. In the problem of gravity wave generation by vortical motions in a rotating frame, however, the Rossby deformation radius is an additional length scale, which is unity in the nondimensionalization used here. The Lighthill theory assumes that the quadrupole source may be concentrated at a single point. If this is to be a good approximation, the scale of the vortical flow must be small with respect to the wavelength of the waves it generates, which is the usual low Froude number assumption, and must also be small compared with a Rossby deformation radius. It seems likely that the reason for the rather poor agreement in figure 4.27 is that, although the Froude number is low, the vortices are not very small compared to a Rossby deformation radius, the initial width of the strip being 0.42.

In figure 4.28, the $\partial h/\partial t$ field is shown, at the time of most intense gravity wave emission, for simulations **D**i–iv. As the Froude number increases, the nature of the gravity wave generation appears to change. At low Froude numbers, the generation appears to be a rather long range effect, with gravity waves generated being of much longer wavelength than the scale of the vortical motions. At higher Froude numbers, however, the generation mechanism appears to be a rather more local effect, with gravity waves apparently being "launched" off the edges of the vortices as they rotate. Figure 4.29 shows a sequence of four frames from simulation **D**iv, during the period of generation of its most intense gravity waves, in which this process is illustrated, and figure 4.30 shows the potential vorticity field at the same times.

As the Froude number is increased still further, the gravity waves radiated by the vortex train lose their coherent x–independent structure. Figure 4.31 shows the gravity wave field during simulations **D**v and **D**vi. In comparison with simulations **D**iii and **D**iv, these gravity wave fields appear to be more arc-like, resembling radiation from point sources, rather than x–independent radiation from a line source exhibited at lower Froude numbers.

Figure 4.32 shows the dependence of the gravity wave pseudoenergy flux on the Froude number for experiments **A** – **D**. As in the case of experiments **A** – **C**, experiments **D**i-vi exhibit an optimal Froude number, above which the gravity wave pseudoenergy flux decreases as the Froude number is further increased. The existence of an optimal Froude number is almost certainly due to the fact that the vortex rotation times are increasing very rapidly with Froude

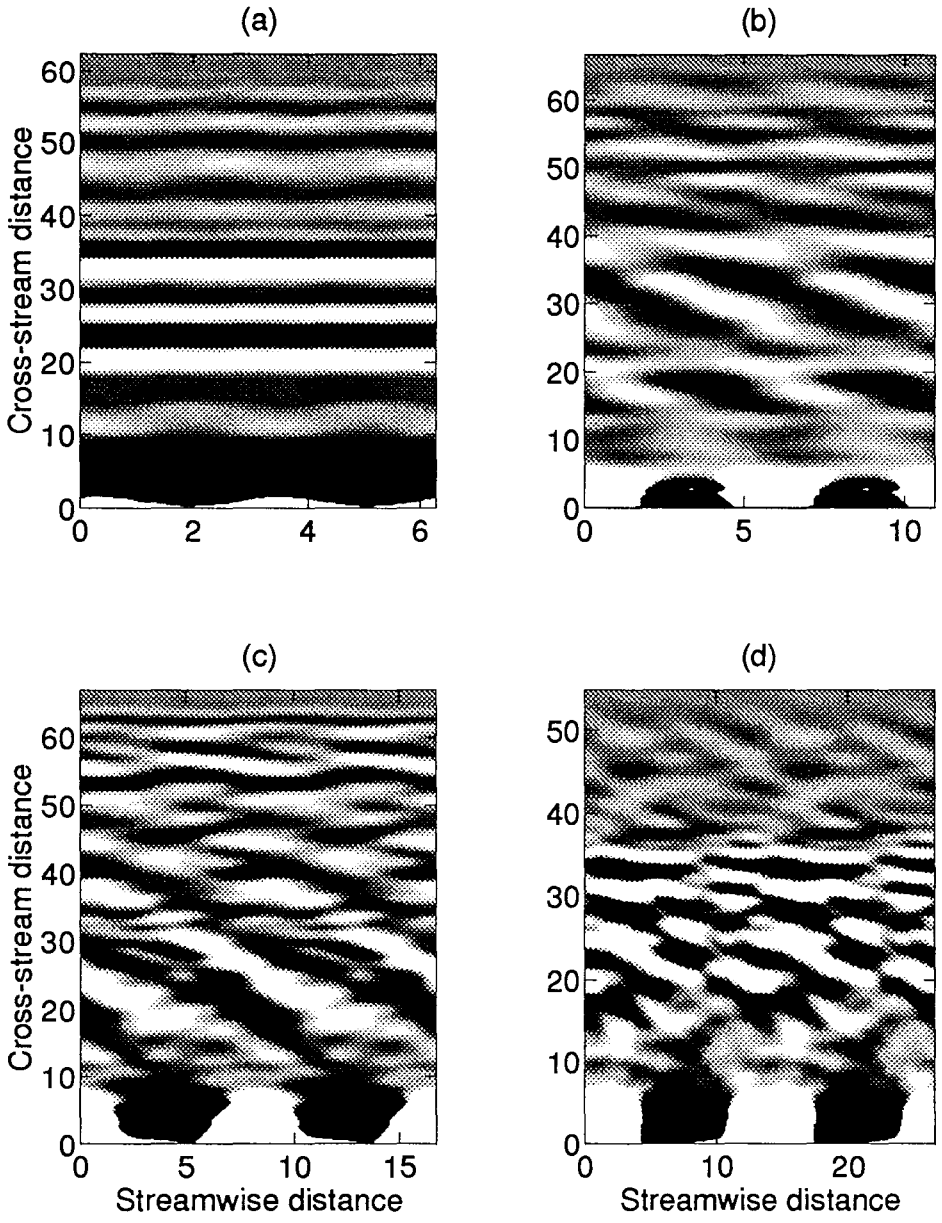

Figure 4.28: The $\partial h/\partial t$ field during the most active phase of gravity wave generation in simulations Di–iv. Two periods of the model domain are shown.

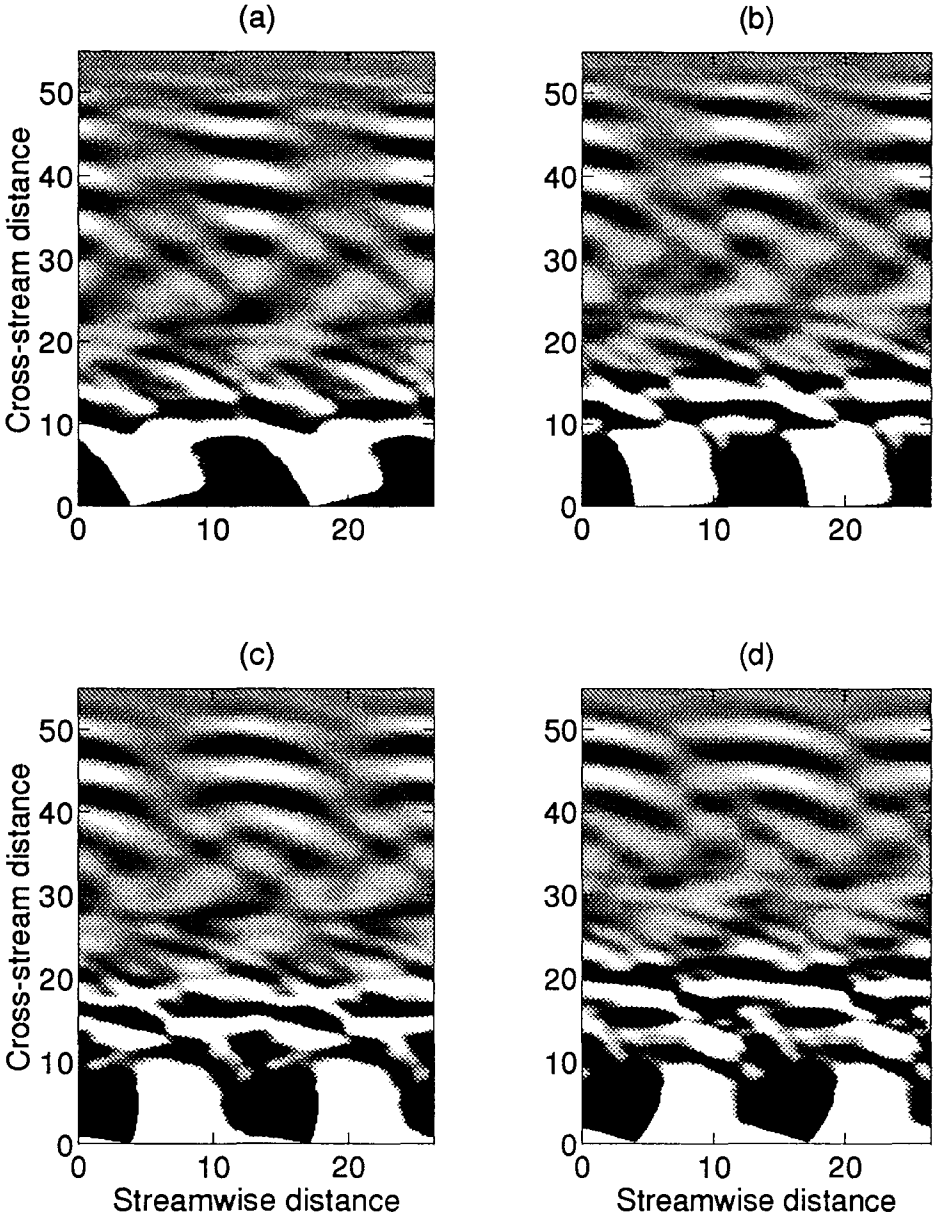

Figure 4.29: The stages of gravity wave emission during simulation Div. Figures a,b,c,d correspond to times 140, 143.75, 147.5 and 151.25 respectively. Two periods of the model domain are shown.

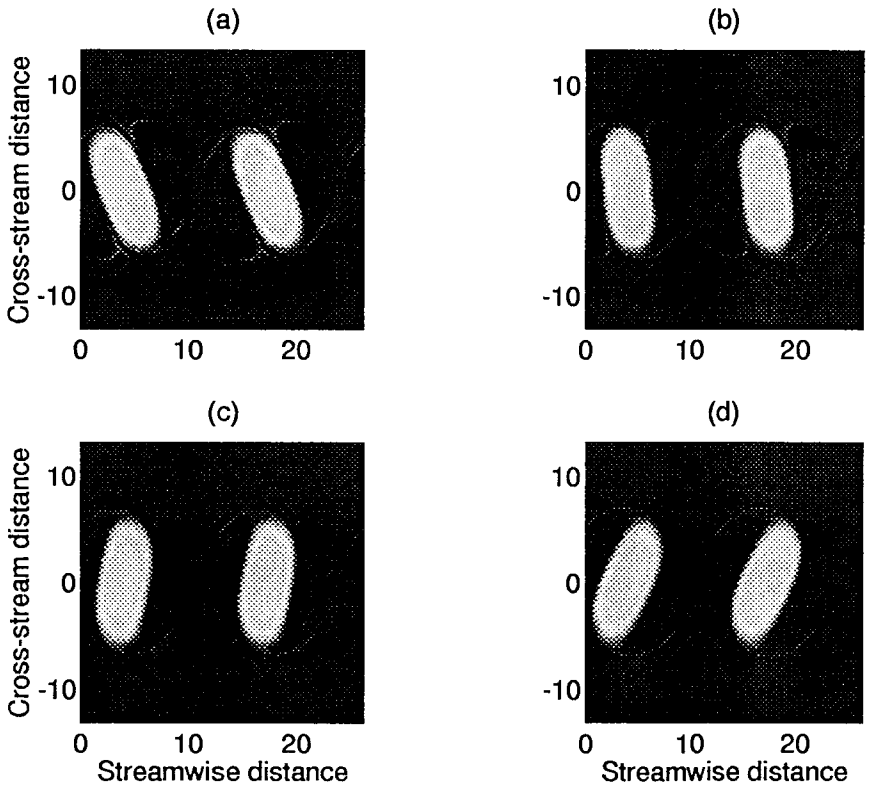

Figure 4.30: The potential vorticity field during the stages of gravity wave emission during simulation **D**iv. Figures a,b,c,d correspond to times 140, 143.75, 147.5 and 151.25 respectively. Two periods of the model domain are shown.

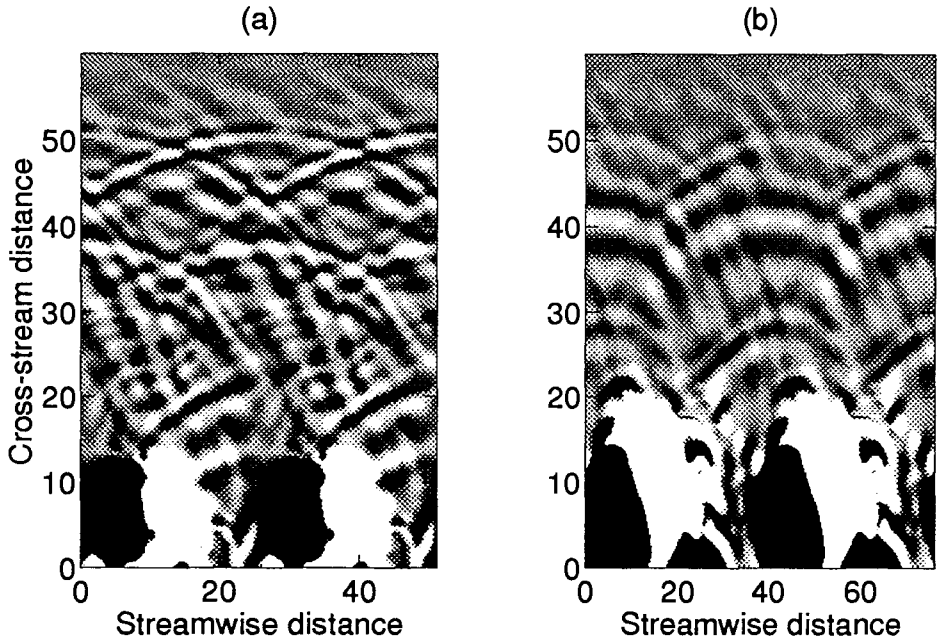

Figure 4.31: The $\partial h/\partial t$ field during simulations **D**v and **D**vi. Two periods of the model domain are shown.

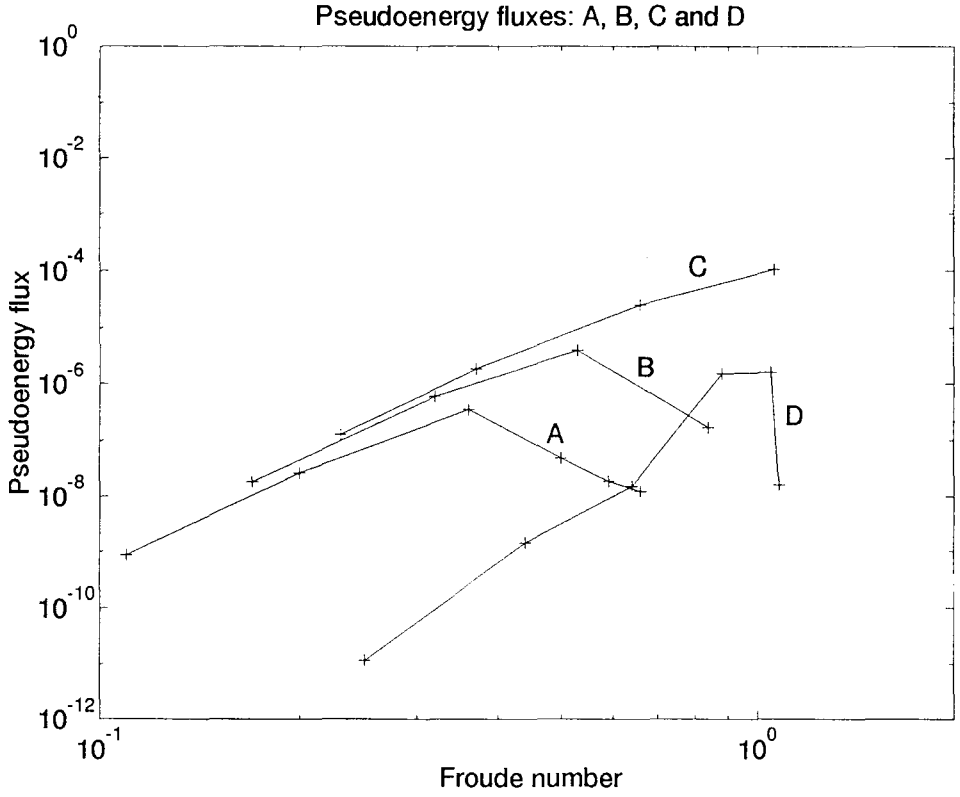

Figure 4.32: The maximum pseudoenergy flux plotted against Froude number for simulations Di-vi

number, and hence the gravity waves are severely inhibited by the presence of background rotation.

It seems clear that the nature of the gravity wave radiation, and its ultimate limitation, is somewhat different in simulations **D**i–vi from that found in simulations **A** – **C**. The gravity wave pseudoenergy flux appears to increase more rapidly with Froude number, at moderate Froude numbers, and the transition from increasing gravity wave amplitudes to decreasing amplitudes as the Froude number is increased is much more abrupt than is found for cases **A** – **C**, with cyclonic potential vorticity in the strip. However, analysis in this case is difficult because, unlike the cyclonic simulations **A** – **C**, the vortices are very much larger, when compared with a Rossby deformation radius, at the critical Froude number at which the transition from increasing to decreasing pseudoenergy fluxes occurs. This means that the Lighthill theory is inapplicable in this limit, and an alternative analytical description of the flow has not been attempted.

The experiments with small positive potential vorticity in the strip are to be contrasted with experiments in which the potential vorticity in the strip is exactly zero. Five experiments were conducted with a strip potential vorticity of zero, with initial strip widths of 0.42, 0.84, 1.26, 2.52 and 6.00. The experiments are labelled **E**i-v repectively.

Figure 4.33 shows the dependence of the vortex nutation times on the Froude number for experiments **E**i-v, with those for experiments **A** – **D** for comparison. Although there appears to be a very gradual increase in vortex nutation times with Froude number in this case, the behaviour is to be contrasted sharply with that found for a strip potential vorticity of just 0.1. A very significant difference in the nature of the vortical flows is thus observed between simulations **D** and **E**, although the general nature of the flow remains broadly similar: the strip rolls up into a periodic chain of vortices which proceed to nutate, albeit at markedly different rates between simulations **D** and **E**, without significant change of form.

The $\partial h/\partial t$ field during simulations **E**ii–v is shown in figure 4.34. At lower Froude numbers, it appears to behave in a similar way to the wave field in simulations **D**, with the gravity waves being launched from the edges of the vortices as they rotate. However, as the Froude number is increased, the radiated wave field does not become less coherent, but rather the wave crests of the launched waves become progressively sharper, almost resembling shock waves in the highest Froude number simulation **E**v.

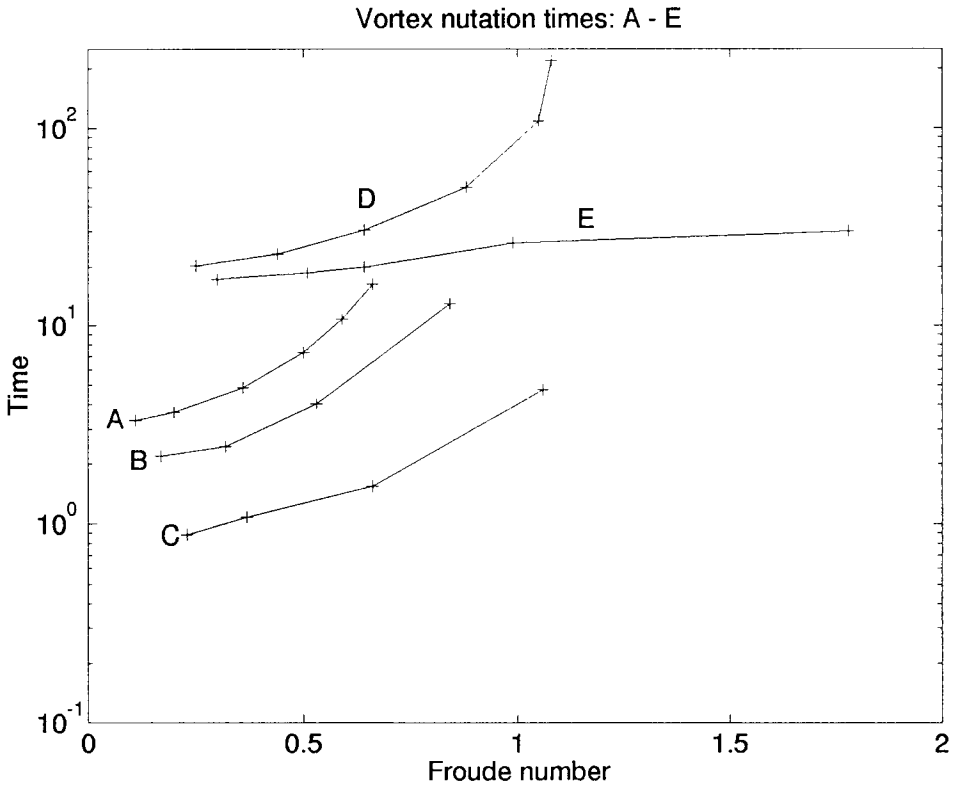

Figure 4.33: Vortex nutation times for simulations Ei-v

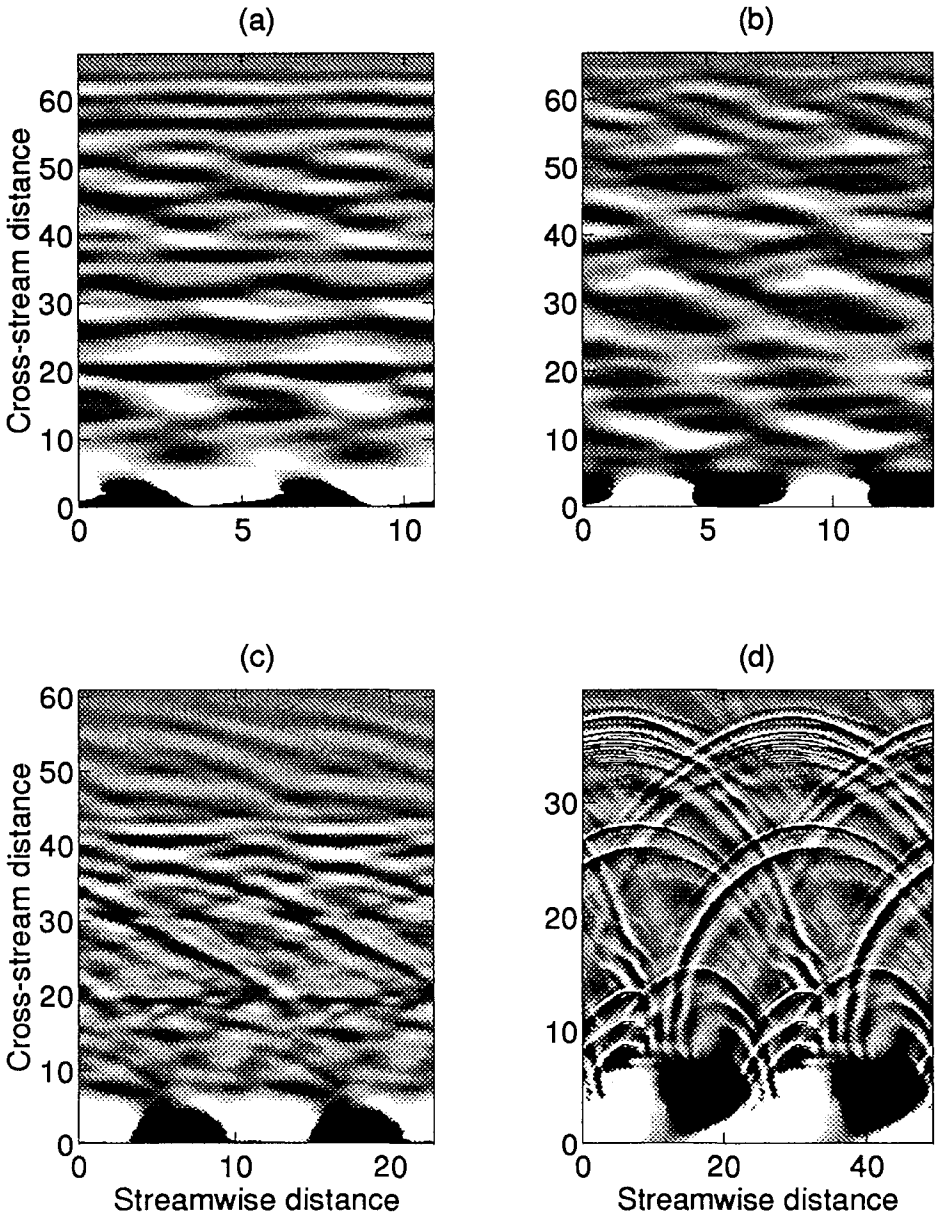

Figure 4.34: The $\partial h/\partial t$ field during simulations Eii-v. Two periods of the model domain are shown.

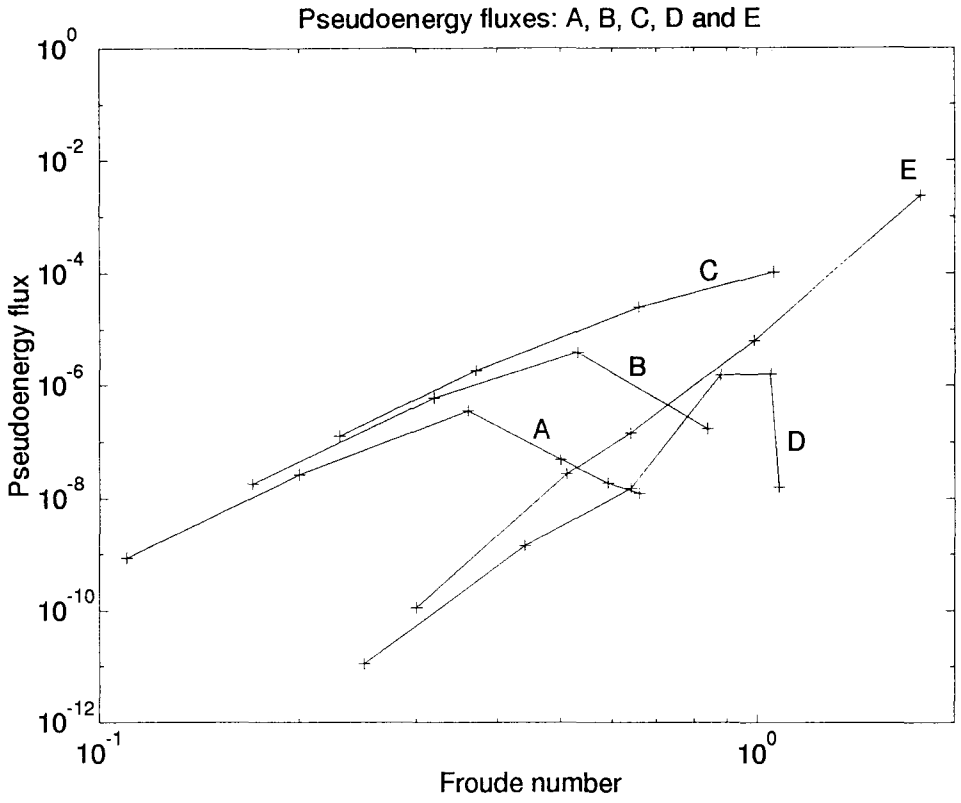

Figure 4.35: Maximum pseudoenergy flux plotted against Froude number for simulations Ei-v

The maximum pseudoenergy flux found in the gravity wave field in simulations Ei-v is shown in figure 4.35, with that found for experiments **A** – **D** for comparison. At moderate Froude numbers the pseudoenergy flux increases strongly with Froude number, in parallel with that observed for simulations Di-iv. However, in case **E** the pseudoenergy flux increases with increasing Froude number apparently without bound, with the gravity wave field apparently becoming highly nonlinear, and somewhat shock–like, at the largest Froude numbers.

4.9 Anticyclonic strips with negative potential vorticity

Having now classified the behaviour of the flows with non-negative potential vorticity, three further sets of simulations were undertaken to investigate gravity wave generation by vortex trains with negative potential vorticity. Strip potential vorticity values of -0.1, -1.0 and -19.0 were investigated, with a range of strip widths in each case.

The experiments with a strip potential vorticity of -0.1 were performed for comparison

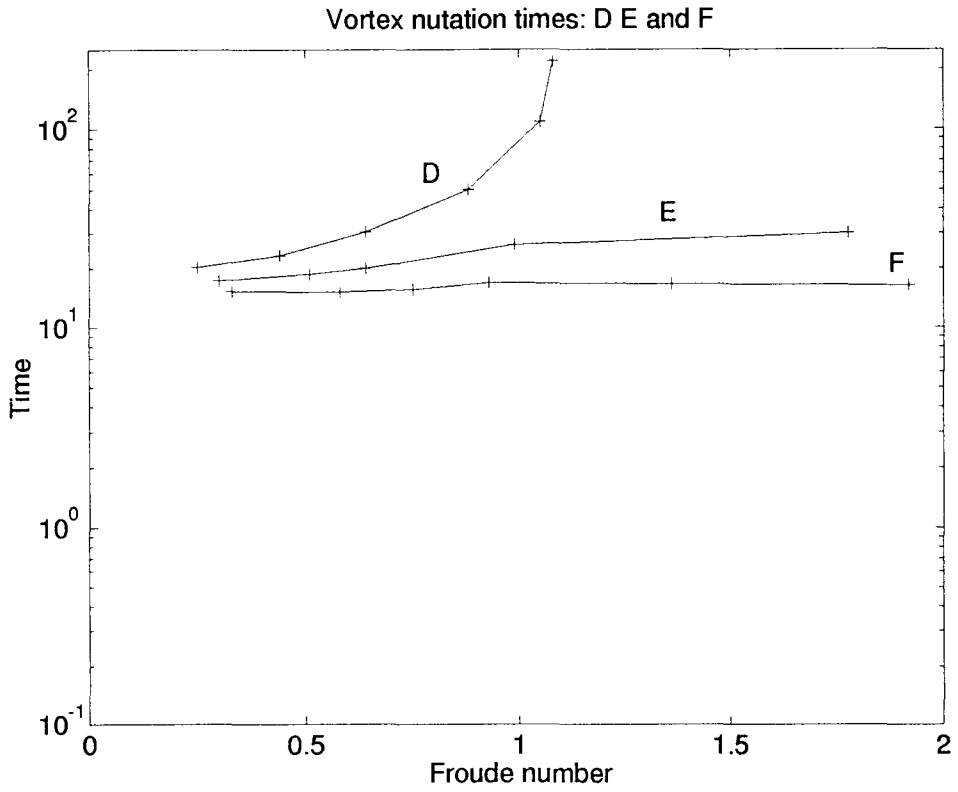

Figure 4.36: Vortex nutation times for simulations **F**i-v

with experiments **E**i-v, in which the strip potential vorticity was zero, to investigate whether any additional effects occurred when slightly negative potential vorticity was present in the simulations. Six simulations were performed with a strip potential vorticity of -0.1. Initial strip widths taken were 0.42, 0.84, 1.26, 1.68, 2.52 and 3.04. Figure 4.36 shows the vortex nutation times for simulations **D**, **E** and **F**. One can see that although there is a substantial difference between a strip potential vorticity of 0.1 and 0.0, there appears to be comparatively little difference between strip potential vorticity of 0.0 and -0.1.

In figure 4.37 the gravity wave pseudoenergy fluxes are shown for simulations **D**, **E** and **F**. Again, although there is a substantial difference between simulations **D** and **E**, there is almost no qualitative difference between simulations **E** and **F**.

The $\partial h/\partial t$ field for simulations **F**iii-vi is shown in figure 4.38. One can readily see that, at large Froude number, both sets of simulations **E** and **F** are tending to produce shock waves, and neither appears to be exhibiting any tendency for the pseudoenergy flux to stop increasing

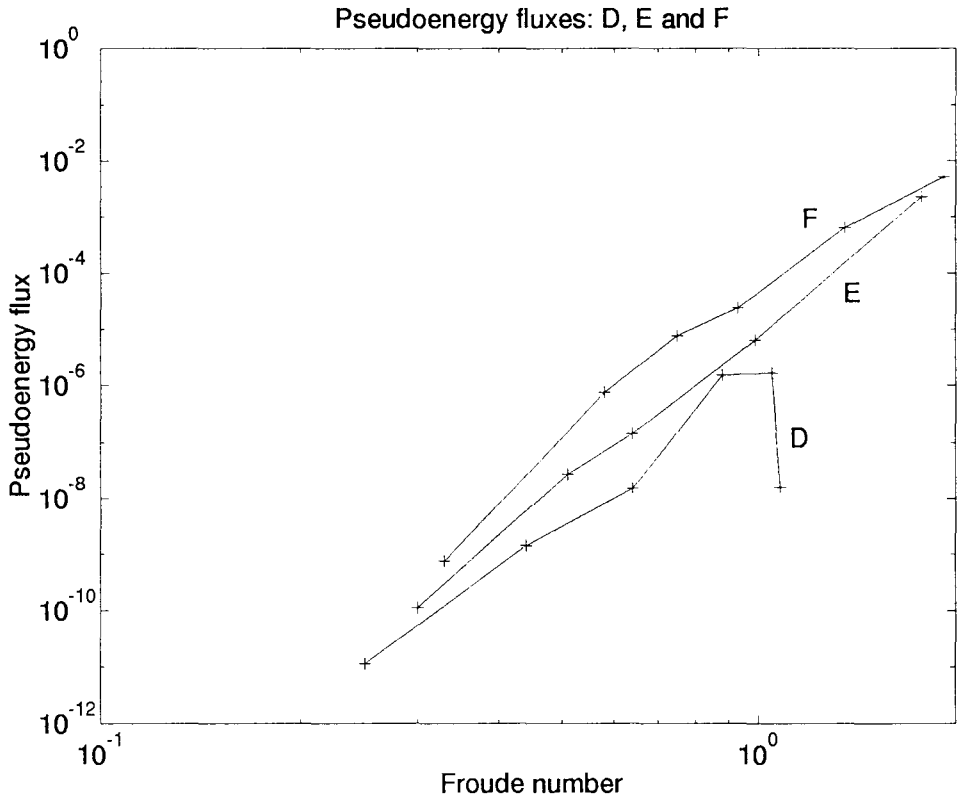

Figure 4.37: Maximum pseudoenergy flux against Froude numbers for simulation sets **D**, **E** and **F**

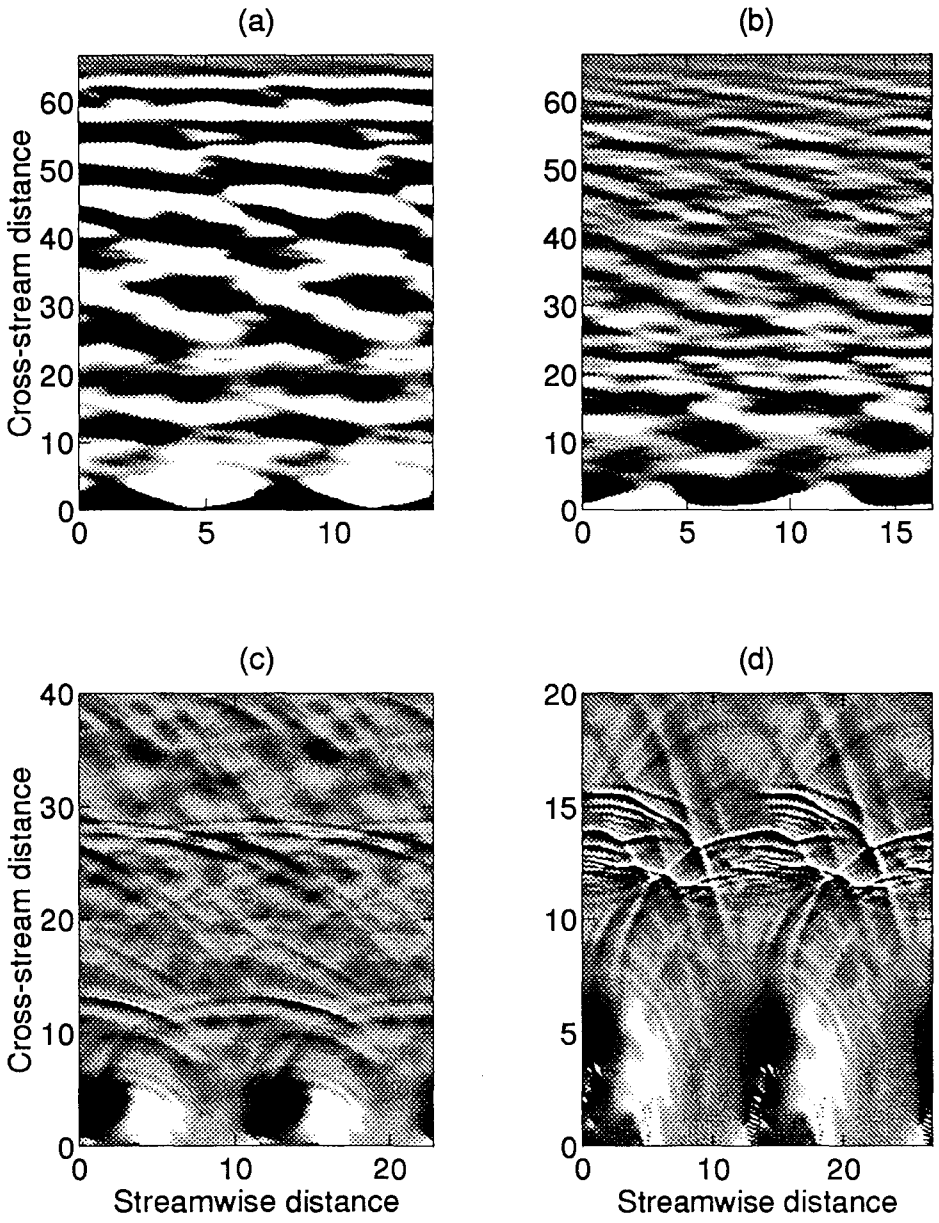

Figure 4.38: The $\partial h/\partial t$ field during simulations Fiii-vi. Two periods of the model domain are shown.

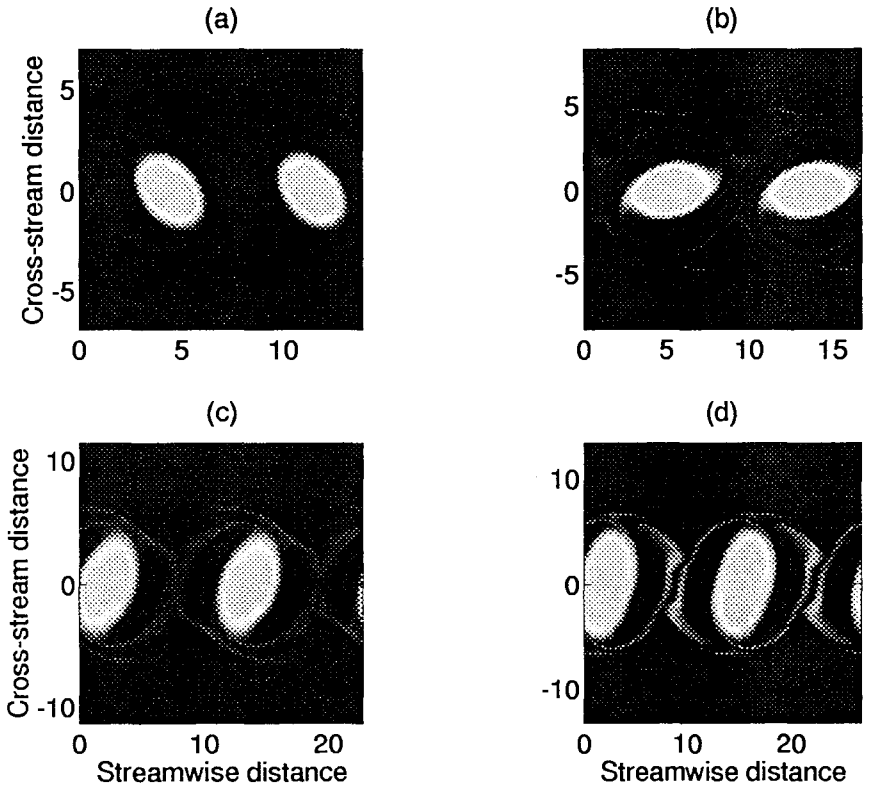

Figure 4.39: The potential vorticity field during simulations **F**iii-vi

with increasing Froude number. It seems reasonable to conclude that there is no appreciable difference between strips with zero potential vorticity, and strips with slightly negative potential vorticity.

The potential vorticity field corresponding to figures 4.38a–d is shown in figures 4.39a–d respectively. In simulation **F**vi, one can see in figure 4.38d that there is some small-scale noise in the $\partial h/\partial t$ field, in the vortical region, and hence the flow may be under–resolved. However, the potential vorticity in figure 4.39d does not exhibit significant small-scale noise, and so we can have some confidence that the performance of the model is at least reasonably good. even in this extreme case with a Froude number of almost 2.0.

Four simulations were then performed with a strip potential vorticity of -1.0. The strips had initial strip widths of 0.07, 0.21, 0.42 and 0.63, and are labelled **G**i-iv. The vortex nutations times do not appear to change significantly with Froude number, and are shown in figure 4.40, with those for simulations **D** – **F** for comparison.

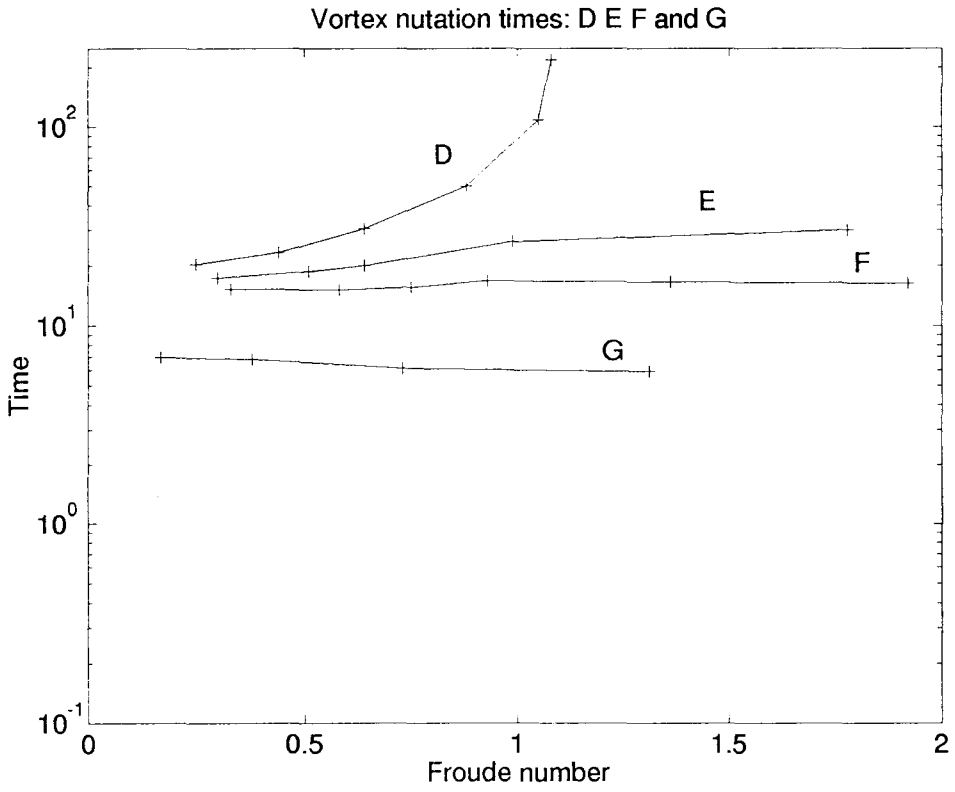

Figure 4.40: Vortex nutation times for simulations Gi-iv

The size of the vortices compared to a Rossby deformation radius is now much smaller than was the case in simulations **D**, **E** and **F**, with the largest initial strip width being 0.63, only 50% wider than the smallest initial strip with in simulations **D**, **E** and **F**. Consequently, the Lighthill theory is significantly more successful at reconstructing the wave field. The x–averaged $\partial h/\partial t$ field, and its reconstruction from the Lighthill source term, is shown for simulations **G**i-iii in figure 4.41, and good agreement is obtained for initial strip widths of 0.07 and 0.21.

However, in line with experiments **E** and **F**, the character of the wave field does depart significantly from that of linear waves as the Froude number is increased. In figure 4.42, the $\partial h/\partial t$ field is shown at the end of each simulation for the cases **G**i-iv. In the first three cases the wave field appears to be well described by linear waves. At low Froude numbers the wave field is dominated by x–independent waves, with x–dependence increasing with increasing Froude number in simulations **G**i-iii. Indeed, linear wave-like motions in the gravity wave field are a pre-requisite for good agreement with the Lighthill theory, observed in figures 4.41a&b, which assumes a linear radiating wave field. In simulation **G**iv, however, the character of the wave field differs markedly from linear wave-like motions, with shock waves appearing in the radiating gravity wave field. In common with simulations **E**v and **F**v, the shocks in simulation **G**iv also appear to originate in the vortical region itself, although they appear to be somewhat sharper in this case.

At this point it should be recognised that the discretization scheme is not designed to capture shocks, and any quantitative discussion of differences between shocks is inappropriate. However, it seems unlikely that a more sophisticated numerical scheme would significantly affect the existence of sharp shock structures in these high Froude number strongly anticyclonic simulations.

The maximum x–averaged pseudoenergy flux is shown against the Froude number in figure 4.43, with the flux for simulations **D** – **F** for comparison. At low Froude numbers, the pseudoenergy flux is increasing as the sixth power of the Froude number. The increase then appears to become more rapid as the Froude number increases, in common with with other anticyclonic simulations **D** – **F**, in which it appeared that the pseudoenergy flux was increasing more rapidly than the sixth power of the Froude number. These do, of course, differ from the cyclonic simulations, in which the pseudoenergy flux never increased more rapidly than the sixth power of the Froude number.

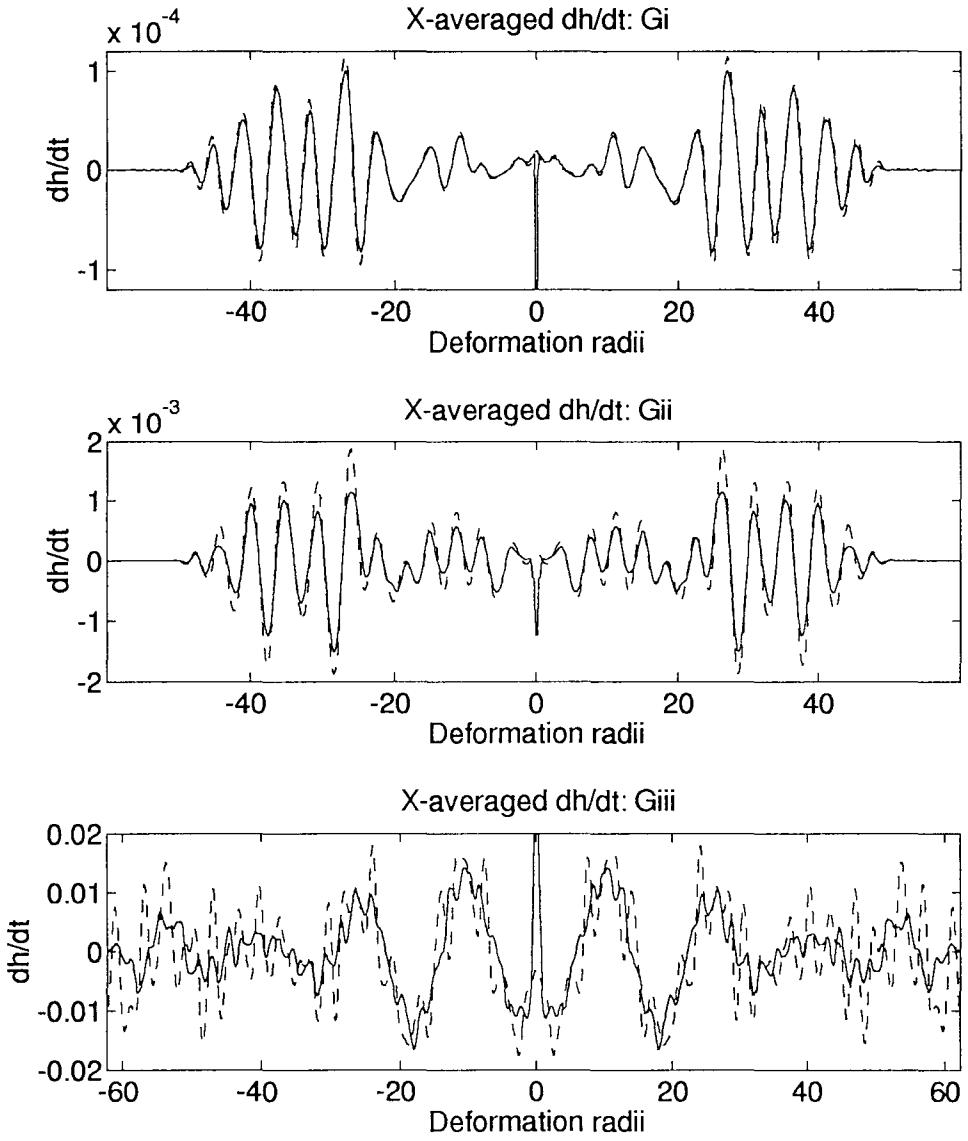

Figure 4.41: The x–averaged $\partial h/\partial t$ field at the termination of simulations **G**i-iii (solid line), and its reconstruction from the Lighthill convolution integral (dashed line)

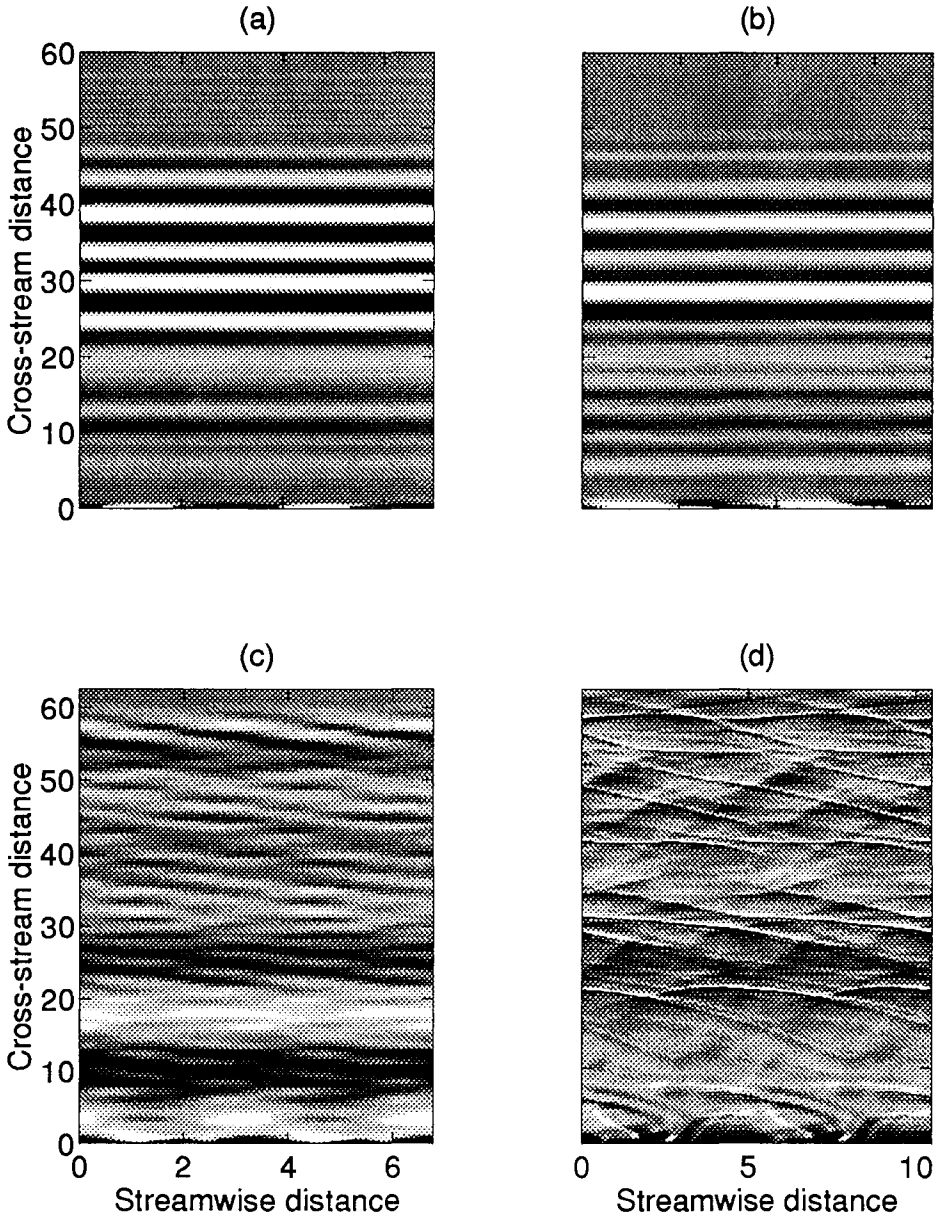

Figure 4.42: The $\partial h/\partial t$ field during the simulations Gi-iv. Two periods of the model domain are shown.

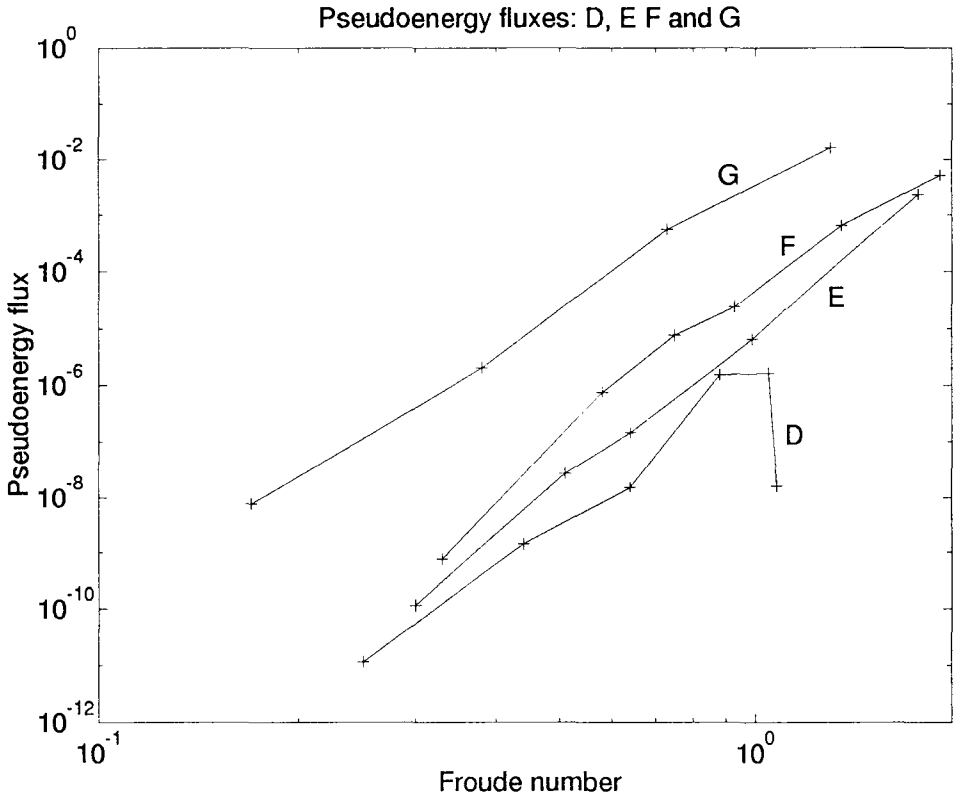

Figure 4.43: The maximum pseudoenergy flux against Froude number for simulations Gi-iv

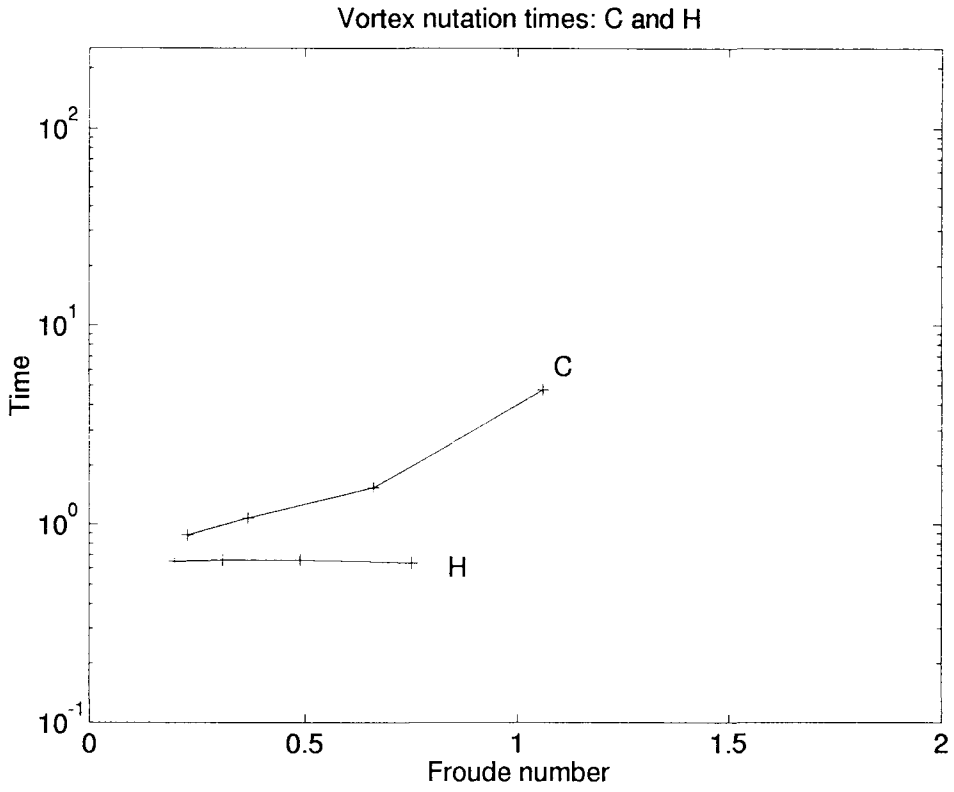

Figure 4.44: Vortex nutation times for simulations **Hi**-iv

Finally, four simulations were performed with a strip potential vorticity of -19.0. These simulations were performed for comparison with simulations **Ci**-iv, in which the strip potential vorticity was taken to be 21.0. Consequently, at low Froude numbers, the dynamics of the strips should be identical in the two cases, with the magnitude of the potential vorticity jump being equal to 20 in both cases. Strip widths of 0.007, 0.013, 0.021 and 0.031 were taken, and the simulations are labelled **Hi**-iv respectively.

Figure 4.44 shows the vortex nutation times for simulations **C** and **H** as a function of Froude number. It can clearly be seen that when there is negative potential vorticity in the strip the nutation times remain almost constant as the Froude number is increased, whereas in the case of positive potential vorticity in the strip the nutation times increase superexponentially.

In figure 4.45 the $\partial h/\partial t$ field is shown at the termination of simulations **Hi**-iv, and in figure 4.46 the comparison with the Lighthill theory is shown. The agreement seems quite good at low Froude numbers, but not as good as in simulations **Ci**-iv, even though the waves remain

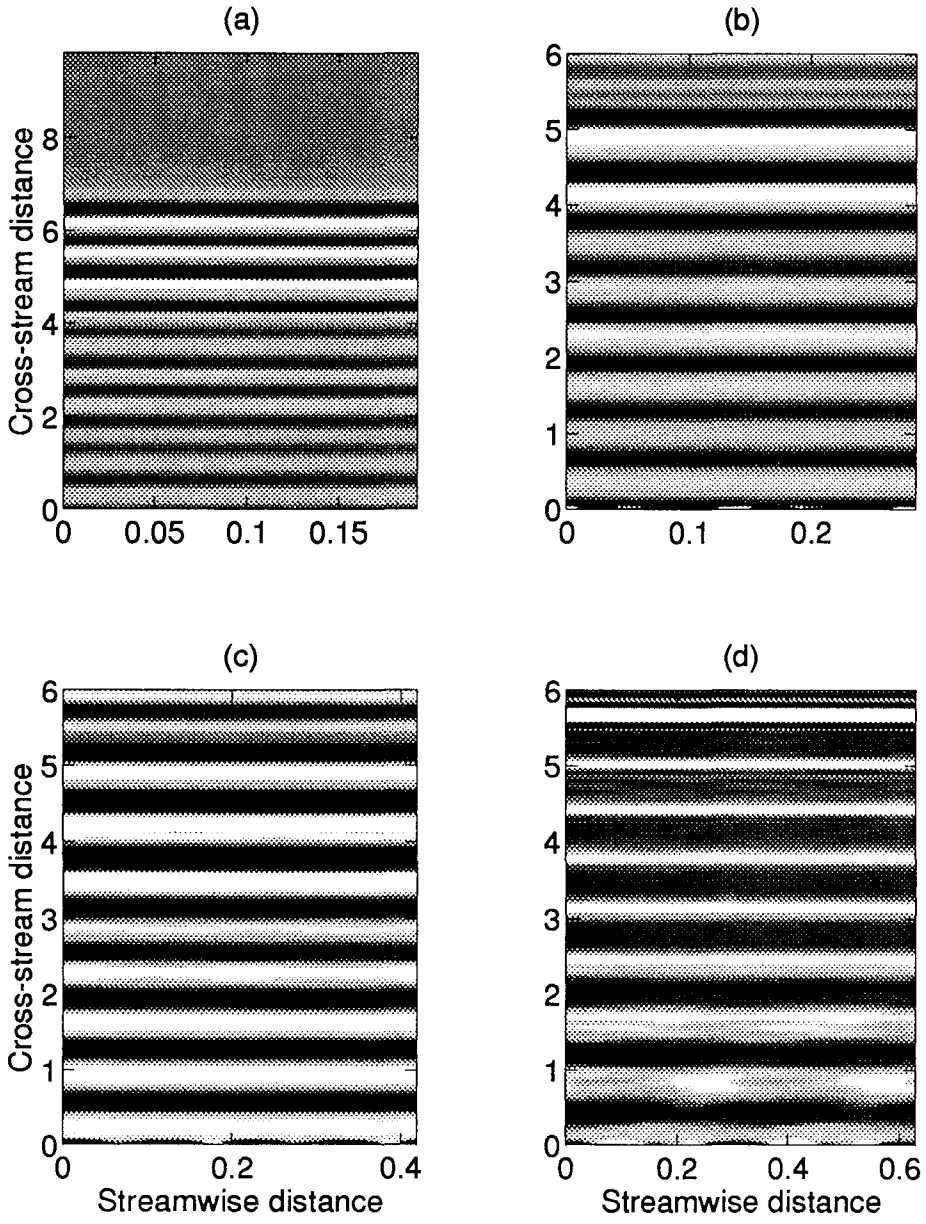

Figure 4.45: The $\partial h/\partial t$ field at the termination of simulations Hi-iv. Two periods of the model domain are shown.

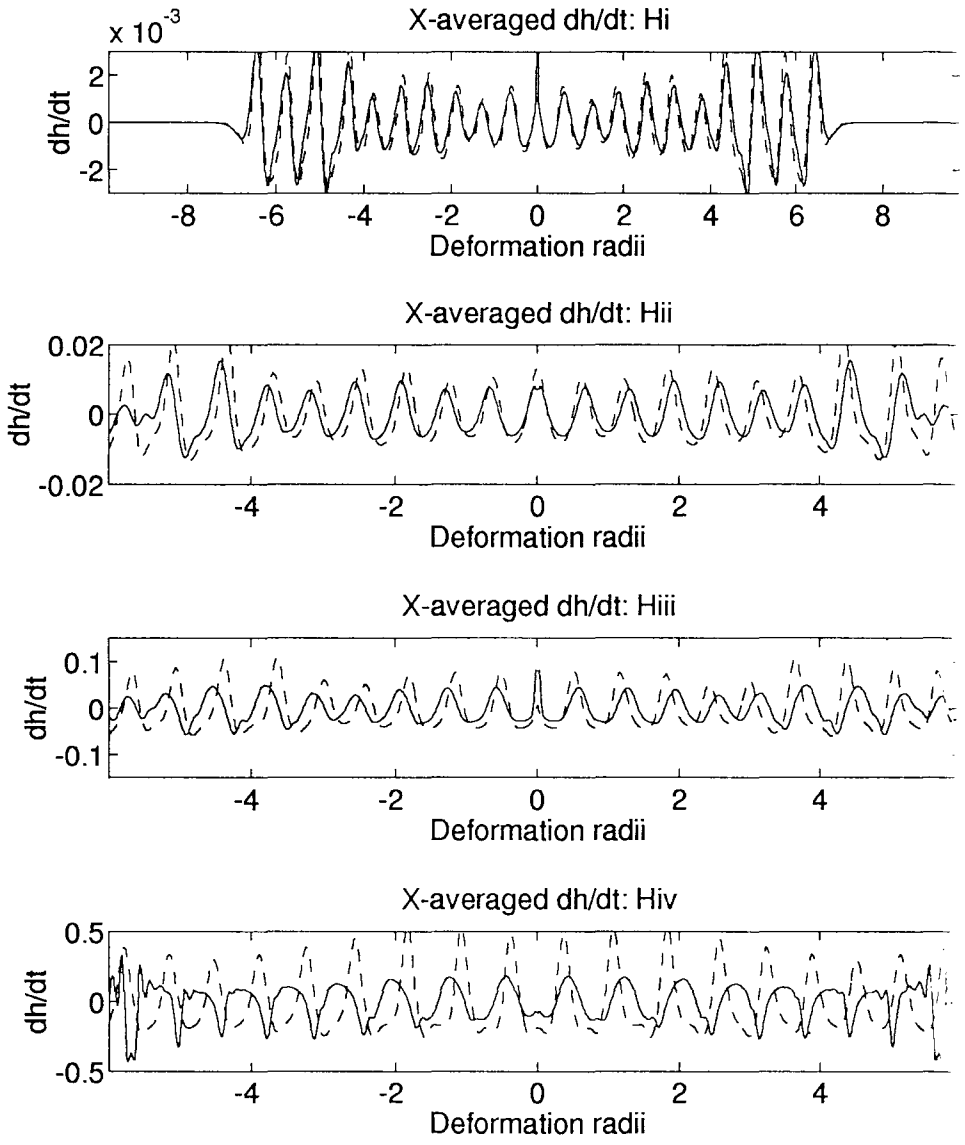

Figure 4.46: The x-averaged $\partial h/\partial t$ field at the termination of simulations H and its reconstruction from the Lighthill convolution integral (dashed lines)

nearly independent of x.

The peak pseudoenergy flux in the gravity wave far field is shown against Froude number for simulations **Ci-iv** and **Hi-iv** in figure 4.47. One can see that, although both sets of simulations are initially quite similar, as the Froude number is increased the simulations **Hi-iv**, with negative potential vorticity in the strip, radiate gravity waves much more strongly that the corresponding cyclonic simulations with the same magnitude of potential vorticity difference between the strip and the background.

When comparing the x–averaged $\partial h/\partial t$ field with its reconstruction from the Lighthll convolution integral (4.7), it is of interest to note that, while in most cases the maxima of the actual and reconstructed field co-incide, in simulations **C** and **H**, shown in figures 4.23 and 4.47 respectively, the maxima appear to be offset. In figure 4.23, the maxima of the field obtained by reconstruction from (4.7) appear to lead those obtained by direct numerical simulation, whereas in 4.47, they tend to lag those obtained by direct numerical simulation. The reason is that the

Lighthill theory assumes that the wave phase speed c_0 is constant everywhere. However, the vortical flow adjusts to rest over the scale of a Rossby deformation radius. In most cases, the radiated waves are of long wavelength compared with a Rossby deformation radius. However, as the potential vorticity in the strip increases, so the frequency of the vortical motion increases, and hence the wavelength of the radiated waves decreases. In cases **C** and **H**, the wavelength of the radiated waves is of the order of a deformation radius, and therefore they may be significantly affected during their propagation through the region over which the flow relaxes adjusts to rest. In the cyclonic case **C**, the layer depth is less near the strip than at infinity, and the waves will tend to propagate more slowly there. Hence, the waves predicted by (4.7) will tend to lead those obtained by direct numerical simulation. Conversely, in the anticyclonic case **H**, the layer depth is greater near the strip than at infinity, and the waves will propagate more quickly there. Hence, the waves predicted by (4.7) will tend to lag those obtained by direct numerical simulation, in agreement with what is found in figures 4.23 and 4.47.

4.10 Discussion

Gravity wave radiation by a train of vortices in shallow water has been studied by direct numerical simulation. The dependence of the gravity waves radiated upon the Froude and Rossby numbers was investigated.

Arguably the most surprising result is that, for cyclonic vortices at moderate Rossby number, increasing the Froude number above 0.35 can lead to a decrease in the amplitude of the gravity waves radiated by the vortex train. This is in contrast to laboratory experiments, and the numerical experiments of Lele & Ho (1993) for a non-rotating gas, in which the acoustic wave amplitudes scaled according to the Lighthill theory for Mach numbers of up to 0.6 or so.

A summary of the results, showing the dependence of the radiated pseudoenergy flux on the Froude number for various Rossby numbers is shown in figure 4.48.

One can see that, in general, whereas positive potential vorticity trains tended to exhibit an "optimal" Froude number for gravity wave generation, the amplitude of gravity waves radiated by negative potential vorticity trains increase apparently without bound as the Froude number increases.

Typical vortex nutation times for all experiments are shown in figure 4.49. One can see

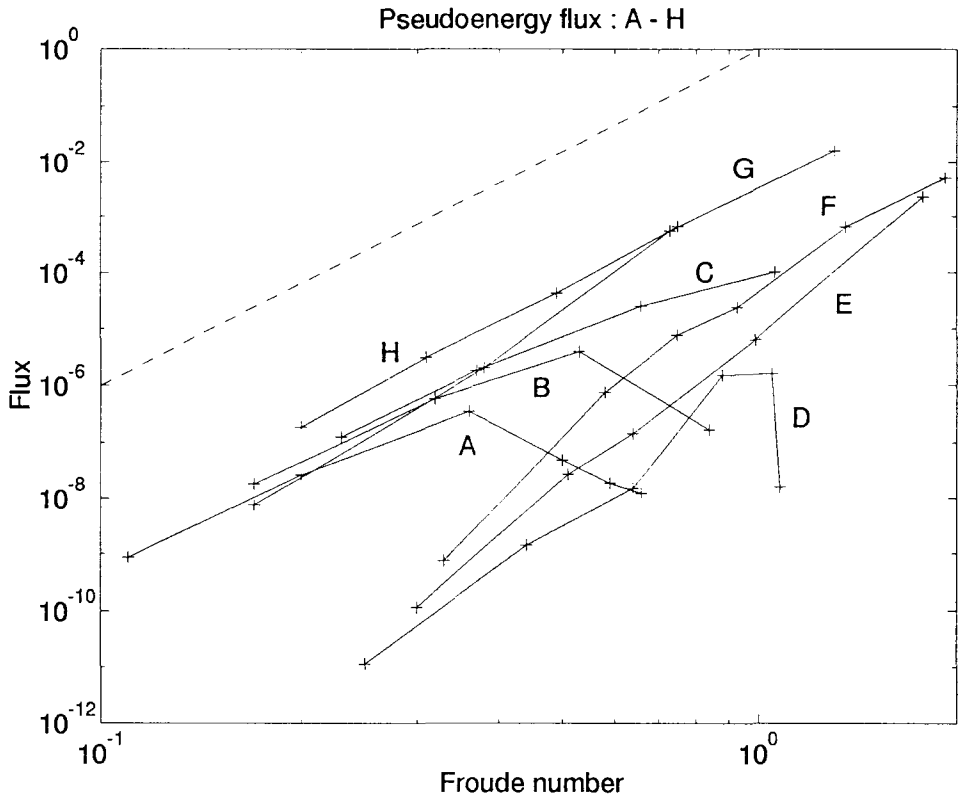

Figure 4.48: Pseudoenergy flux against Froude number for all simulations (solid lines). The gradient of the dashed line corresponds to pseudoenergy increasing as the sixth power of the Froude number

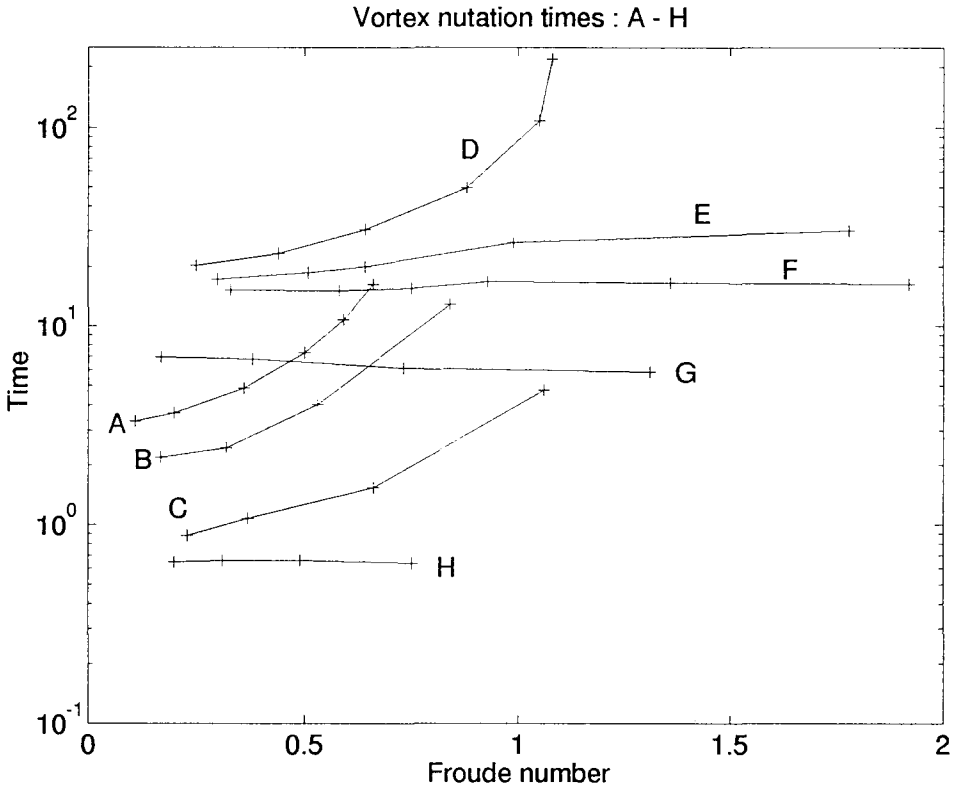

Figure 4.49: Vortex nutation times for all experiments, **A** – **H**

that nutation times increase super-exponentially with Froude number for all cyclonic vortex simulations, **A** – **C**, and also for anticyclonic simulations, when the potential vorticity in the strip is strictly positive. As a result, the intensity of the radiated gravity waves never exceeds about 10^{-4} in simulations **A** – **D**, as the inhibiting effect of the inertial frequency becomes increasingly significant as the nutation times increase. However, when the potential vorticity in the strip is zero or negative, there does not appear to be any significant dependence of the nutation time upon the Froude number, and the radiated gravity wave fluxes apparently increase without bound.

It might be suggested that symmetric instability might account for this difference. Symmetric instability, with wavenumber zero, will exist in parallel flow when $f(f - U_y)$ is negative in some part of the domain (Hoskins, 1974). Although his analysis is for a continuously stratified fluid, it can be readily extended to the shallow water equations (R. T. Pierrehumbert, personal communication). The condition $f(f - U_y) < 0$, which is both necessary and sufficient for symmetric instability, is met, at the initial instant, by flows **F**i-vi, but not by flows **E**i-vi.

However, there seems very little difference between simulations **E** and **F**, even though the initial states of **F** have an additional instability mechanism available to them, not present in the initial states of **E**. Therefore, it would appear that symmetric instability does not play a significant role in these simulations.

It should be noted, however, that all flows were initialized with an eigenmode at finite wavelength, corresponding to the fastest growing barotropic, or "Rossby wave–Rossby wave", instability mode. It may be of interest to repeat some of the experiments **F**, **G** and **H**, initializing with a symmetric instability mode of zero wavelength, or perhaps with a combination of the symmetric and barotropic instability modes, to investigate the characteristics of the gravity wave field which develops under their subsequent nonlinear evolution.

Some asymmetry between cyclones and anticyclones at Rossby and Froude numbers of order unity has been observed in numerical simulations by L. M. Polvani (personal communication). In his simulations, the geometry of the flow is doubly-periodic, and the initial vorticity field is random. The flow is balanced using the nonlinear balance equations (McWilliams, 1985). In time, large coherent vortices develop, and at small Froude number, there is symmetry between cyclonic and anticyclonic vortices. At larger Froude numbers, however, the flow is dominated by large coherent anticyclones, with much of the cyclonic potential vorticity smeared out into thin

filaments. In some simulations, shock waves have been observed, emanating from the anticyclones. Polvani's simulations thus broadly confirm the results presented here, that anticyclones are more vigorous features than cyclones in shallow water dynamics at order-one Froude numbers, capable of generating shock waves in the gravity wave field at sufficiently large Froude number.

Finally, we recall that this study was motivated, in part, by the observation by McIntyre & Norton (1993) that gravity waves of large amplitude were generally not generated by the vortical motions in their disturbed polar vortex simulations. Now, in polar vortex simulations, the majority of the vortical motions are cyclonic, and the potential vorticity is all of one sign throughout the hemispherical domain. Consequently, they are not able to access the regime of zero and negative potential vorticity, which has been demonstrated in this chapter to be the regime in which the strongest gravity wave generation might be expected. The results presented therefore support their findings, and offer some explanation for them.

Chapter 5

Discussion

5.1 Review of aims and objectives of this thesis

In the introduction to this thesis, it was stated that the aims of the thesis were:

- To investigate the generation of gravity waves in the shallow water system, and the dependence of their amplitudes and character on the Froude and Rossby numbers of the basic flow;
- To quantify the effect of the generation of gravity waves in the shallow water system on the potential vorticity distributions which generate them;
- To establish whether, without additional regard to flow geometry, there can or can not exist a slow manifold for the shallow water equations in any region of Froude and Rossby number space.

To be fair, it can not be said that these aims have been neatly divided up, with successive chapters each dealing with one particular aim. The investigation of gravity waves generated by vortical flows in the shallow water system has been an overall objective of the thesis, and each of the three substantive chapters of the thesis has made a significant contribution to it.

The general nature of gravity waves generated by vortical motions was investigated in chapter 2. The Lighthill theory, as extended to the rotating frame by Norton, was confirmed by a matched asymptotic analysis. The analysis enabled an expression to be derived for the effect of gravity wave radiation on the vortical flow. This expression would not be available through a "classical" application of the Lighthill theory, which would predict the amplitude and character of the gravity waves generated, but not their effect on the vortical flow which generates them.

The nature of the back reaction of the gravity waves on the vortical motions which generate them was then analysed with reference to balanced models. The back reaction takes the form of a large scale straining field, whose amplitude depends on time, and is given by a convolution integral involving the entire past history of the vortical flow. Hence it was shown that, without reference to an initial instant of time, the correction to the balanced dynamics which was required to account for the gravity wave radiation at low Froude number could not be regarded as an instantaneous function of the potential vorticity distribution, and could not therefore be regarded as part of the balanced dynamics.

The issue of the existence or non-existence of a slow manifold for the shallow water equations was pursued further in chapter 3, by analysing the character of the instability of an axisymmetric vortex with a potential vorticity which had a single discontinuity at $r = 1$. It was shown that the vortex was unstable to high wave number disturbances at arbitrary Froude and Rossby numbers. The instability is a coupled Rossby wave – gravity wave instability, and can not be part of a slow manifold which does not contain any gravity wave-like features. If a slow manifold were permitted to contain gravity wave-like features, it would then follow from the vortex instability analysis that it could not be unique. Thus, although the existence of a slow manifold can not be entirely ruled out, the notion of a unique slow manifold, entirely devoid of gravity wave activity, certainly can be.

Finally, nonlinear simulations of the shallow water equations were performed to investigate the nature of gravity wave generation by vortical flows at Froude and Rossby numbers of order unity. It was found that cyclonic vortices will tend to become progressively less unsteady as the Froude number is increased. This means that they become progressively less able to generate gravity waves, as typical frequencies in the vortical dynamics become smaller and smaller with respect to the inertial frequency. The result was that cyclonic vortices exhibited an optimal Froude number, above which the radiated gravity wave pseudoenergy flux actually decreased as the Froude number was further increased. It turned out that even for potential vorticity of nine times the background value, the optimal Froude number occurred at about 0.6, and the pseudoenergy flux did not exceed 10^{-6}.

Anticyclonic vortices appeared to behave somewhat differently at moderate Froude number, with the pseudoenergy flux increasing more rapidly than in the cyclonic cases. However, if the potential vorticity was strictly positive, their nutation times also increased super-exponentially with increasing Froude number, thus inhibiting gravity wave radiation. The maximum pseudoenergy flux from anticyclonic vortices with positive potential vorticity did not exceed 10^{-6}, and the Froude number at which the strongest gravity wave fluxes were observed was almost 1.0.

Vortices with zero and negative potential vorticity were not found to become significantly less unsteady as the Froude number increased. At large Froude numbers, it was found that such vortices tended to generate shock waves, which could then propagate through the fluid. The pseudoenergy flux continues to increase with increasing Froude number, at least as rapidly

as the sixth power of the Froude number, up to Froude number of order unity.

In the moderate Froude number regime, the gravity wave field generated was compared with that predicted by a suitably modified version of the Lighthill theory. In general, there seemed good agreement over a range of Froude numbers, provided the vortices were small compared with a deformation radius.

5.2 Suggestions for further research

This thesis has concentrated on specific features of flows which cannot be balanced, and there remains much work to be done in understanding and quantifying these phenomena.

In chapter 2, after the general theory was introduced, the response of an elliptical patch to radiating gravity waves was examined in some detail. The analysis supported the notion of "generalized adjustment" – i.e. the flow adjusts to a state where its gravity wave emission diminishes. This flow is, however, only one of many flows, and it would be of interest to investigate the nonlinear evolution of other vortical structures analytically, using the matched asymptotic expansions approach. A starting point for the study could be the flows classified by Abrashkin & Yakubovich (1984).

The nonlinear numerical experiments of chapter 4 illustrated a substantial difference between cyclonic and anticyclonic vortex motions, particularly when negative potential vorticity was present in the vortices. This phenomenon does not appear to have been studied in such extreme limits, and it would appear that there is much to be done in gaining a fully quantitative understanding of it.

One significant motivation for the numerical work in chapter 4 was to determine the range of validity of the Lighthill theory of aerodynamic sound generation, as applied to gravity wave generation in a rotating frame. The work presented in this thesis is that simple numerical models, at moderate resolution, can be expected to generate a radiated gravity wave field which is in good quantitative agreement with the wave field predicted by the Lighthill theory.

However, only a limited class of flows has been investigated. One serious omission is that there is no mean jet in the flow. Although not conceptually difficult, there is likely to be some technical difficulty in incorporating a mean jet into a modified version of the Lighthill theory.

The point is that, if there is to be a mean jet in rotating shallow water, the fluid will tend to different uniform heights on either side of the jet, far away from it. The Lighthill theory, as presented here, assumes that the background is homogeneous, and some work will be required to incorporate non-uniformity of the background into the theory. Only when this is done, however, will it be possible to test the Lighthill theory in flows with a mean jet in the quantitative way in which it was tested for flows without a mean jet in chapter 4.

Another development which will be required is the incorporation of vertical structure, so that the gravity waves generated by numerical simulations of baroclinic lifecycles can be analysed within the framework of the Lighthill theory.

Ultimately, we may wish to use the Lighthill theory as a quantitative tool to predict the intensity of gravity wave emission by jet streaks. To achieve this, we must first develop the theory to such a level that it can be applied to flows of practical meteorological interest. This aim, to be achieved through further analytical work with the shallow water and hydrostatic continuously stratified equations, is now of primary importance in furthering this work, and is being actively pursued. When complete, it should provide an excellent tool for analysing the performance of numerical models in which gravity wave generation is observed, and for assessing the significance of gravity waves generated by vortical motions in the global angular momentum budget, whose significance was first identified by Lindzen (1981).

Abstract

In the present paper the results of the experimental research of magnetic-gravity effects are presented. Anomalous magnetic and thermal changes within a radius of 15 meters from the researched device were measured as well.

PACS: 41.20.-q; 44.60.+k; 76.50.+q

1. Introduction

There has been a great interest in examining non-linear effects in the system of rotating magnetic fields. Such effects have been observed in the device called Searl's generator or Searl Effect Generator (SEG) [1-4]. A SEG consists of a series of three concentric rings and rollers that circulate around the rings. All parts of SEG are based on the Law of the Squares [5]. The rollers revolve around the concentric rings, but they do not touch them. There's a primary north-pole and primary south pole on the rollers and a primary north-pole and primary south-pole on the concentric rings. Obviously, the north-pole of the roller is attracted to the south-pole of the concentric rings and vice versa.

The rollers have a layered structure similar to the concentric rings. The external layer is titanium, then iron, nylon and the last internal layer was made from neodymium. John R.R. Searl has supposed that electrons are given off from the central element (neodymium) and travel out through other elements. Dr. Searl contends that if nylon had not been used, the SEG would act like a laser and one pulse would go out and it would stop, build up, and another pulse would go out. The nylon acts as a control gate that yields an even flow of electrons throughout the SEG [4].

In [4] it was shown that in the process of magnetization of the plate and rollers, the combination of constant and variable magnetic fields for creating a special wave (sine wave) pattern on a plate surface and rollers surface was used. The basic effects consist of the rollers self-running around the ring plate with a concurrent reduction of weight and an increasing occurrence of propulsion. These effects come about because of a special geometry of experimental setup. It was shown that the operation of the device in the critical regime is accompanied by biological and real physical phenomena.

Other information where similar effects are be mentioned can be found in the books, *Unconventional Flying Objects* [6] and the *Homopolar Handbook* [7] which includes papers on magnetized dielectrics. In this paper we present the experimental device the results we have obtained.

2. Description of the Experimental Installation

The basic difficulty arises in choosing the materials and maintaining the necessary pattern imprinting on the plate and roller surfaces. To simplify the technology we decided to use a one-ring design with one-ring plate (stator) and one set of rollers (rotor). It is obvious, that it was necessary to strengthen the roller rotor near the bearings and balance the rollers well. In the suggested design, air bearings were used which provided the minimum losses due to friction.

From the available description [1-4] it was not clear how to build and magnetize a stator with a one-meter diameter. In order to make the stator, separate magnetized segments of rare earth magnets with a residual induction of 1T were used. The segments were magnetized in a usual way by discharging a

capacitor-battery system through a coil. Afterwards, the segments were assembled and glued together in a special iron armature, which reduced magnetic energy. To manufacture the stator, 110 kg of neodymium magnets were used and 115 kg of neodymium were used to manufacture the rotor. High-frequency field magnetization was not applied. It was decided to replace an imprinting technology described in [1-5] with cross-magnetic inserts having a flux vector directed at 90 degrees to the primary magnetization vector of the stator and rollers.

For the cross inserts, modified rare earth magnets with a residual magnetization of 1,2 T and coercive force a little bit greater than in a base material were used. In Fig.1 and Fig.2 the joint arrangement of stator 1 and rotor, made up of rollers 2, and a way of their mutual gearing or sprocketing by means of cross magnetic inserts 19, are shown. Between the stator and roller surfaces the air gap δ of 1-mm is maintained.

No layered structure was used except a continuous copper foil of 0.8 mm thickness, which wrapped up the stator and rollers. This foil has direct electrical contact to magnets of the stator and rollers. Distance between inserts in the rollers is equal to distance between inserts on the stator. In other words, $\mathbf{t_1} = \mathbf{t_2}$ in Fig.2.

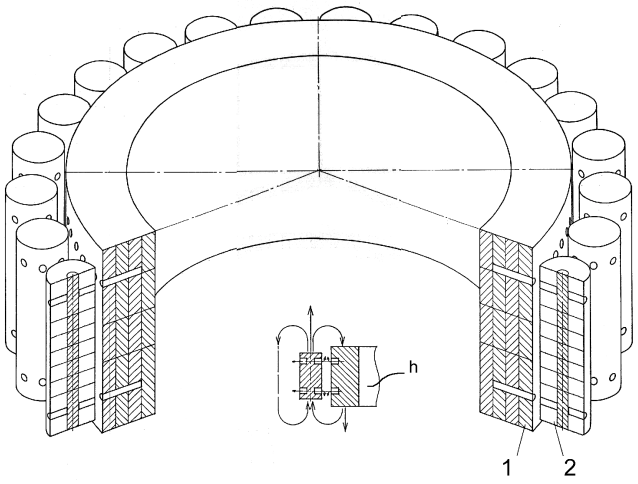

Fig.1. Variant of one-ring converter.

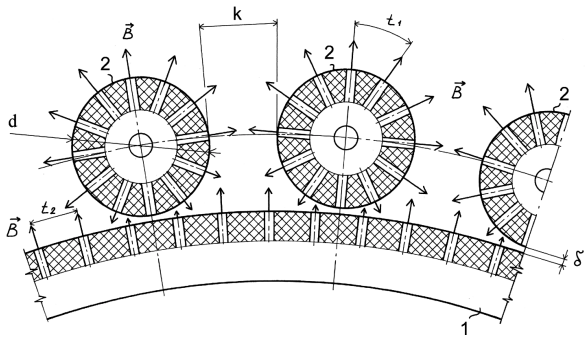

Fig.2. Sprocket effect of magnetic stator and roller inserts.

The ratio of parameters of the stator 1 and the rotor 2 in Fig.2 is chosen so that the relation of stator diameter D to the roller diameter d is an integer equal to or greater than 12. Choosing such ratio allowed us to achieve a "magnetic spin wave resonant mode" between elements of a working body of the device since the circumferences also maintained the same integer ratio.

The elements of magnetic system were assembled in a uniform design on an aluminum platform. In Fig. 3 the general view of the platform with the one-ring converter is displayed. This platform was supplied with springs and shock absorbers with limited ability to move vertically on three supports. The system has a maximum value of displacement of about 10 mm and was measured by the induction displacement meter, 14. Thus, the instantaneous change of the platform weight was defined during the experiment in real time. Gross weight of the platform with magnetic system in the initial condition was 350 kg.

The stator, 1, was mounted motionlessly, and the rollers, 2, were assembled on a mobile common separator, 3, also regarded as the rotor, connected with the basic shaft, 4, of the device. The rotary

moment was transferred through this shaft. The base of the shaft was connected through a friction clutch, 5, to a starting motor, 6, which accelerated the converter up to a mode of self-sustained rotation. The electrodynamics generator, 7, was connected to the basic shaft as a main loading of the converter. Adjacent to the rotor, electromagnetic inductors, 8, with open cores, 9, were located.

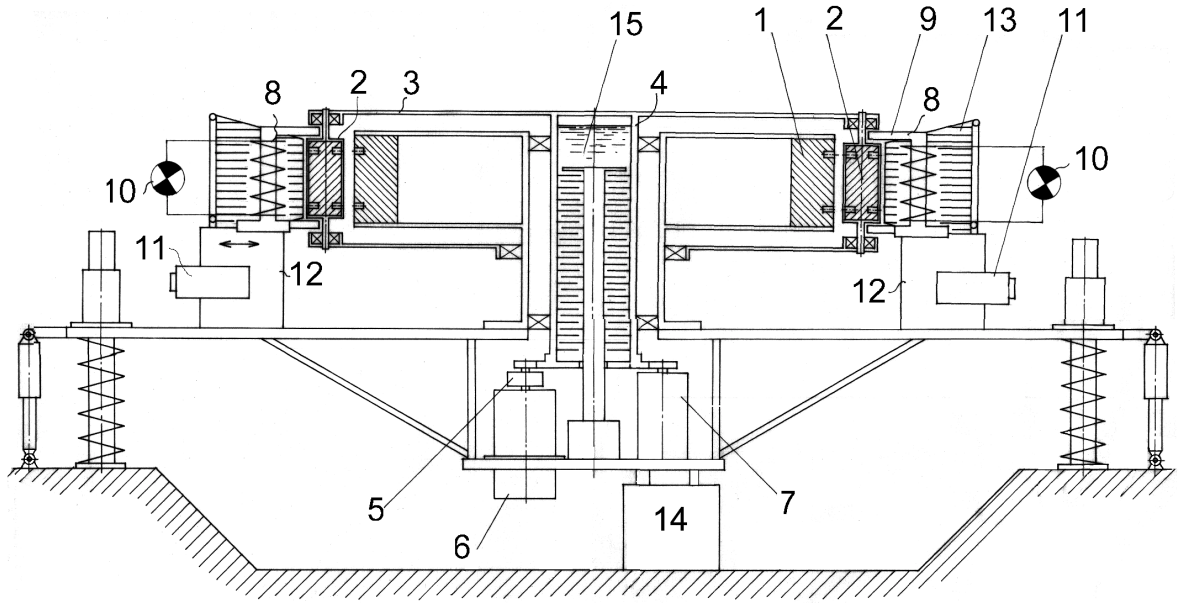

Fig.3. The general view of the one-ring converter and platform.

The magnetic rollers, 2, crossed the open cores of inductors and closed the magnetic flux circuit through electromagnetic inductors, 8, inducing an electromotive force emf in them, which acted directly on an active load, 10 (a set of inductive coils and incandescent lamps with a total power load of 1 kW). The electromagnetic inductor coils, 8, were equipped with an electrical drive, 11, on supports, 12. Driven coils for smooth stabilization of the rotor's rpm were used but the speed of the rotor could be adjusted by changing the main loading, 10.

To study the influence of high voltage on the characteristics of the converter, a system for radial electrical polarization was mounted. On the periphery of the rotor ring, electrodes, 13, were set between the electromagnetic inductors, 8, having an air gap of 10 mm with the rollers, 2. The electrodes are connected to a high-voltage source; the positive potential was connected to the stator, and the negative to the polarization electrodes. The polarizing voltage was adjusted in a range of 0-20 kV. In the experiments, a constant value of 20 kV was used.

In case of emergency braking, a friction disk from the ordinary car braking system was mounted on a basic shaft of the rotor. The electrodynamics generator, 7, was connected to an ordinary passive resistive load through a set of switches ensuring step connection of the load from 1 kW to 10 kW through a set of ten ordinary electric water heaters.

The converter undergoing testing had in its inner core the oil friction generator of thermal energy, 15, intended for tapping a superfluous power (more than 10 kW) into the thermo-exchange contour. But since the real output power of the converter in experiment has not exceeded 7 kW, the oil friction thermal generator was not used. The electromagnetic inductors were connected to an additional load,

which was set of incandescent lamps with total power 1 kW and facilitated complete stabilization of the rotor revolutions.

3. Experimental results

The magnetic-gravity converter was built in a laboratory room on three concrete supports at a ground level. The ceiling height the lab room was 3-meters, the common working area of the laboratory was about 100 sq. meters. Besides the presence of the iron-concrete ceiling, in the immediate proximity from the magnetic system there was a generator and electric motor, which contained some tens of kilograms of iron and could potentially deform the field's pattern.

The device was initially started by the electric motor that accelerated the rotation of the rotor. The revolutions were smoothly increased up to the moment the ammeter included in a circuit of the electric motor started to show zero or a negative value of consumed current. The negative value indicated a presence of back current. This back current was detected at approximately 550 rpm. The displacement meter, 14, starts to detect the change in weight of the whole installation at 200 rpm. Afterwards, the electric motor is completely disconnected by the electromagnetic clutch and the ordinary electrodynamics generator is connected to the switchable resistive load. The rotor of the converter continues to self-accelerate and approach the critical mode of 550 rpm where the weight of the device quickly changes.

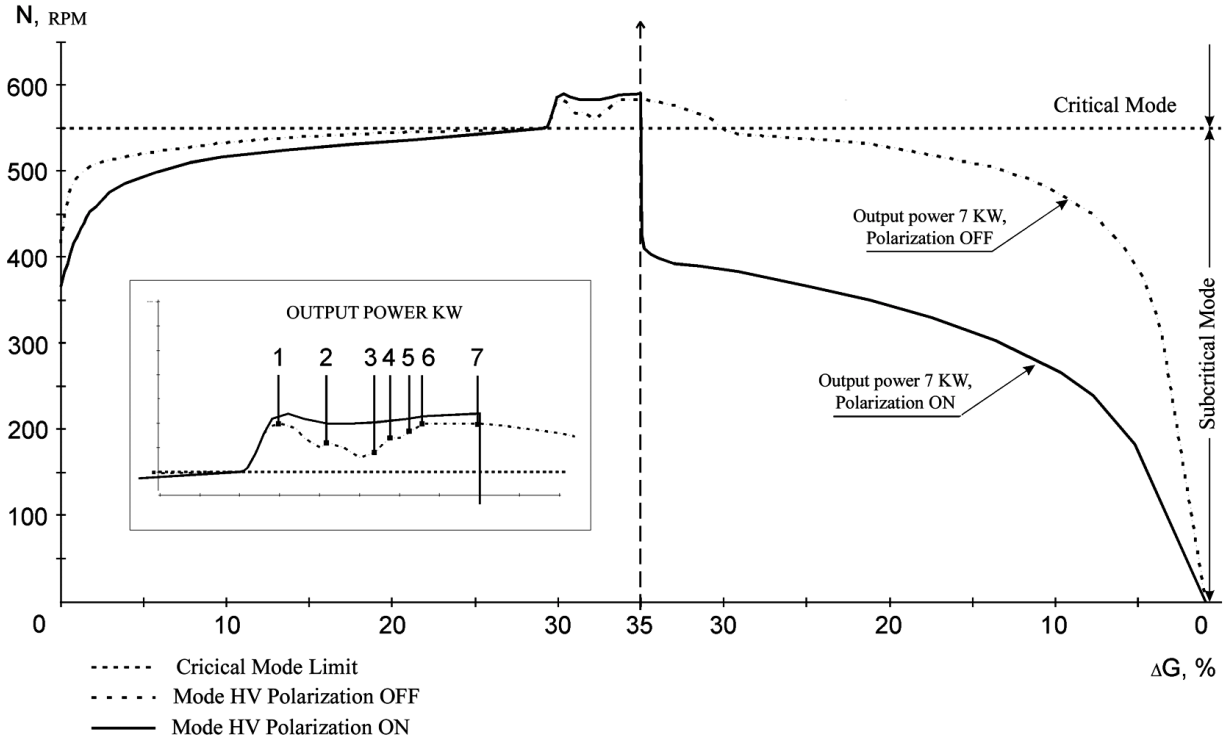

Fig. 4. -G, +G changes in weight of the platform vs. rpm

In addition to the dependence on the speed of rotation, the weight differential depends on the generated power through the load and on the applied polarizing voltage as well. As seen in Fig.4, at the maximum output power equal to 6-7 kW, the change of weight $\Delta\mathbf{G}$ of the whole platform (total weight is about 350 kg), reaches 35 % of the weight in an initial condition $\mathbf{G_i}$. Applying a load of more than 7 kW results in a gradual decrease in rotation speed and an exit from the mode of self-generation, with the rotor coming to a complete stop subsequently.

The net weight $\mathbf{G_n}$ of the platform can be controlled by applying high voltage to polarization ring electrodes located at a distance of 10 mm from external surfaces of the rollers. Under the high 20 kV voltage (electrodes having negative polarity) the increase of tapped power of the basic generator to more than 6 kW does not influence $\Delta\mathbf{G}$ if the rotation speed is kept above 400 rpm. "Tightening" of this effect is observed as well as the effect of hysteresis on $\Delta\mathbf{G}$ (a kind of "residual induction"). The experimental diagrams given on Fig.4 illustrate the +G and –G modes of the converter operations vs. rotor rpm.

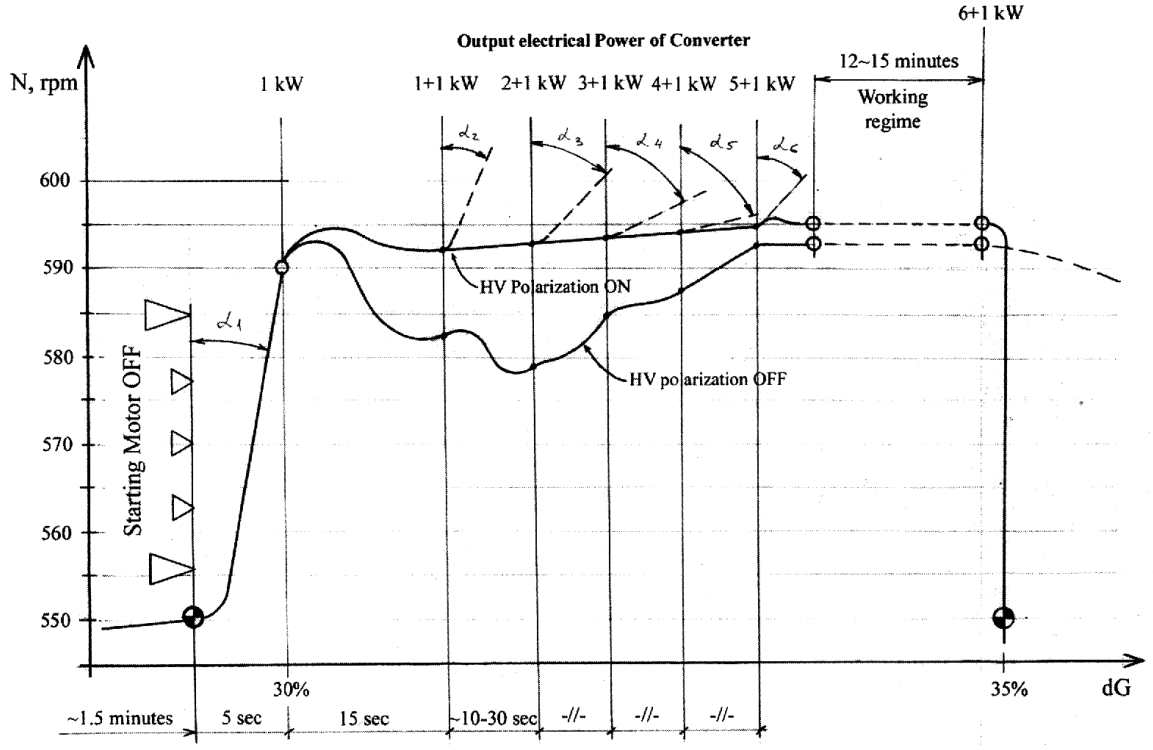

Fig.5 Diagrams of a rotor accelerating and loading of the converter.

The effect of a local change of the platform weight is reversible, relative to the direction of rotor turning, and has the same hysteresis. A clockwise rotation causes the critical mode to occur in the area of 550 rpm and the propulsion force against the direction of gravitation vector is created. Correspondingly, a counter-clockwise rotation causes the critical mode to occur the in area of 600 rpm and a force in the direction of gravitation vector is created. The difference in approach to a critical mode of 50 - 60 rpm was observed. It is necessary to mention that the most interesting region are situated above the critical area of 550 rpm, but due to of a number of circumstances the implementation of such research was not possible. It is necessary to note, that probably there are also other resonant modes appropriate to higher rpm of a rotor and to the significant levels of useful loading and weight changing. Proceeding from the theoretical assumptions, the dependence of tapped mechanical energy from the parameters of magnetic system of the converter and rpm of a rotor has a nonlinear character and the received effects are not optimum. From this point of view, the revealing of the maximal output power, of the maximal change of weight and resource of the converter represents the large practical and scientific interest. In tested sample of the converter the using of higher rpm was inadmissible because of unsufficient mechanical durability of the magnetic system, which was built from separate pieces.

In Fig.5 the dependence of weight of a platform and its output power, removed into resistive loading from rpm of a rotor of the converter is explained in detail. The diagrams are constructed for a case of HV polarization ON (top diagram) and HV polarization OFF (bottom diagram). The time from the start moment of the engine up to a mode of self-generation of the converter, at the rotation of a rotor clockwise, approximately is equal 1.5 minutes. (The power of starting engine was about of 2 KW with a reduction on the shaft of the converter is equal 1/10). At achievement of a critical mode (550 rpm.), the change of gross weight of a platform already achieves +/-30% from $\mathbf{G_i}$. In the point of transition to a resonant mode, the revolutions with the large acceleration has increases up to 590 rpm and weight has changes up to + /-35% from $\mathbf{G_i}$. In this time an unpleasant high frequency whistling sound became audible. This place of the diagram begins at once after a critical point (inclination of a curve $\boldsymbol{\alpha_1}$). At achievement of 590 rpm, the first stage of resistive loading in 1 kW is connected to the electrodynamics generator. The whistling sound at once stops, the revolutions are sharply reduced and ΔG also is changing. As soon as the revolutions begin to grow again, the second switchable load is connected and rotor's rpm are stabilized at a level of 590-595 rpm. ΔG continues to change. The increasing of switchable loading occurs by steps in 1 kW up to total power of 6 kW. All intervals in time are equal approximately of 10-30 sec. Afterwards, the short-term increasing of revolutions and then the full stabilization of a mode during of 12-15 min were observed.

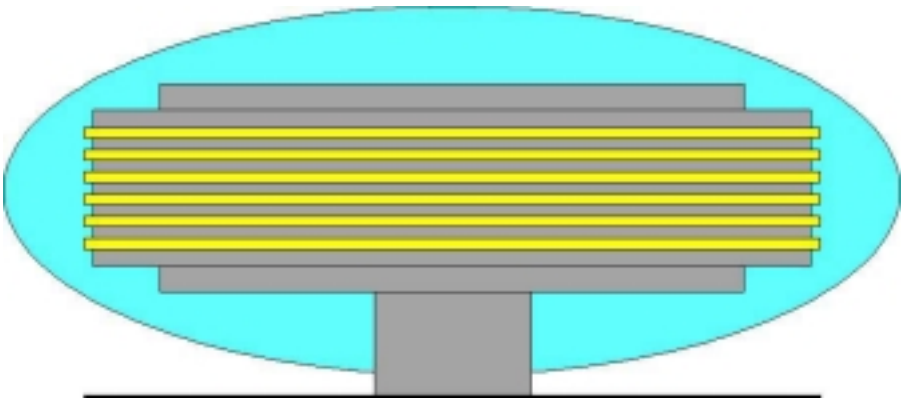
More than 50 launches of this converter with absolute repeatability within three months were carried out. It is necessary to note, that revolutions will grow with acceleration reflected on the Fig.5 by corners $\boldsymbol{\alpha_1}\ldots\boldsymbol{\alpha_5}$, if the generator is not switched to the next step of loading, the rpm will continue increasing. Twice as much loading was required to return to a previous rpm mode.

The above discussion concerns a mode with high voltage polarization of 20 kV "plus" on a "grounded" stator. Without the 20 kV polarization voltage (lower curve) the diagram is approximately the same, but indicates the more hard character of loading and faster change of weight of a platform due to decreasing of rpm.

Other interesting effects include the work of the converter in a dark room when corona discharges are observed around the converter's rotor as a blue-pink glowing luminescence and a characteristic ozone smell. In Fig.6 the cloud of ionization covers the area of a stator and a rotor and has accordingly a toroidal form.

Fig.6. Corona discharges around the converter.

On the background of luminescence glowing on rollers' surfaces, we distinguished a «wave picture.» A number of more vigorous strips of discharges around the rollers were observed. These discharges were of a white-yellow color but the characteristic sound for arc discharges was not audible. На поверхностях статора и роликов не имелось никаких видимых эрозионных повреждений as well as. Erosive damage induced by arc discharges were not present on any surfaces of the stator or the rollers .



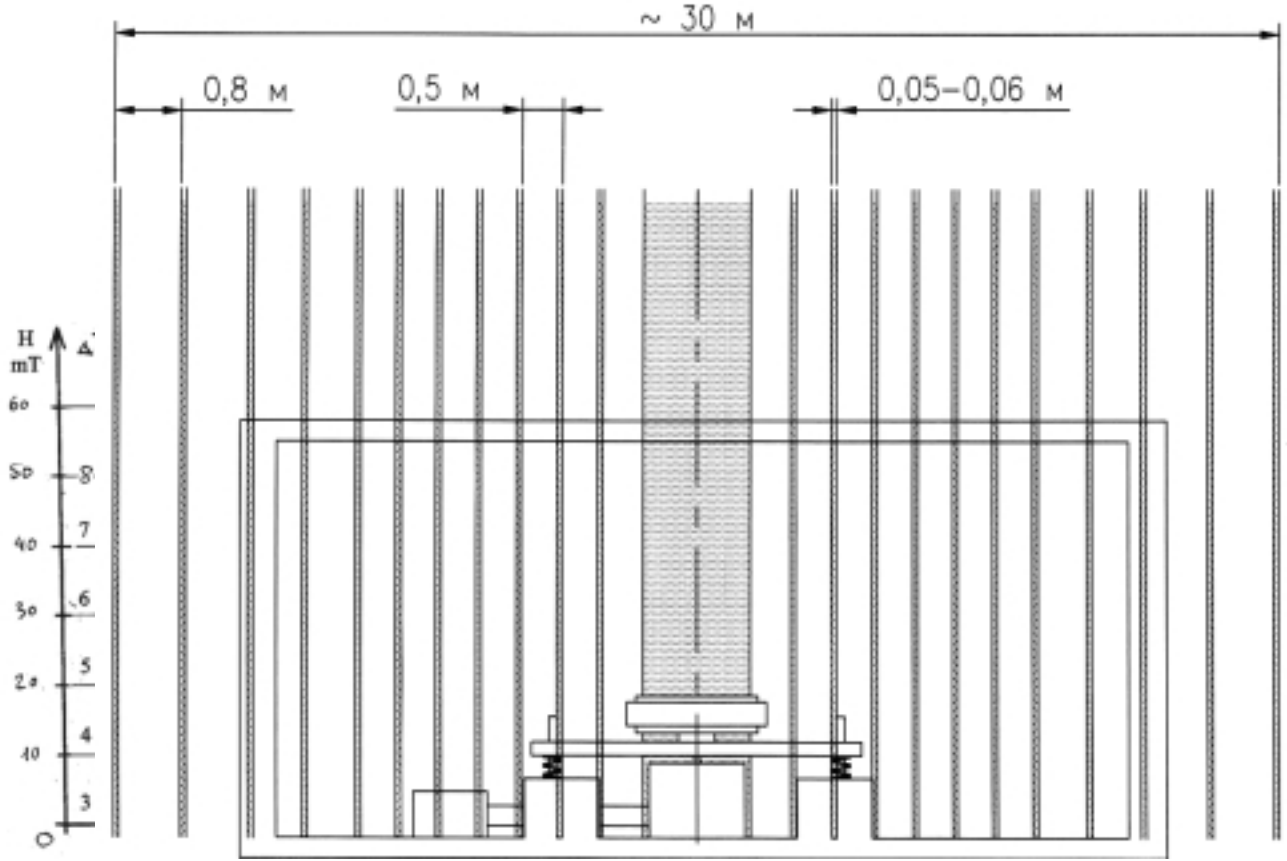
One more effect previously not mentioned was observed i.e. the vertical concentric magnetic "walls" around the installation. We noticed and measured the abnormal permanent magnetic field around the converter within the radius of 15 me-

ters. For the magnetic field measurement the Russian magnetometer F4354/1 was used. Magnetometer used the Hall-effect sensor in the copper shielding. The zones of an increased intensity of a magnetic flux 0.05 T located concentrically from the center of the installation were detected. The direction of the magnetic field vector in these walls coincided with the direction of the rollers' field vector. The structure of these zones reminded us of circles on water from a thrown stone. Between these zones, this portable magnetometer did not register abnormal magnetic fields. The layers of an increased intensity are distributed practically without losses up to a distance of about 15 meters from the center of the converter and quickly decrease at the border of this zone. The thickness of each layer is about 5 - 6 cm. The border of each layer has sharp shape, the distance between layers is about 50 - 80 cm where the upper limit is seen when moving from the center of the converter. A stable picture of this field was observed as well as at a height of 6 m above the installation (on the second floor above the lab). Above the second floor, measurements were not carried out. The similar picture was observed and outside of a room of laboratory, directly in the street, on the ground. The concentric walls are strictly vertical and no had appreciable distortions. In Fig.7 the schematic arrangement of the converter in a room of laboratory and arrangement of concentric magnetic fields are shown.

Fig.7. Schematic placing of the converter and pattern of magnetic fields in the lab's room.

An anomalous decrease temperature in the vicinity of the converter was also found. While the common temperature background in laboratory was + 22°C (±2°C) a fall of temperature equal to 6-8°C was noticed. The same phenomenon was observed in concentric vertical magnetic walls as well as. The measurements of temperature inside the magnetic walls were carried out by an ordinary alcohol thermometer with an inertia of indication about 1.5 min. In the magnetic walls the temperature changes can even be distinctly observed by hand. When placed into this magnetic wall the hand feels very cold at once. A similar picture was observed at the height above installation, i.e. on the second floor of the laboratory as well as despite the ferro-concrete blocking of the ceiling and also on open air outside of the laboratory.

Fig.8. Dependence of intensity of a magnetic



field and changes of temperature vs rotor's rpm of the converter.

Concentric magnetic walls and the accompanying thermal effects begin to show themselves by an appreciable image beginning approximately from of 200 rpm., and linearly grow with increasing of revolutions up to a critical mode. The measurements above 600 rpm were not made because of fear of destruction of magnetic system. In Fig.8 the curve of intensity of a magnetic field in мT and change of temperature in Celsius degrees due to rpm changing is represented.

4. Discussion

All the results we obtained are extremely unusual and require some theoretical explanation. Unfortunately, the interpretation of results within the framework of the conventional physical theory cannot explain all the observed phenomena besides the change of weight. It is possible to interpret the change of weight either as a local change of gravitational force or as an antigravity force repelling its own field. Direct experiment, confirming the presence of a draft force was not performed, but in any case both interpretations of the weight change do not correspond to the modern physics paradigm. A reconsideration of the standard theory of gravitation is possible if we take into consideration space-time curvature. For example, the Kerr metric usually represents the field exterior to an axially symmetric rotating body and distinguishes between positive and negative spin directions as well as forward and backward time directions [8]. An examination of the physical vacuum as a source of these phenomena may also lend itself to better interpretation since the Maxwell stress-energy tensor in the vicinity of the converter undergoes a complex evolution.

From the modern physics position, electrification and luminescence of the converter's magnetic system in the near zone is not completely clear. The phenomenon of the magnetic and thermal "walls" may be connected with Alphen's magnetic-sound waves raised in near zone in magnetized plasma induced by a variable magnetic field of a rotating rotor [9]. The energy exchange between ambient air molecules and the converter may be occurring. At the present time we can not give an exact description of the interactions mechanism and transformation of energy, but without a relativistic we are completely unable to give a physically substantial theory of these phenomena.

In conclusion, we emphasize that issues of the biological influence effects and especially of the variations of real time stream effects, which must be taking place in an operative zone of the converter, were not considered at all. These issues are extremely important and absolutely unexplored; though there are some mentions of J.R.R.Searl about healing action of the SEG's radiation. Our own experience allows us to make only cautious assumption that the short-term stay (dozen minutes) in a working zone of the converter with the fixed output power of 6 kW remains without observed consequences for those exposed. The present paper is only a beginning.

PHYSICS OF GRAVITATIONAL WAVE DETECTION: RESONANT AND INTERFEROMETRIC DETECTORS

Peter R. Saulson*
Department of Physics
Syracuse University, Syracuse, NY 13244-1130

ABSTRACT

I review the physics of ground-based gravitational wave detectors, and summarize the history of their development and use. Special attention is paid to the historical roots of today's detectors.

1 The Nature of Gravitational Waves

1.1 What Is a Gravitational Wave?

There is a rich, if imperfect, analogy between gravitational waves and their more familiar electromagnetic counterparts. A nice heuristic derivation of the necessity for the existence of electromagnetic waves and of some of their properties can be found in, for example, Purcell's *Electricity and Magnetism*.[1] A key idea from special relativity is that no signal can travel more quickly than the speed of light. Consider the case of an electrically charged particle that is subject to a sudden acceleration of brief duration. It is clear that the electric field cannot be everywhere oriented in a precisely radial direction with respect to its present position; otherwise information could be transmitted instantaneously to arbitrary distances simply by modulating the position of the charge. What happens instead is that the field of a charge that has been suddenly accelerated has a kink in it that propagates away from the charge at the speed of light. Outside of the kink, the field is the one appropriate to the charge's position and velocity before the sudden acceleration, while inside it is the field appropriate to the charge subsequent to the acceleration. In each of those regions, the field looks like a radial field for the appropriate charge trajectory, but the kink itself has a transverse component, necessary to link the field lines outside and inside. The transverse field propagating at the speed of light away from the accelerating charge is the electromagnetic wave.

Heuristically, we can use similar reasoning to think about the case of gravitational fields. If the gravitational field of a mass were radial under all circumstances, then instantaneous communication would be possible. The transmitter could be a mass whose position could be modulated, and the receiver would be a device that determined the orientation of its gravitational field. In order that gravity not be able to violate relativity, it must be the case that the gravitational field of a recently accelerated body contains a transverse kink that propagates away from it at the speed of light. This transverse kink is the gravitational wave that carries the news that the body was recently accelerated.

It is helpful to consider the radiation from an extended system, a more realistic description than the point particle moved by prescription assumed in the foregoing paragraphs. In the electromagnetic case the lowest order moment of a charge distribution involved in radiation is the dipole moment, radiation by a time varying monopole moment (i.e., electric charge itself) being forbidden by the law of conservation of charge. The law of conservation of energy plays a similar role in forbidding monopole gravitational radiation, since that would require the total mass of an isolated system to vary. In addition, though, there can be no time-varying mass dipole moment of an isolated system; conservation of linear momentum forbids this. The difference between the gravitational case and the electromagnetic one is that the "gravitational charge-to-mass ratio" is the same for all bodies, by the Principle of Equivalence; the equal and opposite reaction that accompanies any action on a given body precisely cancels second time derivatives of the mass dipole moment of any isolated system. Similarly, the law of conservation of angular momentum forbids the gravitational equivalent of the magnetic dipole moment from varying in time. The lowest order moment of an isolated mass distribution that can accelerate is its quadrupole moment

$$I_{\mu\nu} \equiv \int dV \left(x_\mu x_\nu - \frac{1}{3}\delta_{\mu\nu} r^2 \right) \rho(\mathbf{r}) .$$

The second time derivative of the mass quadrupole moment plays the same role in gravitational radiation as does the first time derivative of the charge dipole moment in electromagnetic radiation, that of leading term in typical radiation problems.

But what is the analog of the electric field in gravitational wave problems, that is to say, the wave field amplitude itself? An answer comes from study of the Einstein field equations in the weak field limit. Specifically, one considers the case where the space-time metric can be approximated as $g^{\mu\nu} = \eta^{\mu\nu} + h^{\mu\nu}$, where $h^{\mu\nu}$ is a small perturbation of the Minkowski metric $\eta^{\mu\nu}$. Then, if one chooses a particular coordinate condition (the so-called "transverse traceless gauge"), the Einstein equations become a wave equation for the perturbation $h^{\mu\nu}$. Furthermore, the perturbation takes on a particular form: for a solution to the wave equation corresponding to a wave travelling along the z axis, h must be a linear combination of the two basis tensors

$$h_+ = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

and

$$h_\times = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} .$$

Notice that for this wave along the z axis, the effects of the wave are only in the x and y components. In other words, the wave is transverse.

1.2 The Effect of Gravitational Waves on Test Bodies

The statement that the gravitational wave amplitude is the metric perturbation tensor h is probably hard to visualize without considering some examples. Imagine a plane in space in which a square grid has been marked out by a set of infinitesimal test masses (so that their mutual gravitational interaction can be considered negligible compared to their response to the gravitational wave). This is a prescription for embodying a section of the transverse traceless coordinate system mentioned earlier, marking out coordinates by masses that are freely-falling (i.e., that feel no non-gravitational forces).

Now imagine that a gravitational wave is incident on the set of masses, along a direction normal to the plane. Take this direction to be the z axis, and the masses to be arranged along the x and y axes. Then, if the wave has the polarization called h_+, it will cause equal and opposite shifts in the formerly equal x and y separations between neighboring masses in the grid. That is, for one polarity of the wave, the separations of the masses along the x direction will decrease, while simultaneously the separations along the y direction will increase. When the wave oscillates to opposite polarity, the opposite effect occurs.

If, instead, a wave of polarization $h_\times$ is incident on the set of test masses, then there will be (to first order in the wave amplitude) no changes in the distances between any mass and its nearest neighbors along the x and y directions. However, $h_\times$ is responsible for a similar pattern of distance changes between a mass and its next-nearest neighbors along the diagonals of the grid.

There are several other aspects of the gravitational wave's deformation of the test system that are worth pondering. Firstly, the effect on any pair of neighbors in a given direction is identical to that on any other pair. The same *fractional* change occurs between other pairs oriented along the same direction, no matter how large their separation. This means that a larger *absolute* change in separation occurs, the larger is the original separation between two test masses. This property, which we can call "tidal" because of its similarity to the effect of ordinary gravitational tides, is exploited in the design of interferometric detectors of gravitational waves.

Another aspect of this pattern that is worthy of note is that the distortion is uniform throughout the coordinate grid. This means that any one of the test masses can be considered to be at rest, with the others moving in relation to it. In other words, a gravitational wave does not cause any absolute acceleration, only relative accelerations between masses. This, too, is fully consistent with other aspects of gravitation

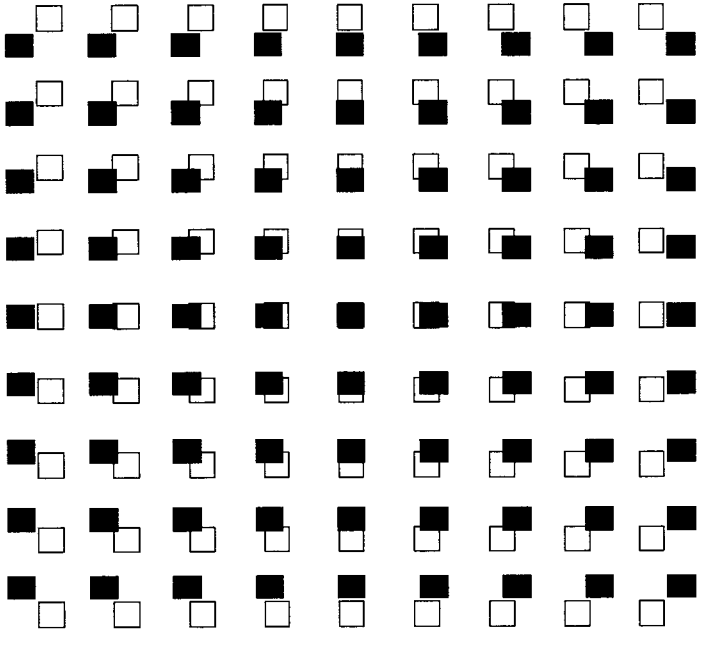

Fig. 1. An array of free test masses. The open squares show the positions of the masses before the arrival of the gravitational wave. The filled squares show the positions of the masses during the passage of a gravitational wave of the plus polarization.

as described by the general theory of relativity: a single freely-falling mass cannot tell whether it is subject to a gravitational force. Only a measurement of relative displacements between freely-falling test masses (the so-called "geodesic deviation") can reveal the presence of a gravitational field.

1.3 A *Gedanken* Experiment to Detect a Gravitational Wave

In the discussion in the preceding section, we took it for granted that the perturbations h_+ and $h_\times$ to the flat-space metric were, in some sense, real. But it is only by considering whether such effects are measurable that one can be convinced that a phenomenon like a gravitational wave is meaningful, rather than a mathematical artifact that could be transformed away by a suitable choice of coordinates.

To demonstrate the physical reality of gravitational waves, consider the example system of the previous section. We will concentrate our attention on three of the test masses, one chosen arbitrarily from the plane, along with its nearest neighbors in the $+x$ and $+y$ directions. Imagine that we have equipped the mass at the vertex of this "L" with a lamp that can be made to emit very brief pulses of light. Imagine also that the two masses at the ends of the "L" are fitted with mirrors aimed so that they will return the flashes of light back toward the vertex mass.

First, we will sketch how the apparatus can be properly set up, in the absence of a gravitational wave. Let the lamp emit a train of pulses, and observe when the reflected flashes of light are returned to the vertex mass by the mirrors on the two end masses. Adjust the distances from the vertex mass to the two end masses until the two reflected flashes arrive simultaneously.

Once the apparatus is nulled, let the lamp keep flashing, and wait for a burst of gravitational waves to arrive. When a wave of $\hat{h}_+$ polarization passes through the apparatus along the z axis, it will disturb the balance between the lengths of the two arms of the "L." Imagine that the gravitational wave has a waveform given by

$$h^{\mu\nu} = h(t)\hat{h}_+.$$

To see how this space-time perturbation changes the arrival times of the two returned flashes, let us carefully calculate the time it takes for light to travel along each of the two arms.

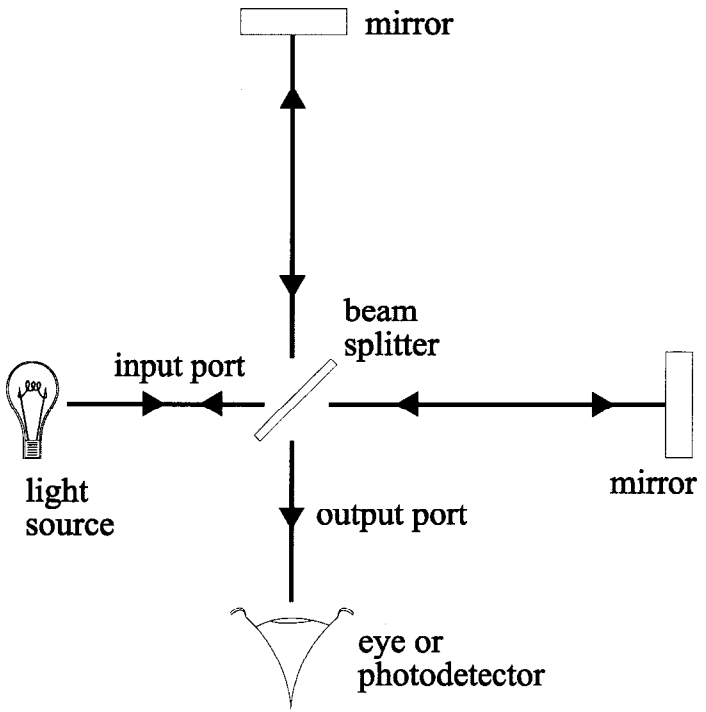

Fig. 2. A schematic diagram of an apparatus that can detect gravitational waves. It has the form of a Michelson interferometer.

First, consider light in the arm along the x axis. The interval between two neighboring space-time events linked by the light beam is given by

$$\begin{aligned} ds^2 = 0 &= g_{\mu\nu}dx^\mu dx^\nu \\ &= (\eta_{\mu\nu} + h_{\mu\nu})\, dx^\mu dx^\nu \\ &= -c^2dt^2 + (1 + h_{11}(2\pi ft - kz))\, dx^2. \end{aligned} \tag{1}$$

This says that the effect of the gravitational wave is to modulate the square of the distance between two neighboring points of fixed coordinate separation dx (as marked, in this gauge, by freely-falling test particles) by a fractional amount h_{11}.

We can evaluate the light travel time from the beam splitter to the end of the x arm by integrating the square root of Eq. (1)

$$\int_0^{\tau_{out}} dt = \frac{1}{c}\int_0^L \sqrt{1 + h_{11}}dx \approx \frac{1}{c}\int_0^L \left(1 + \frac{1}{2}h_{11}\,(2\pi ft - kz)\right) dx, \tag{2}$$

where, because we will only encounter situations in which $h \ll 1$, we've used the binomial expansion of the square root, and dropped the utterly negligible terms with more than one power of h. We can write a similar equation for the return trip

$$\int_{\tau_{out}}^{\tau_{rt}} dt = -\frac{1}{c}\int_L^0 \left(1 + \frac{1}{2}h_{11}(2\pi ft - kz)\right) dx. \tag{3}$$

The total round trip time is thus

$$\tau_{rt} = \frac{2L}{c} + \frac{1}{2c}\int_0^L h_{11}(2\pi ft - kz)dx - \frac{1}{2c}\int_L^0 h_{11}(2\pi ft - kz)dx. \tag{4}$$

The integrals are to be evaluated by expressing the arguments as a function just of the position of a particular wavefront (the one that left the beam-splitter at $t = 0$) as it propagates through the apparatus. That is, we should make the substitution $t = x/c$ for the outbound leg, and $t = (2L - x)/c$ for the return leg. Corrections to these relations due to the effect of the gravitational wave itself are negligible.

A similar expression can be written for the light that travels through the y arm. The only differences are that it will depend on h_{22} instead of h_{11} and will involve a different substitution for t.

If $2\pi f_{gw}\tau_{rt} \ll 1$, then we can treat the metric perturbation as approximately constant during the time any given flash is present in the apparatus. There will be equal and opposite perturbations to the light travel time in the two arms. The total travel time difference will therefore be

$$\Delta\tau(t) = h(t)\frac{2L}{c} = h(t)\tau_{rt0}, \tag{5}$$

where we have defined $\tau_{rt0} \equiv 2L/c$.

If we imagine replacing the flashing lamp with a laser that emits a coherent beam of light, we can express the travel time difference as a phase shift by comparing the travel time difference to the (reduced) period of oscillation of the light, or

$$\Delta\phi(t) = h(t)\tau_{rt0}\frac{2\pi c}{\lambda}. \tag{6}$$

Another way to say this is that the phase shift between the light that traveled in the two arms is equal to a fraction h of the total phase a light beam accumulates as it traverses the apparatus. This immediately says that the longer the optical path in the apparatus, the larger will be the phase shift due to the gravitational wave.

Thus, this *gedanken* experiment has demonstrated that gravitational waves do indeed have physical reality, since they can (at least in principle) be measured. Furthermore, it suggests a straightforward interpretation of the dimensionless metric perturbation h. The gravitational wave amplitude gives the fractional change in the difference in light travel times along two perpendicular paths whose endpoints are marked by freely-falling test masses.

1.4 Another Way to Picture the Effect of a Gravitational Wave on Test Bodies

In standard laboratory practice, it is not customary to define coordinates by the world-lines of freely-falling test masses. Instead, rigid rulers usually are used to do the job. The forces that make a rigid ruler rigid are something of a foreign concept in relativity, appearing ugly and awkward after the gravitational force has been made to disappear by expressing it as the curvature of space-time. On the other hand, non-gravitational forces are not only a fact of nature, but part of the familiar world of the laboratory. For many purposes, it is convenient to retreat from a purely relativistic picture and instead use a Newtonian picture in which gravity is treated as force on the same level as other forces.

What we are seeking is not a different theory of gravitational waves, but a translation of the theory discussed in the previous section into more familiar language. So let us reconsider the same *gedanken* experiment as before, but imagine that we have augmented the equipment with a rigid ruler along each axis. We saw that when a gravitational wave passed through our set of test masses, the amount of time it took for light to travel from the vertex mass to the end mass and back was made to vary. How can we

describe how this came about in the standard language of the laboratory? If we imagine (notwithstanding their fixed coordinates in the transverse traceless gauge) that the test masses have moved in response to the gravitational wave, we can have a consistent picture of the effect. What is necessary is that the gravitational wave give a tidal force across the pair of masses that will cause them to move apart by the amount necessary to account for the change in light travel time through the system. It is as if the far masses felt forces whose magnitude were given by

$$F_{gw} = \frac{1}{2} m L \frac{\partial^2 h_{11}}{\partial t^2}, \tag{7}$$

where m is the mass of each of the two test bodies, and L is the separation between their centers of mass.

There are several features of this expression that are worthy of note. The force is proportional to the mass of the test bodies, as required by the Principle of Equivalence. The force is also proportional to the separation between the two test masses, making it akin to conventional gravitational tidal forces. The dependence of the gravitational wave force on the second time derivative of h is reminiscent of Newton's Second Law $F = m\ddot{x}$. A natural interpretation follows: in a conventional laboratory coordinate system, free masses actually change their separation by an amount $\Delta L = hL/2$.

Note how in two different coordinate systems the same phenomenon (and particularly the same measurement) is described in completely different language. In transverse traceless coordinates, the free test masses still just fall freely, each marking out its own coordinate (by definition) under any gravitational influence, but the light travel time between them changes as the metric of space-time varies. In standard laboratory coordinates, light travel time changes because the test masses move. Neither of these pictures is more "correct" than the other. The laboratory-coordinate picture is markedly more convenient for seeing how to combine the effect of a gravitational wave with the effects of noise forces of various kinds. The transverse traceless coordinates offer the most clarity when one wants to consider extreme cases, such as test masses separated by distances comparable to or longer than the gravitational wave's wavelength.

2 Generating Gravitational Waves

As mentioned above, the second time derivative of the mass quadrupole moment I plays the same role in gravitational wave emission as does the first derivative of the charge dipole moment in electromagnetic radiation problems, that of strongest source term in most situations. More specifically, the expression for gravitational wave generation is

$$h_{\mu\nu} = \frac{2G}{Rc^4} \ddot{I}_{\mu\nu}, \tag{8}$$

usually referred to as the "quadrupole formula."[2]

Something about this expression should immediately give one pause—the prefactor of $2G/c^4$. In SI units, this has the value 1.6×10^{-44} sec^{2}kg^{-1}m^{-1}. It will take tremendously large values of $\ddot{I}/R$ in order for even modest values of h to be generated. *A priori*, one can think of two strategies that might work: make R small, or make $\ddot{I}$ large.

2.1 Laboratory Generators of Gravitational Waves

To construct a source of gravitational waves in the laboratory would allow one to have the benefit of placing it as close as possible to one's detector, thus exemplifying the first strategy in the previous paragraph. Of course, it would have other benefits as well. Control of the waveform, polarization, and other features would enable the detector to be carefully optimized to match the signal. At an even deeper level, confidence in the detection of gravitational waves could be assured by the requirement that they must be seen when, and only when, they were being emitted.

What one would really like to do is to replicate for gravitational waves what Hertz was able to accomplish for electromagnetic ones. His experiments of 1886–'91 not only conclusively demonstrated the existence of electromagnetic waves, they validated Maxwell's theory of electromagnetic radiation by exploring the rich phenomenology of polarization, reflection, and interference. They also began the process of harnessing the phenomenon for practical use. Marconi's work started by his following closely in Hertz's footsteps, and real long-distance communication via radio was not long in coming.

Unfortunately, no practicable way has been conceived to replicate Hertz's success in the gravitational domain. Assume we could construct a dumbbell consisting of two masses of one ton each, at either end of a rod two meters long. Spin this quadrupole about an axis orthogonal to the connecting rod passing through its midpoint, at an angular frequency $f_{rot} = 1$ kHz. Neglecting for simplicity the contribution of the connecting rod, we have a system very similar to a binary star system. The amplitude of the gravitational waves generated by this device will be

$$h_{lab} = 2.6 \times 10^{-33}\text{m} \times \frac{1}{R}. \tag{9}$$

Before we rush to plug in a distance R of a few meters, as Hertz was able to do for his experiment, we need to remember that wave phenomena are only distinguishable from near-field effects in the "wave zone," that is, at distances from the source comparable to or larger than one wavelength. With $\omega_{rot} = 2\pi \times 1$ kHz, we have $\lambda = 300$ km! The receiver for our Hertzian experiment must be at least that far away from the transmitter. Hertz's electromagnetic experiments involved waves of six meters down to 60 cm in length, so the distance across the lab was fine for him.

At a distance of one wavelength, our laboratory generator gives gravitational waves of amplitude

$$h_{lab} = 9 \times 10^{-39}. \tag{10}$$

This is pretty small.

Even creating such a strong source as this may not be practicable. Consider the stress in the connecting rod of the dumbbell. It must supply the centripetal force necessary for the masses to move in a circle. If the rod were made of good steel, it would need a cross-sectional area substantially greater than that of a one ton sphere in order not to fail under the stresses in a device with the parameters we have assumed. So we'd have to reduce the rotation frequency to keep the generator from flying apart, with a consequent reduction in the transmitted wave amplitude.

2.2 Astrophysical Sources of Gravitational Waves

Even if a gravitational version of the Hertz experiment is not feasible, all is not lost for the detection of gravitational waves. The best reason for optimism that detectable levels of gravitational radiation exist comes from the presence in the universe of objects with truly remarkable values of $\ddot{I}$. These systems are so extreme that even though their distances from our detectors are quite large, they still generate gravitational waves with amplitudes that exceed by almost 20 orders of magnitude the signal strengths from laboratory generators of the type described above.

It would be beyond the scope of this review to describe in detail all of the many astronomical objects that might be important sources of gravitational waves. Readers are urged to consult the article by Finn in these proceedings for further information on the variety of possible sources. But for the sake of a self-contained treatment, we show here how to estimate the magnitude of the strongest gravitational waves arriving at the Earth.

For the case of a binary star, there is an elegant way (due to Kafka[3]) of writing the amplitude of the quasi-sinusoidal gravitational wave strain. We can massage the quadrupole formula into a manifestly dimensionless form by recognizing that the mass dependence can be rewritten as a proportionality to the product of the Schwarzschild radii $R_s = 2GM/c^2$ of the stars. The frequency dependence and all of the stray factors remaining collect nicely as the separation r of the two stars. The gravitational wave amplitude is

$$h_{ns} = R_{s1}R_{s2}/rR. \tag{11}$$

If the binary consists of two neutron stars, then the Schwarzschild radii are both about 4 km. Astronomers estimate that within a sphere of radius 200 Mpc, roughly one of these sytems will coalesce each year. When the stars have a separation of ten diameters (or around 200 km), then the signal we would receive from that distance will have an amplitude of almost 10^{-23}. The stars can probably approach closer still before the system is destroyed.

A glance at this expression shows why a neutron star binary is a good choice as a strong source of gravitational waves. The substantial masses of the two stars make the numerator large. The fact that they are compact objects means that their separation r can be quite small. We could always wish that the distance R to the nearest example of such a system were smaller, but even so our estimated signal strength, while small in absolute terms, is certain dramatically larger than we were able to produce in our model laboratory generator.

Perhaps the only sort of astronomical system we can imagine that might generate stronger gravitational waves would be a binary system consisting of two black holes. Although it may be hazardous to treat such dramatically relativistic objects with the quasi-Newtonian physics used to derive Eq. (11), it will probably still give a good order of magnitude estimate. The possible advantages of black holes as sources of gravitational waves are twofold. Firstly, it is possible that the masses of black holes may be substantially in excess of the 1.4 $M_\odot$ typical of neutron stars. Secondly, black holes can approach to a separation r as close as their Schwarzchild radius R_s without disruption; instead the two will coalesce into a single larger black hole. Thus we guess that the gravitational signal from a black hole coalescence could be as large as

$$h_{bh} \sim R_s/R. \tag{12}$$

For a pair of 10 $M_\odot$ black holes at 200 Mpc, this expression would indicate a signal of $h \sim 5 \times 10^{-21}$.

Of course, we do not have nearly such secure knowledge of the existence of such binary systems as we do for the neutron star case. There is strong evidence for the existence of 10 $M_\odot$-class individual black holes in binary systems with main sequence stars.[4] The abundance of black hole binaries in this mass range is unknown, so the validity of our choice of 200 Mpc as a fiducial distance is uncertain at best.

One weakness of the elegant expressions Eqs. 11 and 12 is that they do not explicitly refer to the frequency of the gravitational wave. As we will see later, the various kinds of detectors of gravitational waves will each function best only in a certain band of frequencies. For reference, we anticipate the results of that discussion with the following summary: resonant-mass detectors work best in the vicinity of 1 kHz, interferometric detectors from around 10 Hz to a few kHz, and space interferometers between around 10^{-4} and 10^{-1} Hz. The strongest black hole signal will come at the frequency f_{qnm} of the lowest quasi-normal mode of the resulting combined black hole,

$$f_{qnm} \approx 0.7 \frac{c^3}{2GM}.$$

This makes resonant-mass detectors best suited for looking for black holes with masses of 10 $M_\odot$. Terrestrial interferometers will look for 3 $M_\odot$ to 1000 $M_\odot$ objects, while interferometers in space will search for black holes in the range near 10^6 $M_\odot$.

2.3 Summary

The contrast between terrestrial and astronomical sources of gravitational waves is striking. In spite of the fact that astronomical generators will only be found at distances far beyond the optimum, their other physical parameters are such that they will provide the strongest available gravitational wave signals. The contrast is so strong that this advantage alone must outweigh the ability to control the character and timing of the signal that would be inherent in a laboratory generator. Instead, even the most basic experiments on the nature of gravitational waves will necessarily involve astronomical observations.

3 Weber and the Birth of Gravitational Wave Detection

3.1 Weber's Original Vision

It is reasonable to ask the question whether even the astronomical signals are large enough to be detected by any conceivable device. On the face of it, the odds are daunting. A strain of 10^{-20}, for example, only generates relative motion of 10^{-20} meters between two test masses separated by one meter. Compare this with other characteristic length scales, and the challenge is clear: wavelength of visible light of 10^{-6} meter, atomic diameter of 10^{-10} meter, nuclear diameter of 10^{-15} meter. Nevertheless, it appears that gravitational wave signals from astronomical sources will probably soon be detected. It is the purpose of the rest of this review to show how this is possible.

There are at least two questions that might be raised by consideration of the numbers listed in the previous paragraph. The first is whether measurements of a macroscopic body can be capable of resolving motions substantially smaller than nuclear diameters. The second question that one might ask is whether success might be easier if the scale of the apparatus were made substantially larger than a meter, in order to take advantage of the fact that test masses separated by a larger distance will move by a proportionally larger amount in response to a gravitational wave of a given strength. Pondering the answers to these questions will lead to understanding of the most promising techniques for gravitational wave detection.

The postwar atmosphere of optimism about astronomical progress must have swept up Joseph Weber in the late 1950s. Weber became convinced that the time was right to try to extend the astronomical revolution beyond the electromagnetic spectrum. At that time, it was not obvious that strain sensitivities of 10^{-22} should be the goal. It was equally plausible that objects such as we discussed above might possibly be abundant enough that their typical distance might be the few kpc associated with galactic dimensions instead of 200 Mpc. So strains of 10^{-17} or perhaps even stronger might have been the proper goal to aim for. (Weber knew of a very optimistic estimate of wave strength by Wheeler,[5] which would allow an energy density of order of the cosmological closure density.) Weber's thinking showed the way to achieve such strain sensitivities; indeed, devices following directly in a line of development from his first instrument have in the past few years approached rms sensitivities of 10^{-19}, with the prospect of extension to a new generation of detectors sensitive to waves with amplitudes of order 10^{-20} or better.

Weber's early thinking is described in his *Physical Review* article of 1960,[6] and placed in the larger context of his thinking about general relativity in a small monograph published in 1961.[7] He describes a conceptual detector, in reciprocal relationship to a gravitational wave emitter, as a simple "mass quadrupole," sketched as two masses connected by a spring. Weber extends the general relativistic equation of geodesic deviation to include the non-gravitational forces applied by the elastic restoring force and the mechanical dissipation in the spring. The equation of motion of the system

then becomes that of a simple harmonic oscillator, with the driving term given by the effective force from the gravitational wave [our Eq. (7)].

Weber next shows how an extended elastic body behaves in such a way that each of its normal modes of vibration can be studied independently. (The gravest mode of a cylinder has a large quadrupole moment, and is the one that is usually used for detection.) He focuses attention on the use of a piezoelectric crystal as the detecting body, partly because he hopes that the electric field will make it a detector with effective size larger than half an acoustic wavelength, but also in large measure because the electric fields generated by the gravitational-wave-induced stress will give an integrated voltage between its ends that may be "large enough to be observed with a low-noise radio receiver." Weber calculates the amount of mechanical power that a sinusoidal gravitational wave can dissipate in the resonant detector as a function of frequency, then invokes the standard electrical network theorems to show what fraction of this power can be transferred to the input impedance of an amplifier.

A simple discussion of sensitivity follows. Weber first remarks that "in microwave spectroscopy it has been found that all spurious effects other than random fluctuations can be recognized." Then Weber states that the excitation of the detector must exceed the noise power associated with its thermal excitation.

Finally, Weber discusses possible practical experimental arrangements. In most of the discussion the devices are supposed to be made of large blocks of piezoelectric material. But in a footnote Weber states that the experimental work he is carrying out with David Zipoy and Robert L. Forward will probably make use of a large block of metal instead. (This is justified on the grounds that a half-wavelength at the 1 kHz frequency being contemplated is already large; thus the piezoelectric length-enhancement effect may not be necessary, and in any case such a large block of piezoelectric material "may not be obtainable as a single crystal".)

Two experimental strategies are foreseen: use of a single detector with examination of its output for a diurnal cycle associated with the scanning of its sensitivity pattern across the sky, and the cross-correlation of a pair of detectors so that external influences (presumably gravitational waves) can be distinguished from "internal fluctuations." He notes the necessity of preventing the excitation of the detector by "earth vibrations," and discusses an "ingenious" idea of Zipoy's for what is now called active vibration isolation.

Weber's very concise discussion is remarkable for the prescience with which it foreshadowed not only his own work, but that of so many others. It also marks a watershed in the history of general relativity. In a single blow, Weber wrested consideration of gravitational waves from theorists concerned about issues such as exact solutions, and appropriated the subject instead for experimentalists trained in issues of radio engineering. The boldness and brilliance of this move are remarkable.

3.2 The Logic of Weber's Idea

Weber sweeps quickly over a variety of issues that are worthy of more leisurely consideration. We'll give an overview of the important issues in this section, then devote the rest of this review to discussing their implications.

The detector Weber outlined can be divided into several subsystems: a set of test masses that respond to the gravitational wave, a transduction system that converts this mechanical response to a convenient electrical signal, a low-noise pre-amplifier, and a post-amplification averaging and recording mechanism. Notwithstanding the cleverness of Weber's original version, many variations on his basic scheme are possible, and indeed are responsible for much of the progress since he first announced the results of gravitational wave observations in 1969.[8]

Let's see how to analyze the original Weber design into these canonical subsystems. Weber explicitly pointed out how one could construct an analog of a pair of lumped test masses by monitoring an internal mode of vibration of an extended block of elastic material. In the version where this block is made of piezoelectric material, the same material serves both as test masses and as transducer from mechanical to electrical signal form. In the version in Weber's footnote (the one he actually built) a large aluminum cylinder serves as the set of test masses; piezoelectric strain gauges glued about the girth of the cylinder perform the transduction. The pre-amplifier is Weber's low-noise radio receiver. No averaging filter is shown in Weber's diagrams, but is implicit in his discussion.

Perhaps the most interesting choice that Weber made was to connect his test masses in a resonant system. It appears that Weber, at least in 1961, thought this was a necessity. In a footnote, he cites previous work by Pirani[9] in which the latter considered "measurement of the Riemann tensor by comparing accelerations of free test particles," but Weber continues, "The results of this chapter indicate that interacting particles must be used, in practice." In fact, it is not required either in principle or in practice, but it is interesting to consider why Weber may have thought so then, and what advantages still accrue to the use of resonant masses.

Weber couches a good deal of his discussion in terms of steady sinusoidal signals, still a common practice in much of engineering and even more so around 1960. If a gravitational wave did have this form, then masses connected by a spring give a resonant amplification of the response to a signal at the resonant frequency. The amount of this amplification is given by the resonator's quality factor Q, and can be substantial; Weber quotes an estimated $Q \sim 10^6$, still not a bad ballpark number.

On the other hand, there is essentially no resonant amplification if one has a sinusoidal signal whose frequency does not closely match the resonant frequency of the detector, or if the signal has a broad-band frequency content, as it would if it were a brief burst. Resonant amplification only comes about when the input force drives the resonant system with the proper phase for a substantial number of cycles; this can only occur when there is a good match between the signal frequency and the mechanical resonant frequency.

But even though the search for gravitational waves has come to focus mostly on burst-like signals, the resonant-mass configuration can still give a powerful advantage, albeit one not discussed by Weber in his 1961 book. A weak signal must compete for visibility against the noise in the pre-amplifier stage. This is why Weber made a point of calling for the lowest noise levels possible in this component. The noise in such amplifiers is generally of a broad-band character, best characterized by its power spectral density $S_v(f)$ which is typically roughly constant (or "white") over a wide range of frequencies. Usually there is an additional $1/f$ component that dominates at low frequencies.

The extent to which this noise competes with a signal depends in an essential way on the duration of the signal. We use the term "burst" to refer to a signal of limited duration in time; call its length τ_s. A fundamental theorem of signal detection states that the optimum contrast between a given signal and white noise can be attained when the time series containing the noise plus any possible signals is convolved with a template of the same form as the signal. This is called the *matched filter* when it is implemented in real time by an analog device. The heuristic idea behind such an optimum is that the matched filter rejects all components of the noise that do not "look like" the signal for which one is searching. Still, some noise passes through the matched filter. How much? If the Fourier transform of the signal waveform $v(t)$ is given by $V(f)$, then it passes noise power of

$$N^2 = \int_{-\infty}^{\infty} |V(f)|^2 S_v(f) df.$$

Another very general theorem of Fourier analysis takes the form of a classical "uncertainty relation." It states that there is an inverse relationship between the duration of a signal in the time domain and its width in the frequency domain:

$$\Delta f \Delta \tau \approx 1.$$

See what this implies for the question at hand. If we are looking for a brief signal, then its matched filter passes noise of a wide bandwidth. Thus, brief signals compete much less well against broad-band pre-amplifier noise than does a long-duration signal of the same amplitude.

Here is where a resonant detector of gravitational waves can make a difference even when one is looking for a broad-band signal. If the gravitational wave signal $h(t)$ contains substantial power in the vicinity of the detector's resonant frequency, then it will excite the motion of the detector's mode at an amplitude $\Delta L \sim hL$, not much different from if the test masses were free. But the subsequent behavior of the resonant detector is quite different from if the detector were made of free masses. The motions of free test masses only persist for the duration τ_s of the gravitational wave signal. But the resonant detector "rings" for a time of order of the damping time of the resonance,

$$\tau_d = \frac{Q}{\pi f_0} \gg \tau_s,$$

where f_0 is the resonant frequency of the detector.

It is the motion of this resonant system, converted to electrical form by the transducer, that is presented to the input terminals of the pre-amplifier. So it is an electrical signal of long duration τ_d that competes with the amplifier noise. As a long duration deterministic signal, its matched filter has a much narrower width in frequency than had the original signal $h(t)$, and so passes a much smaller proportion of the amplifier noise. Thus, the resonant response of the test mass system allows a weak signal to compete more effectively against amplifier noise than would be the case with free masses.

3.3 The Cost of Resonant Detection

This advantage of resonant-mass detectors is substantial; it is responsible for the continued vitality of the Weber style of detector over 30 years after it was first proposed. Still, it comes with a price that is not negligible. Implementing the matched filter described above, which is essential to attaining the advantage of the resonance, is tantamount to averaging the output of the amplifier for times of order τ_d. In the jargon of the field,

such a system has a low *post-detection bandwidth* (usually shortened simply to "bandwidth.") The averaging washes out any details of the waveform $h(t)$ on time scales short compared to τ_d. What one gains in signal-to-noise ratio, one gives up in temporal resolution. Whether this is a price one ought to be willing to pay or not depends on the stakes: if it is absolutely necessary even to detect the signal, averaging with a matched filter is certainly worthwhile. If the signal could be detected anyway, averaging simply throws away information, and should be avoided. In the high signal-to-noise case, the resonance does not help, but neither does it hurt much—a simple filtering operation could remove the resonant signature and allow reconstruction of the original signal waveform.

(N.B.: As we will show below, the actual choice of matched filter for a resonant detector is more subtle than that just described. Instead of τ_d, a shorter averaging time is almost always the optimum choice. Nevertheless, the qualitative thrust of the argument given in the previous paragraph still applies.)

3.4 Free-Mass Detectors as an Alternative

Given the trade-off between sensitivity and bandwidth that resonant systems tempt one to make, it is worth exploring whether there are other entirely non-resonant detection schemes that can achieve high sensitivity to gravitational waves without sacrificing signal bandwidth. In fact, such free-mass detectors have been developed by a variety of workers, including the same Robert Forward who worked with Weber on the original resonant detector.[10,11] The essential advantage of free-mass detectors comes from the fact that the farther apart their test masses are placed, the larger is the relative displacement between them caused by a given gravitational wave amplitude $h(t)$. (This scaling relation holds true up to the point that the light travel time between the masses becomes comparable to the period of the wave; that is when separation of the masses becomes comparable to the wavelength of the wave.) But the resonance in a resonant detector comes roughly when the sound travel time across the bar matches the period of the wave. That is to say, resonant detectors reach their optimum sensitivity when the separation of the test masses is of order of the acoustic wavelength at the gravitational wave frequency. Since the speed of sound in materials is of order 10^{-5} of the speed of light, a free-mass detector at its optimum length can have an advantage in signal size of 10^5 over a resonant-mass detector at its optimum length.

Another advantage is that no resonance is used to boost the signal. Thus, in principle a free-mass detector can have a completely white frequency response. This ideal can not be completely achieved in practice, since some of the noise sources discussed below have strong frequency dependences of their own. Still, it is possible to achieve useful bandwidths measured in decades rather than in fractions of an octave.

This signal size advantage would be a hollow one if there were no sensitive way to measure the relative displacement of test masses separated by many kilometers. Fortunately, there are such ways. As we saw above, the travel time of electromagnetic signals between the test masses can be measured with great precision. Interferometry using visible or near-infrared light to measure the separation of free masses has become a well-developed technology that now is completely competitive with the best resonant-mass detectors, and which is about to undergo a great leap in sensitivity as new instruments of multi-kilometer scale come on line in the next couple of years. Radio ranging between interplanetary space probes separated by many millions of kilometers has been used for some time; optical interferometers in solar orbit, with million kilometer baselines, are now being planned.

The conceptually simpler free-mass detectors are in practice substantially more complicated devices; the freedom of the test masses must be tamed by servo systems to keep them operating properly. This is in part what is responsible for the time lag in their development, even though they were conceived not much later than resonant-mass detectors. In the remainder of the review, we will discuss both styles of gravitational wave detector.

4 Noise Sources

In this section, we will focus our attention on understanding the most fundamental noise sources with which the practice of gravitational wave detection has to contend. Perhaps not surprisingly, the list will seem to have little to do with general relativity or with gravitational waves, as such. The chief concerns of gravitational wave detector designers are those that would confront anyone attempting to measure the effect of a very weak force on a mechanical system: Brownian motion (also known as thermal noise), and noise from the readout system (both in its direct influence on the output of the system and through its "back-reaction" on the mechanical front end). A ubiquitous but non-fundamental noise source, seismically-induced vibration, is treated as well.

It is pedagogically simpler to introduce the topics first in the context of interferometers. Then, we will describe how similar considerations apply to resonant-mass

detectors, where the signal processing issues are a bit more subtle.

4.1 Thermal Noise

The first recognition of a classical physical limit to measurement precision occurred when thermal noise was discovered in galvanometers, in the early 1930's.[12] The premier current-measuring instrument of their day, galvanometers typically consist of a coil of wire suspended from a fine fiber so that it rests between the poles of a strong permanent magnet. Leads from the coil are attached to the external source of current, which generates a torque about the vertical axis. The resulting angular displacement of the coil can be read through an optical lever arrangement that uses a small mirror fixed to the coil.

From our point of view as students of mechanical instruments, the components of a galvanometer that make it function as a current-measuring device are less interesting than its basic mechanical features as a single degree-of-freedom oscillator: an inertia element (characterized by the moment of inertia I of the coil, mirror, and connecting fixtures), an elastic element (represented by the torsional spring constant κ of the fiber from which the coil was suspended), mechanical damping (from some combination of air friction, electrical resistance, and internal friction in the suspension), and a means of observing the angular coordinate θ (the optical lever).

Attempts to make current measurements of the highest precision confronted the fact that, scrutinized carefully, the angle of the coil was not strictly fixed, but instead jittered about its mean position. At first, it seemed natural to attribute the motion to seismic excitation of the galvanometer and its surroundings. But careful mounting of galvanometers to rigid piers isolated from excess building vibrations only went so far in minimizing the noise. Furthermore, seismic noise is typically strongly variable with time, depending on the violence of the weather and on the diurnal cycle of human activity. But well-constructed galvanometers exhibit a noise whose amplitude does not vary in time.

It was not long after Einstein's explanation of Brownian motion as the result of random impacts upon the observed object by molecules from the surrounding fluid that physicists recognized that galvanometers were exhibiting the same phenomenon. According to the Equipartition Theorem, each degree of freedom of a system in thermodynamic equilibrium at temperature T should have an energy whose expectation value is $k_BT/2$. Applying this to the potential energy $\frac{1}{2}I\omega_0^2\theta^2$ associated with the angular displacement θ of the galvanometer, one finds

$$\theta_{rms} = \sqrt{\frac{k_BT}{I\omega_0^2}}, \tag{13}$$

where $\omega_0 = \sqrt{\kappa/I}$ is the resonant frequency of the galvanometer. The heuristic explanation of this theorem is the essentially atomic nature of all mechanisms of dissipation; in this case by the random impact of air molecules on the coil (in cases where air friction dominates the damping) or the random motion of electrons through the coil driving a noisy magnetic torque (if electrical dissipation dominates).

Because it is rooted in thermodynamics, this result has a generality far beyond the details of any particular system. There is a natural analogy between the galvanometer's torsional oscillator and the fundamental longitudinal mode of a Weber-style resonant-mass detector of gravitational waves. Note one striking feature of Eq. (13): even though the origin of the fluctuations lies in the mechanism that is responsible for the dissipation, the rms displacement does not depend on the magnitude (let alone on the mechanism) of the dissipation.

Subsequent work brought recognition of analogous phenomena in other systems. Perhaps the most important was the discovery of the electrical analog of Brownian motion by Johnson and Nyquist in 1928.[13,14] But full recognition of the essential unity of all thermodynamic fluctuation phenomena awaited the formulation of the Fluctuation-Dissipation Theorem. A particularly useful form was established in 1951 and 1952 by Callen and co-workers.[15] We will quote it in a form most directly applicable to mechanical systems, but the derivations in the original papers make it clear how it can be applied to any linear system in thermodynamic equilibrium.

In Callen's formulation, it is convenient to describe the dynamics of a physical system in terms of the network functions called the impedance and admittance, as measured at the point of interest in the system. These are defined in terms of the steady-state response of the system to sinusoidal excitation. The impedance Z is defined as the complex ratio of the force applied at the point of interest to the resulting velocity at that point. That is, if the system is driven with a force $F_0e^{i\omega t}$ and it responds in the steady state with $v = v_0e^{i(\omega t+\phi)}$, then the impedance is

$$Z(\omega) = \frac{F_0}{v_0}e^{-i\phi}.$$

A point mass has an impedance $Z_m(\omega) = i\omega m$, a Hooke's Law spring has $Z_k(\omega) = k/i\omega$, and a dashpot that supplies a force $F = bv$ thus has an impedance $Z_b = b$. The

related concept called the admittance Y is defined by

$$Y(\omega) \equiv Z^{-1}(\omega) = \frac{v_0}{F_0} e^{i\phi}.$$

With these preliminaries, Callen's Fluctuation-Dissipation Theorem can be succinctly stated. The thermodynamic fluctuations analogous to Brownian motion have a magnitude given by the application at the point of interest of a random force with a power spectrum

$$S_F(\omega) = 4k_B T Re(Z). \tag{14}$$

The strength of the applied force power spectrum is proportional to the dissipative (real) part of the impedance; hence the name "fluctation-dissipation" theorem. Note that this expression has the same form as the more familiar power spectrum for the Johnson noise voltage, $S_V(\omega) = 4k_B T R$, where the resistance R is the real part of the electrical impedance. The similarity is not accidental, but is only one example of the many phenomena unified by the theorem.

An alternative form of the theorem, more useful in some situations, directly gives the displacement fluctuation power spectrum instead of the equivalent applied noise force. It states

$$S_x(\omega) = \frac{4k_B T}{\omega^2} Re(Y). \tag{15}$$

Again, the power spectrum scales with the amount of dissipation in the system.

Clearly, this description of fluctuation phenomena is richer than the Equipartition Theorem, since here we have expressions for the entire power spectrum of the fluctuations, not just their rms amplitude. But are the two descriptions even consistent? The rms fluctuation, for example, the expression in Eq. (13), has no dependence on the magnitude of the dissipation. But Eq. (15) shows that the fluctuation power spectrum is proportional at each frequency to the amount of dissipation at that frequency. How can both be true? An oscillator with low dissipation shows a very pronounced peak in its response at the resonance frequency, while one with larger dissipation exhibits a less dramatic peak. So, although the driving noise force is smaller when the dissipation is smaller, the response on resonance is greater. The two effects precisely cancel, as can be verified by direct integration, thus guaranteeing that the integral of the power spectrum Eq. (15) is equal to what one would predict from the Equipartition Theorem.

These two faces of thermal noise, rms magnitude, and power spectrum, are each important in the appropriate context. In a broad-band gravitational wave detector, such as one using an interferometer, the power spectrum carries the most valuable information.

This insight is embodied in the universal choice to suspend the test masses as pendulums. Pendulums are chosen because they are the best way known to create a low frequency oscillator with very low dissipation. Heuristically, most of the restoring force in a pendulum comes from the tension in its wires (due in turn to the gravitational force on the mass); this process has no dissipation associated with it. The only unavoidable dissipation is that associated with the flexure of the wires, but in a properly designed pendulum the fraction of restoring force associated with flexure is small. Hence, the internal friction in the wires is "diluted" by a large factor (perhaps of order 10^3).

Similarly, one wants to minimize the thermal noise associated with internal vibrations of the test masses. This can be achieved only by making the masses out of a material with very low dissipation. Fortuitously, fused silica has very low mechanical dissipation at acoustic frequencies at room temperature.

A standard design rule in those devices is to attempt to place all resonances (such as those associated with the pendulum suspension of the test masses or those involving internal vibrations of the test masses themselves) outside of the frequency band in which signals will lie. When this is done, only the off-resonance amplitude of the power spectrum is important. The off-resonance transfer function of an oscillator to a given force is controlled by the compliance of the resonator in the low frequency limit, and by the inertia of the oscillator above resonance. If the dissipation that sets the driving force can be made low, so can the power spectrum of thermal noise at the frequencies of interest.

4.2 Readout Noise and the Quantum Limit

All experiments need readout and recording systems to register the effects for which we are searching. If the effect is large enough, then these functions can be carried out essentially perfectly. But in the case of the tiny mechanical effects we expect from gravitational waves, even to make the mechanical system's response large enough to record requires very carefully designed readout systems. It is not possible in all cases to ensure that the noise in the readout system is small compared to the mechanical noise in the test masses.

Readout noise has two faces, either one of which may dominate depending on the circumstances. The most familiar is additive noise that competes with a fair copy of the mechanical signal in the output of the measuring system. But measurement systems also unavoidably add mechanical noise to the front end; this "back reaction" noise

must also be kept small if the highest possible precision is to be attained.

The trade-off between additive noise and back-reaction noise is most familiar to physicists from discussions of the quantum mechanical Uncertainty Principle. And, indeed, the Uncertainty Principle governs the ultimate precision of a large class of measurements.

4.2.1 The Heisenberg Microscope as a Prototype Measuring Instrument

It is convenient to make a mental division of a gravitational wave interferometer into two parts. Call the nearly freely-falling mirrored test masses (and the space-time between them) the "system to be measured," and the laser, light beams, and photodetector the "measuring apparatus." There is a deep analogy here with the archetypal quantum mechanical measurement problem called the "Heisenberg microscope." Bohr gave a particularly clear description of it, using a semi-classical treatment. In his 1928 essay "The Quantum Postulate and the Recent Development of the Quantum Theory," Bohr wrote:[16]

> In using an optical instrument for determinations of position, it is necessary to remember that the formation of the image always requires a convergent beam of light. Denoting by λ the wave-length of the radiation used, and by ϵ the so-called numerical aperture, that is, the sine of half the angle of convergence, the resolving power of a microscope is given by the well-known expression $\lambda/2\epsilon$. Even if the object is illuminated by parallel light, so that the momentum h/λ of the incident light quantum is known both as regards magnitude and direction, the finite value of the aperture will prevent an exact knowledge of the recoil accompanying the scattering. Also, even if the momentum of the particle were accurately known before the scattering process, our knowledge of the component of momentum parallel to the focal plane after the observation would be affected by an uncertainty amounting to $2\epsilon h/\lambda$. The product of the least inaccuracies with which the positional co-ordinate and the component of momentum in a definite direction can be ascertained is just given by [the uncertainty relation].

In a gravitational wave interferometer, we are hardly dealing with a microscopic system: the test masses will have masses of 10 kg or more. Yet because we aspire to such extreme precision of measurement, it is crucial to consider the sort of quantum effects usually relevant only for processes on the atomic scale. Note that we are not satisfied to know our test masses' precise positions at one moment only; we want to know the history of the path length difference of the interferometer. Perturbations of the momenta of the masses cannot be ignored, therefore, since the value of the momentum at one time affects the position later.

In the Heisenberg microscope, the phenomenon conjugate to the registration of the arrival of a photon that has bounced off an atom is the recoil of the atom caused by the change in the photon's momentum upon reflection. In a gravitational wave interferometer we register an arrival rate of photons that depends on the difference in phase between electromagnetic fields returning from the two arms. We can recognize the conjugate phenomenon by looking for a fluctuating recoil that can affect the same degree of freedom that we measure. Fluctuating radiation pressure on the test masses causes them to move in a noisy way. The resulting fluctuation in the length difference between the two arms shows how this effect can alter the phase difference between light arriving from the two arms; this identifies it as the conjugate phenomenon.

4.2.2 Shot Noise in an Interferometer

The general principles discussed above can be made much clearer by consideration of specific cases. In an interferometer, all of the physics involved in the fundamental noise limits can be made explicit.

First, consider the question of the direct or "additive" noise, which sets the limit to how small a strain can be recognized. A Michelson interferometer with free mirrors can be described as a transducer from gravitational wave strain to output light power. Part of the reason for its good sensitivity comes from the fact that the output power changes from zero to its maximum and back again with a change in path length difference of only one optical wavelength, of order 1 μm. But it would clearly not be sufficient to only register the difference between one fringe and the next; with a precision of one optical wavelength, even if the arm lengths were as long as useful (of order of half the gravitational wavelength, or 150 km for waves of frequency 1 kHz) one could only register strains of about 10^{-11}.

The key to reaching strain sensitivities of 10^{-21} lies in determining the path length difference to a tiny fraction of a fringe, say 1 part in 10^{10}. Is this possible?

First, recall that the output power is given by

$$P_{out} = P_{in} \cos^2(k_x L_x - k_y L_y). \tag{16}$$

Consider in particular the behavior of the interferometer near an operating point at

which half of the maximum possible power exits the output port. At this point, the change in output power is maximized for a given change in path length difference. If we want to observe a very small change in arm length difference, then we must be able to recognize a very small change in the output power of the interferometer. In other words, the readout precision of an interferometer is limited by the precision with which we can measure optical power.

The fundamental limit to this power measurement is the so-called "shot noise" in the light. We can model the light flux at the photodetector as a set of discrete photons whose arrival times at the photodetector are statistically independent, although with a deterministic mean rate $\bar{n}$. Whenever we count a number of discrete independent events characterized by a mean number $\bar{N}$ per counting interval, the set of outcomes is characterized by a probability distribution $p(N)$ called the *Poisson distribution*,

$$p(N) = \frac{\bar{N}^N e^{-\bar{N}}}{N!}. \tag{17}$$

(This is also colloquially referred to as "counting statistics.") When $\bar{N} \gg 1$, the Poisson distribution can be approximated by a Gaussian distribution with a standard deviation σ equal to $\sqrt{\bar{N}}$.

We are trying to determine the rate of arrival of photons $\bar{n}$ (with units of $\sec^{-1}$), by making a set of measurements each lasting τ seconds. The mean number of photons in each measurement interval is $\bar{N} = \bar{n}\tau$. The Poisson fluctations of the measurement process mean that the fractional precision of a single measurement of the photon arrival rate (or, equivalently, of the power) is given by

$$\frac{\sigma_{\bar{N}}}{\bar{N}} = \frac{\sqrt{\bar{n}\tau}}{\bar{n}\tau} = \frac{1}{\sqrt{\bar{n}\tau}}. \tag{18}$$

This says that if we were to try to estimate $\bar{n}$ from measurements for which $\bar{n}\tau \sim 1$, then the fluctuations from instance to instance will be of order unity. If $\bar{n}\tau$ is very large, then the fractional fluctuations are small.

Let's carry through the calculation for the power fluctuations, and thence to the noise in measurements of h. Each photon carries an energy of $\hbar\omega = 2\pi\hbar c/\lambda$. If there is a power P_{out} at the output of the interferometer, then the mean photon flux at the output will be

$$\bar{n} = \frac{\lambda}{2\pi\hbar c} P_{out}. \tag{19}$$

At the half-power operating point,

$$\frac{dP_{out}}{dL} = \frac{2\pi}{\lambda} P_{in}. \tag{20}$$

We can also consider this to be the sensitivity to the test mass position *difference* δL, since the interferometer is equally sensitive (with opposite signs) to shifts in the length of either arm.

Now consider the fluctuations in the mean output power $P_{out} = P_{in}/2$, averaged over an interval τ. The mean number of photons per interval is $\overline{N} = (\lambda/4\pi\hbar c)P_{in}\tau$. Thus we expect a fractional photon number fluctuation of $\sigma_{\bar{N}}/\bar{N} = \sqrt{4\pi\hbar c/\lambda P_{in}\tau}$. Since we are using the output power as a monitor of test mass position difference, we would interpret such statistical power fluctuations as equivalent to position difference fluctuations of a magnitude given by the fractional photon number fluctuation divided by the fractional output power change per unit position difference, or

$$\sigma_{\delta L} = \frac{\sigma_N}{N} \Big/ \frac{1}{P_{out}} \frac{dP_{out}}{dL} = \sqrt{\frac{\hbar c\lambda}{4\pi P_{in}\tau}}. \tag{21}$$

Recall that we can describe the effect of a gravitational wave of amplitude h as equivalent to a fractional length change in one arm of $\Delta L/L = h/2$, along with an equal and opposite change in the orthogonal arm. The net change in test mass position difference is $\delta L = Lh$, so if we interpret brightness fluctuations in terms of the equivalent gravitational wave noise σ_h, we have $\sigma_h = \sigma_{\delta L}/L$, or

$$\sigma_h = \frac{1}{L}\sqrt{\frac{\hbar c\lambda}{4\pi P_{in}\tau}}. \tag{22}$$

There is no preferred frequency scale to this noise; the arrival of each photon is independent of the arrival of each of the others. Note also that the error in h scales inversely with the square root of the integration time. These facts can be summarized by rewriting Eq. (22) as the statement that the *photon shot noise* in h is described by a white amplitude spectral density of magnitude

$$h_{shot}(f) = \frac{1}{L}\sqrt{\frac{\hbar c\lambda}{2\pi P_{in}}}. \tag{23}$$

4.2.3 Radiation Pressure Noise in an Interferometer

A hint at where quantum mechanics might have some deep relevance comes when we consider how shot noise scales with the optical power used in the interferometer. As shown in Eq. 23 above, the shot noise readout precision improves as the square root of the optical power. Taken at face value, this would suggest that we could achieve arbitrarily good measurement precision, so long as we were able to use an arbitrarily powerful laser to illuminate the interferometer.

That conclusion is encouraging, but ought to cause some unease. After all, didn't Einstein fail to find a way to defeat the Uncertainty Principle's limit to the precision of mechanical measurements?[17] Or did he just blunder not to consider using an interferometer to make the measurements?

Of course not. An interferometer is in fact very much like the "Heisenberg microscope" of Bohr. The lesson we should draw from that example is that we must not neglect the effects of recoil in an interferometer. In effect, an interferometer with free masses is a Heisenberg "macroscope": the role of the small object whose position is to be determined is played by the set of macroscopic test masses. Their large size gives an obvious advantage against recoil, but can't make the effect vanish entirely.

The recoil effect does have one extra bit of subtlety, though. Recall that the measurement we make in a Michelson interferometer has to do with the difference in length of the two arms. So the recoil force we need to calculate is not the common mode force (the component that is equal in the two arms), but only the noise in the difference of the recoil forces in the two arms. If we use a naive picture in which photons independently choose which arm to enter, then the origin of a differential recoil force noise is clear. Each photon enters either one arm or the other; whenever one arm gains a photon, the other loses one.

To estimate the size of this effect, first recall that the force exerted by an electromagnetic wave of power P reflecting normally from a lossless mirror is

$$F_{rad} = \frac{P}{c}. \tag{24}$$

The fluctuation in this force is due to shot noise fluctuation in P. That is

$$\sigma_F = \frac{1}{c}\sigma_P, \tag{25}$$

or, in terms of an amplitude spectral density

$$F(f) = \sqrt{\frac{2\pi\hbar P_{in}}{c\lambda}} \tag{26}$$

independent of frequency.

This noisy force is applied to each mass in an arm. For now, let us consider a simple "one-bounce" interferometer. We will allow the mirrors at the ends of the arms to be free masses, but in this example assume that the beam splitter is much more massive than the other mirrors. The fluctuating radiation pressure from the power $P_{in}/2$ causes each mass to move with a spectrum

$$x(f) = \frac{1}{m(2\pi f)^2}F(f) = \frac{1}{mf^2}\sqrt{\frac{\hbar P_{in}}{8\pi^3 c\lambda}}. \tag{27}$$

The power fluctuations in the two arms will be anti-correlated. The radiation pressure noise is then

$$h_{rp}(f) = \frac{2}{L}x(f) = \frac{1}{mf^2L}\sqrt{\frac{\hbar P_{in}}{2\pi^3 c\lambda}}. \tag{28}$$

4.2.4 The Standard Quantum Limit

Thus we have two different sources of noise associated with the quantum nature of light. Note that they have opposite scaling with the light power-shot noise declines as the power grows, but radiation pressure noise grows with power.

If we choose to, we can consider these two noise sources to be two faces of a single noise that we can call optical readout noise, given by the quadrature sum

$$h_{o.r.o.}(f) = \sqrt{h^2_{shot}(f) + h^2_{rp}(f)}. \tag{29}$$

At low frequencies, the radiation pressure term (proportional to $1/f^2$) will dominate, while at high frequencies the shot noise (which is independent of frequency, or "white") is more important. We could improve the high frequency sensitivity by increasing P_{in}, at the expense of increased noise at low frequency. At any given frequency f_0, there is a minimum noise spectral density; clearly, this occurs when the power P_{in} is chosen to have the value P_{opt} that yields $h_{shot}(f_0) = h_{rp}(f_0)$.

When we solve for P_{opt} and insert it into our formula for $h_{o.r.o.}$ we find

$$h_{QL}(f) = \frac{1}{\pi fL}\sqrt{\frac{\hbar}{m}}. \tag{30}$$

We have renamed this locus of lowest possible noise $h_{QL}(f)$, for "quantum limit," to emphasize its fundamental relationship to quantum mechanical limits to the precision of measurements. Note that the expression does not depend on P_{in} or λ, or any other feature of the readout scheme, even though such details were useful for our derivation. Thus, this examination of the workings of our Heisenberg microscope provides an instrument-specific derivation of the Heisenberg Uncertainty Principle. And it reminds us of the truth Bohr's remarks expressed, that in any measurement the Uncertainty Principle emerges from the specific mechanism of the measurement.

There was a moment when some physicists believed, on seemingly sound physical grounds, that this picture of how photons interact with a beam splitter was so flawed that interferometers could perhaps evade the Uncertainty Principle.[18] The argument can be made based on quotation from quantum mechanical Scripture, Dirac's *The Principles of Quantum Mechanics*.[19] There one can read that photons in an interferometer travel down both arms simultaneously; furthermore, it is written that interference can only take place between a photon and itself, so the very existence of interference in a quantum mechanical world is proof of this picture. If this were taken as absolute and literal truth, then it would appear to rule out any differential radiation pressure at all, since the number of photons, and hence the recoil forces, would be identical in the two arms. Without the resulting differential recoil of the test masses, there is no quantum limit. Gravitational waves could in principle be measured with arbitrary precision. Some physicists defended this as gospel, despite the fact that the argument appeared to use quantum mechanical reasoning to disprove quantum mechanics.

The stubbornly naive were untroubled by this argument, and expected the Uncertainty Principle to hold. Some physicists read a few pages further in Dirac's book, to the passage explaining that allowing the possibility of energy measurements, say by observation of recoil of the mirrors, causes collapse of the wave function in such a way that photons end up either in one arm or the other. (Dirac's first discussion refers to an interferometer with rigidly fixed mirrors.) The learned were saved from error by the work of Caves,[20] who invoked the concept of vacuum fluctuations to explain the quantum mechanical behavior of photons at a beam splitter. A vacuum electromagnetic field with zero-point fluctuations enters the interferometer through the output port; its superposition with the field from the laser causes the light to behave in the way expected from semi-classical reasoning.

4.3 Seismic Noise

We have neglected to consider above another source of noise in gravitational wave detectors that is so common and important as to be essentially ubiquitous. This is what is commonly called seismic noise, the continual shaking of the terrestrial environment due to a variety of contingent causes, ranging from small earthquakes to ocean waves driven by large weather systems to automobiles striking potholes in poorly paved streets. Such a complex phenomenon can have no simple explanation from basic physics, yet dealing with it forms a substantial part of the challenge to designers of gravitational wave detectors. (Only moving the whole detector into space suffices to remove it entirely from consideration.)

At a reasonably quiet location, the spectrum of seismic noise from 1 Hz to several hundred Hz can be approximated as

$$x(f) = \begin{cases} 10^{-7}\mathrm{cm}/\sqrt{\mathrm{Hz}}, & \text{from 1 to 10 Hz} \\ 10^{-7}\mathrm{cm}/\sqrt{\mathrm{Hz}}(10\mathrm{Hz}/f)^2, & \text{for } f > 10 \text{ Hz}. \end{cases} \tag{31}$$

The magnitude of this mechanical noise background is distressingly large. The rms amplitude of the noise over this interval is of order 1 μm. The good news is that the spectrum falls with increasing frequency f. But even so, throughout the range of frequencies of interest to gravitational wave detectors, it involves motions many orders of magnitude larger than would be driven by any conceivable incident gravitational wave. There is no possibility of success unless the effects of seismic noise can be strongly attenuated.

It is straightforward to see the way in which seismic noise mimics a gravitational wave signal in an interferometer. As long as the separation between the mirrors is not very small, then the seismic inputs to each mirror are effectively independent; the difference in arm lengths is driven by the quadrature sum of the noise at all mirrors. The situation is a bit more subtle for a resonant mass detector. If it is suspended at its midpoint, it would appear that its internal modes should not be excited by any motion of the suspension point. However, this argument assumes perfect symmetry of the resonator about the suspension. The approximate symmetry of real systems may give several orders of magnitude of effective isolation, but the seismic spectrum is so large that additional isolation is always required.

Fortunately, the design of seismic isolators is a well-developed art. One can construct mechanical multi-pole low-pass filters that provide outstanding attenuation at frequencies well above those of the filter poles. The art of doing so was introduced to the field of gravitational wave detection by the founder, Weber.[21]

4.3.1 A Simple Two-Pole Isolator

The essence of vibration isolation can be understood using only ideas from freshman physics. Imagine that the object to be isolated has mass m. Assume that it is a rigid body, and that we are only interested in its motion x_m in a single direction. Then we can treat the object as a point mass. If it rests on the ground, it shares the ground's motion x_g, so $x_m = x_g$. To isolate the mass, replace the rigid connection to the ground

with a compliant connection, that is, attach it to the ground through a spring with spring constant k. Then the equation of motion of the mass is

$$m\ddot{x}_m = -k(x_m - x_g). \tag{32}$$

With the usual frequency domain ansatz $x_m(t) = x_m \exp(i\omega t)$, $x_g(t) = x_g \exp(i\omega t)$, Eq. (32) can be solved for the vibration transfer function

$$\frac{x_m}{x_g} = \frac{\omega_0^2}{\omega_0^2 - \omega^2}, \tag{33}$$

where $\omega_0^2 \equiv k/m$. The asymptotic behavior of Eq. (33) reveals the essential features of an isolator—although for low frequencies $\omega \ll \omega_0$, $x_m/x_g \approx 1$ (the mass moves rigidly with the ground), and at high frequencies $\omega \gg \omega_0$, $x_m/x_g \approx \omega_0^2/\omega^2$ (the amplitude of the mass's motion falls steeply with increasing frequency.)

(The transfer function of Eq. (33) has the unphysical feature that it predicts an infinite response at the resonant frequency ω_0. This problem is remedied if we add a damping force to our oversimplified model. Even so, an isolator does have the unfortunate feature that it gives a resonant amplification of the input noise for frequencies near ω_0.)

So, a strategy for isolation is as follows: to isolate an experiment for signal frequency ω, construct an isolator with a low enough resonant frequency ω_0 so that the isolation factor ω_0^2/ω^2 is sufficiently small to reduce the seismically driven value of x_m to a tolerable level.

4.3.2 Isolation Stacks

If it proves difficult to make ω_0 sufficiently low (it often does), another straightforward idea can often be made to work instead. Make two or more isolators with resonant frequencies as low as is convenient, then cascade them with the system you want to isolate farthest from the noisy ground. Solving for the resonant frequencies of the coupled chain of isolators is a normal mode problem that may get complicated. But the high frequency limit of a chain of N isolators, each with resonant frequency ω_0 by itself, has the simple form

$$\frac{x_m}{x_g} \approx \left(\frac{\omega_0^2}{\omega^2}\right)^N. \tag{34}$$

In Weber's original experiment, a vibration isolation "stack" of alternating steel plates and rubber sheets was used. No details are given in the text of his papers, but the idea was clear, and was adopted by those who followed Weber as well. Among the nice features of this isolator are: rough equality of the isolation in all degrees of freedom (since the rubber is compliant in both compression and in shear), and a small level of resonant amplification (since the rubber is rather lossy).

4.3.3 Isolation for Interferometers

The pendulum that provides a low-dissipation suspension for the test mass in an interferometer also provides two poles of seismic isolation. Typically, the resonant frequency is close to 1 Hz. This single stage might almost provide enough isolation for gravitational wave measurements in the vicinity of 1 kHz, but certainly requires substantial augmentation for good sensitivity at lower frequencies. This additional isolation needs to be at least roughly isotropic, since there are a variety of cross-coupling mechanisms that can make vertical noise couple to the phase of the light beam.

The simplest way to add isolation is to suspend the pendulum from a stack of the sort used to isolate a resonant-mass detector. Since interferometers are usually aimed at having good sensitivities down to the lowest possible frequencies, there is a strong incentive to make a stack with the lowest possible resonant frequencies.

More dramatic re-engineering of the basic stack concept can yield greater rewards. The strongest effort in this direction has been made by the VIRGO group in Pisa.[22] The basic idea is to build a stack based on many cascaded pendulums, but to build enough vertical compliance into each pendulum stage to give effective vertical resonant frequencies comparable to the 1 Hz resonances of the pendulum stages. In its original version, the vertical springs were air springs made of flexible bellows. This yielded impressive performance, which was improved even further when the vertical compliance was enhanced by magnetic anti-springs arranged to cancel some of the vertical stiffness. The original version would have made seismic noise negligible (compared with shot noise) for all frequencies above 10 Hz, while the enhanced version would work down to 4 Hz. The air springs did suffer from one serious drawback; the temperature coefficient of the spring force is determined by the ideal gas law, a much stronger sensitivity than elastic springs. Drifts proved very hard to control. To remedy this problem, the system was completely redesigned, with the air springs replaced by pre-stressed steel cantilevers in the form of narrow triangular blades, supplemented with magnetic anti-springs.

4.4 Noise in Resonant-Mass Detectors

Key features The essential complication in understanding resonant-mass detectors (as compared to interferometric detectors) is that the degree of freedom of interest is that of a simple harmonic oscillator (or a collection of them, as we'll see in the next section). So in addition to any intrinsic frequency dependence in the noise, there is a deliberately constructed resonant transfer function in the detector itself. As we saw earlier in this review, the resonance was introduced as part of a strategy for overcoming wide-band noise in the amplifier.

The use of this strategy involves different heuristic concepts than are appropriate for interferometers. In particular, optimizing the sensitivity of a resonant detector to short bursts almost always involves choosing to average the output over times that are long compared with the length of the burst itself. Then, the measurable quantity is no longer $h(t)$, but is instead net change in the vector amplitude (magnitude and phase) of the resonator's oscillation. This in turn can be expressed in terms of the energy that the wave would have deposited in a resonator at rest.[23] If the gravitational waveform $h(t)$ has a Fourier transform $H(f)$, then that excitation energy E is (for an optimal orientation between bar and wave)[24]

$$E = \frac{M v_s^4}{L^2} \left| H\left(f_0\right) \right|^2 , \tag{35}$$

where M is the total mass of the bar, v_s is the speed of sound in the material, L is the overall length of the bar, and f_0 is the resonant frequency.

The distinctive features are twofold: characterization of all candidate events by a single number (usually its "energy" or else $T \equiv E/k_B$), and a signal-to-noise optimization that involves choosing the right averaging time (or bandwidth).

Resonant transducers The second generation of resonant-mass detectors replaced Weber's piezoelectric transducer with a kind of a bridge circuit, in which the mechanical motion unbalanced the bridge by modulating the inductance or capacitance of one leg of the bridge. As with piezoelectric transducers, achieving a high level of coupling has proven difficult to achieve. A standard measure of the coupling is the Gibbons-Hawking parameter β, defined as "the proportion of elastic energy of the detector that can be extracted electrically from the transducer in one cycle."[25] In principle, the excitation of the bridge could be increased without limit, but in practice large fields usually lead to excess dissipation in the transducer even before electrical breakdown occurs. Transducers have been limited to working values of β of around 10^{-2}.

A heuristic way of understanding the design problem is to think of the issue as an attempt to design a transducer that makes a reasonable electrical impedance at its output appear to the mechanical system as a mechanical resistance sufficient to supply appreciable damping to the bar. With bar masses in excess of one ton, this may seem inordinately difficult. The good values mentioned in the previous paragraph avoided this problem by making use of so-called resonant transducers, which have been adopted almost universally since the idea was proposed by Paik in 1976.[26]

Paik's design called for a smaller mechanical resonator to be attached to the main resonant mass M. The resonant frequency of the smaller resonator itself (i.e., with the larger resonator "clamped") is chosen to match that of the main resonator. The actual coupled system then has two normal modes. If the mass ratio $m/M \equiv \alpha \ll 1$, then it is easy to show that the ratio of the amplitude of motion of the small mass, compared with that of the main resonator, is

$$\left| \frac{x}{X} \right| = \frac{2}{\sqrt{\alpha}}.$$

When a gravitational wave burst interacts with such a resonant system, it will at first mainly excite the vibration of the large bar. (The Paik resonator is a small device at one end of the bar, so the gravitational wave strain has only a small baseline for creating a stretch in its spring.) The free motion of this two-mode system then exhibits "beats," during which the mechanical energy of the main resonator's original motion is transferred into excitation of the small resonator. During this phase of the beat cycle, the effect of the gravitational wave has been transformed into a motion $2/\sqrt{\alpha}$ times larger than in a detector without the resonant transducer. The electro-mechanical transducer is mounted so as to measure the motion of the small mass with respect to the end of the main resonator, thus presenting this larger motion to the rest of the signal processing system.

The advantage this offers in detecting weak signals is probably obvious. The larger motion generates a comparably larger electrical output from the transducer, reducing the importance of a given level of electrical amplifier noise. Another way of seeing the advantage is to recognize the much smaller mechanical impedance required to damp the motion of the smaller mass, which means that β is increased by a factor of order α^{-1}. In present day designs, the mass ratio α is typically of order a few times 10^{-3}. The value is set in an optimization that involves not only thermal noise and additive amplifier noise but the back-action noise as well.

4.4.1 Thermal Noise in Resonant-Mass Detectors

Even though resonant-mass detectors work in a rather different way from free-mass detectors, they still benefit from low levels of dissipation. Here, one makes exactly the opposite design choice in regard to the resonant frequency—rather than trying to put all resonances outside the signal band of interest, the whole detection strategy is based on placing the resonance at a frequency where one expects signal power to be large. So, on the face of it, all of the $\frac{1}{2}k_BT$ of energy contributes to the rms scatter of the instrument's output. But it would be too hasty to conclude that there is no dependence of the effective thermal noise on the dissipation level. The typical resonant-mass detector can have a damping time of order 1000 sec, while the resonant frequency is near 1 kHz (i.e., a quality factor Q of order 10^6). The signal being sought might be a brief burst of radiation, lasting only a millisecond. In this brief interval, the bar's amplitude and/or phase of oscillation are altered. The characteristic time for such changes due to thermal noise is the damping time. So only a small fraction of the thermal noise power is relevant in the detection process. For this reason, low dissipation can be as valuable in resonant-mass detectors as in interferometers.

To make the analogy with free-mass detectors clearer, we can make a frequency domain version of the argument in the previous paragraph. It is most convenient to consider the comparison between the thermal noise driving force, Eq. (14), and the force exerted by the gravitational wave on the detector. A brief burst of gravitational waves will have a broad spectrum; its matched filter will admit power over a wide band. The thermal noise force power spectrum that may obscure the effect of the gravitational wave is broad-band as well; if the dissipation in the bar has the form of velocity damping, then the spectrum is white. The amplitude of this broad band noise spectrum is proportional to the amount of dissipation. So the signal to noise ratio will be better, the smaller is the amount of dissipation.

An expression for the minimum detectable noise $\Delta E_{\rm min}$ (at the 1 σ level) is[27]

$$\Delta E_{\rm min} \approx 2k_BT\frac{\tau_s}{\tau_d}, \tag{36}$$

where T is the temperature, τ_s is the averaging time, and τ_d is the damping time of the bar. In this case (where we assume only thermal noise is important), it is clear that the shorter the averaging time the better the sensitivity.

4.4.2 Readout Noise in a Resonant-Mass Detector

Most of the issues of readout noise discussed above for interferometers were first faced in the context of resonant-mass detectors. We have inverted the historical order solely for pedagogical reasons; the physical origin of readout noise in an interferometer is transparent, and nominally free masses make a more straightforward analogy to the Heisenberg microscope than does the complex amplitude of a resonant mode. A key role was played by Braginsky[28] in calling attention to the necessity of understanding these issues in resonant-mass gravitational wave detectors.

Transducer model The transducer is treated as a black box, in the form of a two-port network, emphasizing the fact that the system has a single input port and a single output port. Unlike the two-ports usually studied in electrical engineering classes, the transducer changes the dimensions of the signal: a mechanical motion at the input is converted to an electrical signal at the output.

One such device is a seismometer pickup: a permanent magnet attached to the end of the bar, arranged so that it moves back and forth in the vicinity of a conducting coil whenever the bar vibrates. Motion of the mechanical system generates an electromotive force in the coil that can be electrically amplified and recorded.

In gravitational wave detectors, the transducers usually involve a reactance (i.e., an inductance or a capacitance) whose value is modified by relative motion between the transducer mass and the end of the bar. This generates an electrical signal by virtue of the fact that the reactive component is placed in one leg of a bridge circuit. This kind of transducer is a passive device. It can add noise if its level of dissipation is large enough so that thermal noise is important.

There has also been development of parametric transducers, in which a balanced bridge (two counter-varying reactances) is excited at microwave frequencies. This is the kind of transducer used on the UWA detector.[29] There is a deep analogy between this kind of transducer and an interferometer.[30] This means that there are both extra benefits (gain in the transducer) and extra complications (such as noise in the oscillator that excites the bridge.)

Pre-amplifier The remaining essential part of the readout system is the low noise pre-amplifier, whose job is to transform the tiny electrical output of the transducer into a signal large enough so that it can be recorded. One needs the noise to be as low as

possible. To describe the noise, and to understand how it affects the detection process, it is valuable to consider a general black box representation of a noisy amplifier as a kind of a two-port network, just as we did for the transducer. Other than the trivial difference that this two-port is an all-electric device, there are two key differences between this kind of two-port and the model transducers discussed above. One is the fact that the amplifier has gain, i.e., it can supply more energy at its output than is supplied by its input. The other is the existence of two sources that represent the generation of noise. They are usually represented as a voltage source and a current source at the input of the two-port network; this is especially convenient, and has wide generality, but is only one of several equivalent ways of representing the noise. More on the general theory of noisy two-port networks can be found in the pioneering paper by Rothe and Dahlke.[31]

It is interesting to pause to inquire why two noise sources are necessary. Recall the Helmholtz theorem, often known in specialized forms as Thévenin's theorem or Norton's theorem.[32] The essence of the theorem is that an arbitrary network of sources and passive components can be represented, as far as its behavior at a given port is concerned, by a single source and a single impedance. But we are dealing here with a network in which two ports are relevant. At each port, one needs an impedance and a source, or their equivalents elsewhere in the circuit. It is traditional to replace the source at the output with an equivalent noise source at the input, whose strength is smaller than the output noise by a factor of the amplifier gain.

These two noise sources play different roles in the measurement process. There is one noise source that is physically present at the input, causing an influence on the system (here the electromechanical transducer) that is attached to the amplifier input. In the jargon of gravitational wave detection, this noise is responsible for "back action," since noise at the input of the pre-amp is thereby applied to the output end of the transducer,where it can cause a mechanical noise force at the transducer input; this is in turn attached to the resonant-mass detector proper. More on this below.

The second noise source (the one replacing the output noise source) is usually referred to as "additive noise": it is added to the amplified signal by the time it appears at the output, without causing any physical effect on the system hooked up to the input.

Amplifier noise in resonant-mass gravitational wave detectors, and the "amplifier limit" In contrast to our discussion of detection strategies in the case where thermal noise dominates, here we discuss the case when additive amplifier noise is the only important noise source. Then, we can best search for a brief burst of gravitational radiation by performing a cross-correlation between the system output and a template consisting of a sinusoid at the mechanical resonant frequency that is damped with the same time constant as the resonance itself. In other words, we look for responses that look like the test mass system suddenly set into resonance. The signal can arrive with any phase of course, so we need to keep track of both sine and cosine components with the bar's damping time. A two-phase lock-in amplifier can be set up to perform exactly this form of averaging.

In this case the energy sensitivity of the detector is given by[27]

$$\Delta E_{\rm min} \approx k_B T_n \frac{\lambda + \lambda^{-1}}{\pi \beta \tau_s f_0}, \tag{37}$$

where T_n is the noise temperature of the amplifier, λ is the ratio of the transducer output impedance to the amplifer noise impedance, β is the Gibbons-Hawking coupling parameter, and τ_s is the averaging time.

Consider the post-detection bandwidth implied by this prescription. The output of the cross-correlation described above is hardly affected if we displace the template with respect to the signal time series by one or even several cycles of oscillation. For there to be a substantial change in the value of the cross-correlation, the template must be displaced by a duration of order the damping time of the mechanical resonance. This means that, if the signal-to-noise ratio is not large, the arrival time of the impulsive gravitational wave signal will be uncertain by of order the damping time. In other words, the post-detection bandwidth Δf of such a signal extraction system is narrow, of order

$$\Delta f \approx 1/\tau_d.$$

For a quality factor of 10^6, this bandwidth is very narrow indeed. Increased bandwidth could be achieved, of course, at the expense of the signal-to-noise ratio, by averaging the output time series for a shorter time than the bar's damping time τ_d.

Combined optimum in the presence of thermal noise and additive amplifier noise When both kinds of noise are present at substantial levels, the best strategy is neither the rapid readout appropriate to thermal noise nor the long averaging time that would be best for amplifier noise. A broad-band output filter will admit too much amplifier noise. Using the narrow-band prescription appropriate to the amplifier-dominated case filters out much thermal noise, but also most of the signal power. Obviously, the optimum in the combined noise case lies somewhere between the extremes, where the net

noise contributions from thermal noise and amplifier noise are equal. Then, the energy sensitivity of the detector is given by[27]

$$\Delta E_{\min} \approx 2k_B T \frac{\tau_s}{\tau_d} + k_B T_n \frac{\lambda + \lambda^{-1}}{\pi \beta \tau_s f_0}, \tag{38}$$

where the averaging time is now to be chosen in such a way as to minimize the sum of the two terms.

The larger is the transducer's coupling β, the smaller is the importance of amplifier noise in units of gravitational wave strength. In the limit of large β, the bandwidth of the resonant-mass gravitational wave detector can approach that given by the thermal noise limit, where the matched template is the signal waveform itself.

For detectors with resonant transducers, bandwidth is also limited by the splitting between the coupled modes of the bar-transducer system. There is a competition between two effects: a small transducer mass gives a large mechanical amplification but a small mode splitting. In the time domain, this would be described as a long beat period; after a signal excites the bar one has to wait for a substantial fraction of the beat period for energy to be transferred to the motion of the transducer mass. This competition could be evaded by the construction of multi-mass transducers with a gradation from intermediate to tiny masses.[33]

Resonant-mass gravitational wave detectors built to date have almost always been substantially under-coupled to their amplifiers. First-generation bars of Weber's type, in which the transduction was performed by piezoelectric transducerss glued around the belly of the cylindrical mass, could only achieve coupling factors of order 5×10^{-6}. One variant constructed by the Glasgow group did achieve a large β.[34] It consisted of a cylindrical bar that had been split in half, then reassembled with a layer of piezoelectric material in effect forming the spring attaching the masses at either end. This design is the closest approach ever to Weber's original vision of a single massive piezoelectric mass as an antenna. In spite of these impressive parameters, the Glasgow bar was never even the most sensitive gravitational wave detector of its day, because the poor mechanical Q of the piezoelectric material gave a large amount of thermal noise.

4.4.3 The Quantum Limit in Resonant-Mass Detectors

One of the key features of Rothe and Dahlke's model of a noisy two-port network is the necessity to describe the noise with two generators, one directly limiting measurement precision and the other disturbing the system being measured. This is reminiscent of concepts most students of physics learn about in the context of quantum mechanics. In fact, quantum mechanics sets a minimum level of amplifier noise that can be expressed in terms of this pair of noise generators.

Quantum mechanical noise in an electrical amplifier A paper by Heffner in 1962 derived the quantum mechanical limit on amplifier noise;[35] its relevance for the gravitational wave detector problem was discovered by Giffard in 1976.[36] What Heffner showed was that, unless an electrical amplifier had a minimum level of noise, it could be used to make measurements of an electrical signal at frequency f that evaded the Uncertainty Principle

$$\Delta n \Delta \phi \geq \frac{1}{2},$$

where Δn is the uncertainty in the number of photons at the frequency f, and $\Delta\phi$ is the uncertainty in the measurement of the phase of the signal.

The amplifier noise that just barely allows measurements at the Uncertainty Principle limit is given by

$$\sqrt{S_v(f) S_i(f)} = \left(\ln \frac{2 - 1/G}{1 - 1/G} \right)^{-1} 2\pi\hbar f.$$

In the limit of large gain G, this limit becomes

$$\sqrt{S_v(f) S_i(f)} = \frac{1}{\ln 2} 2\pi\hbar f. \tag{39}$$

The combination of voltage and current noise power spectra represents yet another pair of conjugate variables governed by an uncertainty relation. This product is proportional to the noise temperature T_n of the amplifier, defined by $k_B T_n \equiv \sqrt{S_v(f) S_i(f)}$.

In the earliest days of the search for gravitational waves, the possible implications of such an amplifier sensitivity limit for the sensitivity of gravitational wave detectors were ignored. Neither Weber's papers nor the canonical theoretical analysis by Gibbons and Hawking mention such a limit. Eventually, cooler heads came to contemplate the fact that gravitational wave detectors ought to obey the Uncertainty Principle.

The electro-mechanical Uncertainty Principle Giffard gave the adaptation of this argument to the electro-mechanical case. His argument is so brief that it is almost hard to state. He points out that the functions of transducer and pre-amplifier together can be thought of as a so-called "mechanical amplifier," a two-port network whose input terminal receives a mechanical signal, but whose output is electrical.

From this, Giffard shows that the Uncertainty Principle requires that unless a gravitational wave signal has a minimum size, no linear gravitational wave detector will be able to register its arrival. He expressed the minimum size in terms of the energy U_s that the wave would deposit in a resonant detector initially at rest. The quantum mechanical limiting sensitivity is

$$U_s > 4\pi\hbar f.$$

As worded above, this argument can seem rather abstract. A heuristic description makes it as vivid as any of Bohr's *gedanken* experiments. In a mechanical amplifier, a crucial quantum mechanical role is played by the back action from the noise source that the Helmholtz Theorem places at the amplifier input. The force noise generator at the mechanical amplifier input (caused by electrical noise acting backwards through the transducer) perturbs the delicate mechanical system, here the resonant-mass system itself. Just as in the Heisenberg microscope, any design trade-off made in an attempt to reduce the position noise ends up increasing the momentum impulse applied to the system being measured.

5 History of Resonant-Mass Detectors

We now turn from a discussion of physics *per se* to a review of the way in which one assembles working gravitational wave detectors in light of the physical principles governing them. We will take a quasi-historical framework for this discussion, as a pedagogically sensible way of grappling with the issues involved. In this section, we will take the chronologically-motivated choice of treating resonant-mass detectors first; then we will start from scratch the overlapping history of interferometric detectors.

By 1966, Joseph Weber had constructed a complete working detector, and by 1968 was reporting coincident observations between detectors separated by 1000 km. The detector contained versions of every essential feature in resonant-mass gravitational wave detectors today, except for the facts that it operated at room temperature and that it used non-resonant strain transducers for its readout. The story of the development of the field since then can be seen as embodying a few key accomplishments: replication of Weber's detectors accompanied by a failure to confirm his claimed detection, clarification of the optimum way to detect gravitational wave signals in a noisy detector and of the sorts of technological developments that could lead to improved detector sensitivity, and the staged implementation of new generations of detectors embodying the improved technology.

5.1 Weber's Detectors as Gravitational-Wave Detection Systems

All of the important elements that make up a working gravitational wave detector are described in Weber's 1966 *Physical Review Letters*.[21] Looking at the signal chain from the front end, we see first the large $1\frac{1}{2}$ ton aluminum cylinder whose fundamental longitudinal mode at 1657 Hz interacts with any incoming gravitational wave. Around its midsection are glued the quartz transducers that give, through the piezoelectric effect, electrical signals proportional to the strain in the aluminum cylinder. Signal leads from those transducers pass through acoustic filters and through the wall of the vacuum chamber, then are connected via another acoustic filter to a superconducting inductance that serves as a "tank circuit" at the input of the low-noise pre-amplifier (whose noise temperature is 50 K.) The output of the pre-amp is connected to further amplification. There follows a rectifier for generating a positive-definite signal proportional to the power out of the amplifier. The end of the signal chain is a recording device, which in 1966 consisted of a pen-and-ink chart recorder.

Another aspect of the detector is the means used to prevent its being excited by influences other than gravitational waves. Isolation against mechanical influences in the form of acoustic or seismic noise is shown clearly in the diagram. Direct acoustic excitation is prevented by the placement of the key parts of the experiment inside a vacuum chamber. Transmission of vibration through the signal leads is attenuated by the acoustic filters mentioned above. The path for vibrations from the floor must pass through a pair of isolation stacks each consisting of three stages of rubber pad/steel block isolators; the aluminum bar is further isolated by a pendulum suspension consisting of a single wire sling that supports the bar about its middle. The top ends of the wire are attached to a beam that spans the space between the isolation stacks.

Further progress in reducing the sensitivity of his bar to spurious external influences enabled Weber to make his 1969 claim of "Evidence for discovery of gravitational radiation".[8] One aspect of this progress consisted of augmenting the electromagnetic shielding of his devices, after tests revealed some sensitivity. A seismometer array was also used to check for correlations between strong vibration of the ground and large detector outputs. But by far the most important system element in this regard was the construction of multiple copies of the complete detector system, and their deployment at spatially separated locations. The network in 1969 consisted of one bar of 66 cm

diameter and 153 cm length (for a resonant frequency of 1657 Hz) located at the Argonne National Laboratory in Illinois, and five other resonant-mass detectors located at the University of Maryland. One bar at Maryland, whose properties matched closely the Argonne bar, was used together with it to look for coincident excitation. Some use of the outputs of the additional bars was made, but the procedure is poorly described.

5.2 Weber's Observational Program

Weber's ongoing research program was concerned with looking for further evidence that the coincident events were real (i.e., not statistical accidents) and that they were in fact due to gravitational radiation. The *Physical Review Letters* of 9 February 1970[37] discusses the statistics from several interesting points of view. The claim that the events are real is buttressed by calculation of the rate of accidental coincidences. For the whole range of threshold levels considered, the number of coincidences exceeds the expected accidental rate by about an order of magnitude. Another even more convincing piece of evidence comes from carrying out a search for coincidences between the output of the two detectors using a scheme in which one of the detectors' outputs was delayed by two seconds, enough to remove any correlation due to excitation by gravitational wave impulses. Just as one would hope, only a small number of coincidences occurred between the offset data streams, at a level consistent with accidentals.

Still another convincing piece of evidence was revealed in the *Physical Review Letters* of 20 July 1970.[38] In it, Weber uses the classic astronomical test of testing for correlation of his event rate with sidereal time. Jansky's claim for the extraterrestrial origin of his observed radio noise had been buttressed in just this way; more recently, Jocelyn Bell had convinced her reluctant thesis advisor Hewish of the extraterrestrial nature of her pulsar signals by a similar test. Weber took advantage of the fact that the response of a cylindrical bar is anisotropic, and that the axes of his bars were oriented East-West, so that their sensitivity pattern was swept across the sky by the rotation of the Earth. The histogram of events versus sidereal time reveals a substantial anisotropy (of order of a factor of two) that peaks when the right ascension of the galactic center crosses the meridian at the mid-point between Maryland and Argonne, and again 12 hours later (as would be expected from the symmetry of the antenna pattern and the transparency of the Earth to gravitational waves). A similar histogram plotting coincidences against the solar time of their occurrence is flat within statistical errors.

One disturbing consequence follows from this observation, if one adopts the natural hypothesis that the sidereal anisotropy indicates that gravitational wave events are originating in the galactic center. Making other reasonable assumptions about the bandwidth of the signals, Weber is led to the conclusion that perhaps as much as 1000 $M_\odot$ per year is being converted into gravitational waves. It is not clear what to make of the inference that the galaxy would be entirely consumed in much less than a Hubble time at such a rate of gravitational luminosity. Weber mentions as possible ways out anisotropic emission from the sources (or focusing of the waves) in such a way that we see higher than average flux, or the possibility that his detector is not working in a linear regime, but is instead being stimulated by very weak gravitational waves to release energy stored in metastable states.

5.3 Early Response to Weber's Claims

Weber's claims attracted a great deal of attention. The experimental evidence appeared very strong. The problems with the energetics of the events could be taken as a strong counter-argument, but they could also be interpreted as a demonstration that a truly remarkable discovery was being made. The review "Gravitational-Wave Astronomy" by Press and Thorne in 1972's *Annual Reviews of Astronomy and Astrophysics*[39] gives testimony to the significance that was attributed to Weber's claims, with its extensive bibliography (completed in December 1971) of papers grappling both with the theoretical consequences of Weber's claims and with experimental ways to improve upon the sensitivity of Weber's detectors. The perceived stakes in the controversy are shown by the three-paragraph introductory section, which is mostly devoted to balancing the possibility of breakthroughs in the making against the alternative that Weber's results are mistaken. This first section concludes with a paragraph, remarkable in a review article, questioning the very urgency of its subject:

> We (the authors) find Weber's experimental evidence for gravitational waves fairly convincing. But we also recognize that there are as yet no plausible theoretical explanations of the waves' source and observed strength. Thus, we feel we must protect this review against being made irrelevant by a possible "disproof" of Weber's results. We have done this by relegating to the end of the article (Section 6) all ideas, issues, and discussions that hinge upon Weber's observations.

Both the theoretical speculation about sources and the quest for better ways to detect the waves are in evidence in one of the most influential papers of this or any other

epoch in the search for gravitational waves. Gibbons and Hawking, both renowned for work rather far removed from experimental physics, wrote in late 1970 the very practical "Theory of the Detection of Short Bursts of Gravitational Radiation."[25] The introduction presents Weber's results as established facts. Section II of the paper discusses possible sources, discussing with equanimity but at some length the extreme gravitational luminosities required. The rest of the paper is devoted to the theory of detecting weak gravitational wave bursts in the presence of noise, and to a clear and original set of proposals for maximizing the signal-to-noise ratio of detectors. Some of one's surprise at the authorship of this paper may be alleviated upon reading the thanks for insights and ideas given (at two places in the text and in the Acknowledgment) to P. Aplin of Bristol University, a very original experimentalist who published little on this subject under his own name.[40]

Gibbons and Hawking pointed out that Weber's own treatment of the theory of gravitational wave detectors, written before he started his observations, had been aimed at their response to steady sinusoidal signals. As such, it gives a misleading idea of the value of the high-Q resonance that characterizes Weber-style detectors. This lack was remedied by Gibbons and Hawking, who (with thanks to Aplin) point out that the low dissipation of a high-Q system means that the level of thermal noise power is low. They go on to show that the high-Q resonance is also of crucial importance in minimizing the effect of Johnson noise in the transducer, here playing the role we would generally call amplifier noise. (A weakness of this light treatment of amplifier noise is that it leaves out the back action effects that enforce the Uncertainty Principle.)

As we saw previously, Gibbons and Hawking noted that there is in fact a competition between these two benefits of low dissipation. To minimize thermal noise, one wants to integrate the output for as short a time as possible, to give the random walk of the resonator's complex amplitude the least opportunity to mask a signal. On the other hand, the importance of transducer/amplifier noise is minimized by integrating for as long as practicable, so that the gravitational wave signal competes with as small a bandwidth of the broadband noise as possible. Gibbons and Hawking showed how to derive the optimum averaging time that minimizes the total noise from these two sources. In so doing, they noted that the averaging time depends on the dimensionless coupling parameter they called β, the definition of which we gave above in Section 4. For Weber's detector they give an estimate of $\beta \approx 5 \times 10^{-6}$.

Gibbons and Hawking go on to note that a large value for β would have two benefits: improving the signal-to-noise ratio by making the gravitational wave signal appear as a larger electrical signal, while simultaneously changing the balance between thermal noise and electrical noise in the direction that causes the optimum sensitivity to be obtained with shorter integration times. In other words, a larger β would yield better sensitivity and high bandwidth. To obtain these benefits, they discuss a novel configuration, proposed by Aplin, that has come to be known as a "split bar." It consists of two large masses (two "ends" of a bar split in half) joined to each other by connection to either face of a layer of piezoelectric material. The benefit comes from the fact that, in this configuration, the piezo is actually functioning as the dominant spring in the system; by storing the bulk of the elastic energy, it is able to produce a larger amount of electrical energy. (In many ways this harks back to Weber's original proposal to make the bar entirely of piezoelectric material.)

Gibbons and Hawking sketch the details of a detector of this sort, in which lead zirconate titanate (PZT) is substituted for crystalline quartz (used by Weber) because of its larger piezoelectric coupling constant. Then, in spite of the fact that the thermal noise power is increased because the piezo is a rather lossy spring, the sensitivity should be increased by more than a factor of ten in energy compared with Weber's detector. At the same time, the optimum sampling time is shortened to 1 msec, so that more detailed information can be extracted from the signal.

In passing, Gibbons and Hawking also note that Weber uses a less than optimal way of searching for gravitational wave events. His definition of an event is a noticeable increase in the energy in the bar's fundamental mode. But a gravitational wave impulse will only increase the energy if it arrives with a particular phase relationship to the bar's previous excitation. If the wave arrives with a different phase, the bar's energy may be decreased, or the effect may instead primarily change the phase of the bar's vibration. They estimate that this means Weber saw only about 1/4 of the events exciting a given bar. And, since the two bars being used for a coincidence have independent phases, only $(1/4)^2 = 1/16$ of the detectable coincidences would have been registered by Weber's technique. This makes the question of the source of the gravitational luminosity that much more difficult to resolve. But it also means that, if Weber's results were real, even more events should be detectable.

Whatever mysteries there may have been regarding Weber's claims that he was detecting pulses of gravitational waves, if they were true they represented one of the most important astronomical and physical discoveries of the 20th century. So it is no surprise that a number of other workers decided to construct gravitational wave detectors. And quite naturally given Weber's apparent success, most of these detectors were built quite

a bit like Weber's. Success looked as if it should come quickly. Although it had taken Weber about a decade, working alone, to design, build, debug, and operate his detectors, those who wanted to follow the recipe he had developed needed much less time. As Weber himself described it:[41]

> The scheme that works is not very difficult to set up and costs about $25,000, excluding pay for the senior physicists involved. Once set up, the instrumentation has run without problems for a little longer than a year and a half. Furthermore, the instrumentation requires a skilled technician about a month to construct. It requires a physicist about two days, starting with an open vacuum chamber to put crystals on the apparatus and make the necessary adjustments to see coincidences. In view of the relative simplicity of the working instrumentation, it seems reasonable to suggest that others start in this way.

A group at Frascati[42] built a detector as close to Weber's as possible, including a close match with his resonant frequency of 1660 Hz. The Munich group of Billing and Winkler[43] also built a quite similar bar. At Moscow State University, a group led by Braginsky constructed another bar that matched Weber's rather closely. At Bell Labs, Tyson[44] began a program of construction along Weber's lines, with less concern to match all of his parameters exactly—the resonant frequency of his largest bar was 709 Hz. At IBM Labs, Garwin and Levine[45] built a small bar of Weber's style; they were convinced that they could improve upon Weber's statistical methods sufficiently to make up for poorer noise levels. Aplin,[40] on the other hand, began to construct a split bar along the lines he had suggested to Gibbons and Hawking. Although he did not succeed in carrying that work through to completion, the idea (and some of the equipment) was taken up by Drever's group in Glasgow.[34] There were also efforts started at Reading and Regina, and in addition, the second generation detectors of much greater sensitivity were planned by groups at Stanford, LSU, and Rome. (More about these later.)

As Weber had predicted, results began to become available very quickly. Unfortunately, it also soon became apparent that no one else was seeing results that looked anything like Weber's. By the time of the 6th Texas Symposium on Relativistic Astrophysics (held in New York December 18-22 1972),[41] several groups were ready to come forward with claims of null results at sensitivities comparable to or better than Weber's. Tyson made the strongest claims for the unreality of Weber's signals, based both on his own failure to find them in his single detector (at sensitivities better than Weber's) as well as his claims that Weber's electronics were too noisy even to record Brownian motion in his bar. Kafka, representing the Frascati and Munich groups (who performed observations in coincidence), was able to report only preliminary results (delivered to him by telegram) of five days of observations, but the failure to find any statistically significant number of coincidences was in strong contradiction to their expectations if Weber's claims were correct. Drever also reported negative results from the high-bandwidth split bar at Glasgow; he, however, tempered his claims of conflict with Weber by noting that his detector would only be expected to see Weber's events if they were of a few milliseconds' duration (an assumption that was plausible but by no means certain).

5.4 Resolution of the Weber Controversy

Over the next year and a half, there was an intensive concentration of effort to attempt to resolve the controversy. The groups listed above continued to accumulate data, none of which confirmed Weber's claim of a substantial flux of strong gravitational-wave pulses. New negative results from Garwin and Levine of IBM Labs were reported in a strongly-worded series of articles in *Physical Review Letters*.[45] Their work was carried out in the explicit belief that Weber's results were spurious, and could be shown to be so by the use of a single detector of well-characterized performance, even if that detector was small. (The titles of the three articles are miniature masterpieces of polemical style: "Absence of Gravity-Wave Signals in a Bar at 1695 Hz," "Single Gravity-Wave Detector Results Contrasted with Previous Coincidence Detections," and "New Negative Result for Gravitational Wave Detection, and Comparison with Reported Detection.") The first results to be reported came from a bar with a mass of 118 kg, the second from a 500 kg bar. Compare with the mass of Weber's principal detectors, 1500 kg.

The letters of the IBM group present the statistics of the noise output of their detectors, along with a careful tutorial on the theory of extracting impulsive signals from noise. This latter theme can be thought of as an explication of the signal processing scheme proposed (in rather telegraphic style) in Gibbons and Hawking's 1971 paper. The key idea was not to rely on net increase in the energy of the bar, but to look for sudden changes, of either sign, in either the magnitude or phase of the detector's complex excitation. The thrust of the papers is that if Weber's results were correct, then even their less massive single detector ought to show substantial departures from the

Gaussian distribution of excitation expected on the basis of thermal and amplifier noise alone. The near-perfect Gaussian fit to their data then constitutes an apparent contradiction of Weber's results.

An important argument used to buttress the claim that the IBM detector was well understood was the application of electrostatic calibration forces to one end of the bar, and the successful detection of those events (within the statistical limits set by the signal-to-noise ratio) by the data processing system. Tyson's 1972 presentation to the Texas meeting had previously emphasized the importance of this fundamental practice of experimental physics, as did the remarks of both Kafka and Drever. Levine and Garwin take Weber to task for having failed to use any calibration method, either as a check of his instruments' front ends or of his data analysis procedure.

A more subtle implicit argument against Weber's work is suggested to the reader of these papers by their admirable clarity, as contrasted with the rather Delphic pronouncements that fill Weber's own contributions to *Physical Review Letters*. Levine and Garwin make this explicit at one point when they compare their results with their best guess at how Weber's would be expressed in similar (sensible) units, complaining "We are thus forced to estimate these quantities, while noting that such information is easily obtained by the experimenter and is normally provided in the publication of a detection experiment."[46]

Garwin led a crusade against Weber's claims at the Fifth Cambridge Conference on Relativity (CCR-5), held at MIT on 10 June 1974.[47] Among the topics discussed was 1) an error in the computer program used by Weber to identify coincidences, shown to generate nearly all of the coincidences in the one data tape shared by Weber with other researchers, and 2) the puzzling feature of Weber's histogram of coincidences versus time delay showing a peak at zero delay in only the central 0.1 second wide bin, in spite of the fact that a 1.6 Hz wide bandpass filter was said to be part of the signal processing chain. But the most spectacular event of the discussion was what even those sympathetic to Garwin's cause might have felt was a trick that bordered on unsportsmanlike conduct. Weber had been given data from the detector of Douglass's group at the University of Rochester, to search for excitations in coincidence with Weber's own detectors; Weber reported at previous meetings that he had detected an excess of coincident events at a level of 2.6 standard deviations above the expected chance rate. According to Garwin's account in a letter to the editor of *Physics Today*,[47] "At CCR-5 Douglass revealed, and Weber agreed, that the Maryland Group had mistakenly assumed that the two antennas used the same time reference, whereas one was on Eastern Daylight Time and the other on Greenwich Mean Time." No stronger way can be imagined of impressing the community with the possibility that Weber was able, by some means, to find coincidences among any two data streams, whether the coincidences actually existed or not.

A panel discussion with almost precisely the same cast of characters as that of the 1972 Texas Symposium was staged at the 7th International Conference on General Relativity and Gravitation in Tel Aviv, June 23-28, 1974.[48] The plot, Weber's lonely claims of detections contradicted by the null results of the others, was also unchanged—the only substantial difference is that Weber's critics had had time to carry out more extensive searches and more careful data analysis. By this time, the Bell Labs group had carried out a coincidence run with an identical bar at the University of Rochester, operated by Douglass. The Munich group (which had by then incorporated the previously independent Frascati group) reported on the results of 150 days of coincident observations. Drever gave a report of a more extensive data run, seven months that had concluded in April 1973, yielding only one candidate coincidence; although this event could not be ruled out as a possible gravitational wave detection, neither could it be positively established as such in spite of the low probability that was estimated for it to have occurred by chance. (The detectors were only 50 m apart, and so may have both been driven by some other kind of influence.) In any event, Drever was able to show that the Glasgow experiment did not show the sort of event rate predicted by Weber's experiment, except under rather implausible assumptions about the nature of the individual gravitational wave pulses. Tyson also briefly reported on the negative results from Garwin and from Braginsky.

How did the physics community deal with these contradictory results? This is an almost classic example of attempted replication of an important claim, but with both opposing camps standing firm in their beliefs that their own results were correct. Valuable insight into the difficulties this situation posed to scientists can be found in the work of sociologist of science Harry Collins, who interviewed many of the principal actors during this period. His results are well worth consulting, even though the quotes from the interviews are reported without identifying the individual speakers.[49]

The other key resource in the written record is the transcripts of the open discussions at the 1972 and 1974 panels. Both Kafka and Tyson point out strongly that Weber (usually) uses a far-from-optimal statistical method to look for signals. Tyson also comes close to accusing Weber of fraud; the method by which Weber has deluded himself and others is said to be continual "tuning" of the statistics used to search for

coincidences, with choice of algorithm and threshold being chosen for each data set in such a way as to maximize the apparent statistical significance. (A similar suggestion was also made by Levine and Garwin.[47]) Weber denies this, but some of his remarks appear to support the accusation by using *ex post facto* reasoning to justify particular choices of pulse-detection algorithms: his test of which method is optimal is which gives a larger number of coincidences, and the choice can vary from one data set to another.

For his part, Weber appears to have believed that the results that contradicted his own did not constitute fair tests of his work, since they were not carried out in an identical way. This may strike some readers as disingenuous, since several of the other detectors were quite close copies indeed of Weber's apparatus. But it appears to be an honest reflection of Weber's belief that he was in fact detecting gravitational waves, and if others couldn't see them there must be something subtly wrong with their detectors. To this day, he continues to claim ongoing detections of gravitational wave pulses with his apparatus.

5.5 Beyond the Weber Era

One of the most interesting features of the Panel Discussion at GR7 was the time spent predicting the future of the field. Both Tyson and Drever gave optimistic predictions for future progress; both have been borne out faithfully, although at slower rates than either would have hoped to see. Tyson described the efforts already begun in 1974 (by groups at Stanford, Louisiana State University, and the University of Rome) to construct Weber-style detectors that were cooled by liquid helium to temperatures of a few degrees Kelvin. The obvious benefit, to reduce the Brownian motion noise (with power proportional to $k_B T$), is important. So, too, is the less obvious benefit that much quieter amplifiers are available at low temperature—these are the Superconducting QUantum Interference Devices, or SQUIDs.

Drever's prediction for future progress focused primarily on inteferometry, the other direction that subsequent history has in fact proven fruitful. It is a brief sketch, without any details or attribution, but still remarkably prescient. Drever starts from the premise that Weber's claimed detection of gravitational wave signals is most likely wrong. Then, he says, the point is no longer to try to verify or extend Weber's results, but instead to ask from first principles what might be the best way to probe the possible existence of gravitational waves, over the widest possible range of properties. Not only is improved sensitivity important, but the ability to look for a variety of signal types over a broad range of frequencies. Drever's own belief in this strategy can be inferred from his having adopted the wide-bandwidth Aplin-style split bar, and from having used the Glasgow detectors not only to search for brief pulses but also for a stochastic background of gravitational waves.

But it was difficult to push this strategy much farther, since the thermal noise in this kind of detector was very large; the losses came predominantly from the piezoelectric material that here serves not only as a transducer but as the primary "spring" for the resonant system, and hopes for reducing them would depend on a program of materials research with uncertain prospects at best. (Note that in the original Gibbons and Hawking paper, the split bar is argued for as the quickest way to give a substantial step in sensitivity, with the explicit assumption that since Weber was already detecting gravitational waves in a sub-optimal way, any sizable increment in sensitivity would immediately yield important dividends.) Instead, Drever recognized the kindred broadband sensitivity inherent in the proposal to build interferometric detectors and, with the prospect of placing the test masses very far apart, the possibility of substantially improved sensitivity as well.

Drever expanded on the themes mentioned briefly at GR7 in a graceful review first given as a talk to the Royal Astronomical Society in 1976, published as an article in 1977.[50] By 1978, when *Annual Reviews of Astronomy and Astrophysics* published its second review of the subject "Gravitational-Wave Astronomy," the authors Tyson and Giffard could write a much more mature piece than could Press and Thorne in 1972.[51] The style is more formal and less heuristic. There is less discussion of rather far-fetched possible sources of gravitational waves, but in its place a much more complete treatment of the theory of extracting weak impulsive signals from the output of a resonant detector. After a summary of the history of the work of Weber and of those who followed him, the authors write

> It must be concluded that the interpretation of the Weber events as gravitational wave pulses is erroneous, since there is no corroborated evidence to date either for an excess number of coincident events or any sidereal correlation.

Similar thoughts, more precisely focused, were expressed in a 1978 paper (written too late to be mentioned by Tyson and Giffard) by Kafka and Schnupp, giving the "Final Result of the Munich-Frascati Gravitational Radiation Experiment."[52] They write that

"Although the non-existence [of Weber's pulses] became obvious a long time ago, it still seems appropriate to publish our final negative result, because our experiment was as similar to Weber's as possible, whereas all other coincidence experiments deviated in one way or the other.... Moreover, we think we have set the lowest upper limits obtained by Weber-type experiments over a reasonable long period of observation," spanning 580 useful days of common observations of the two detectors. The main result of this paper is the null result that the statistics of the coincident excitation of the two detectors was just what would be expected from the laws of chance, given the noise levels in the detectors. Without mentioning Weber specifically, Kafka and Schnupp do remark that

> Scanning our whole data, we could, of course, find periods of a few days, for which at some pair of thresholds the number of coincidences was up to more than 3 standard deviations higher than the average over the various time delays. However, the same was true for arbitrary delays, and zero delay did not seem to be distinguished in any obvious way. However, one should not forget: If one searches long enough in our finite sample of data, one must find some complicated property which distinguishes zero delay signficantly from the others. (Again this is true for an arbitrary delay, but with a different property.)

The paper goes on to pay special attention to two periods, totaling 67 days in length, when the operation of the Munich-Frascati experiment overlapped with times for which the Weber group claimed to have detected substantial rates of coincidences with its own detectors. The authors write: "These results do not give the slightest hint of a simultaneous influence on both detectors. If the significant observations reported by Weber's group for these two periods had been due to gravitational radiation of any kind, they should have shown even more significantly in our experiment." The mention of "any kind" of signals refers to the fact that the present authors used not only the vector-difference algorithm that is optimal for short pulses, but also used for these 67 days the algorithm preferred by Weber, which would be more sensitive for very long wave trains that gradually excited the antenna. Kafka and Schnupp conclude this section by remarking that "we do not have an explanation for Weber's observations," although they suggest the possibility that there might have been some undiagnosed electrical feedback from signals on the telephone line from Argonne into the Maryland bar itself.

The final section of the paper compares the likely strengths and rates of gravitational wave signals from core collapse in supernovae with the then current and possible future sensitivities of gravitational wave detectors. In a dramatic figure, they superpose a model of the rate of supernovae at various distances from the Earth on the natural phase space for gravitational wave searches, event rate versus event strength. The authors point out that, even if one were able to improve the performance of gravitational wave detectors of the Weber type to the limit set by the Uncertainty Priniciple (by cooling, improving Q, or whatever other trick), one would still not have the sensitivity to detect events at the rate of several per year or greater. They conclude, "Because of the difficulties arising from this problem and because one would certainly like to measure more details than just the spectral density of pulses, the Munich group decided not to continue with (low temperature/high quality) Weber-type experiments, but rather with a Weiss-Forward type experiment, i.e., a laser-lighted Michelson interferometer."

In spite of the considerations that moved the Munich group to abandon resonant-mass detectors, the groups that had decided in the early 1970s to build cryogenic versions of the Weber bar pushed ahead. A number of strong reasons can be given to justify this strategy, including the dubious value of relying (as the Munich group did) on signal-strength predictions which necessarily must be ignorant of truly novel astronomical phenomena, as well as the belief that evolutionary development is often a more rapid and reliable strategy for progress than a revolutionary approach. And, although progress was slower than the hopes expressed for it in Tyson's 1974 remarks in Tel Aviv, this route did in fact lead to substantial increases in sensitivity well before the interferometric detectors began to catch up.

The first complete operating cryogenic resonant-mass detector was the one built at Stanford University by the group led by William Fairbank.[53] In addition to the obvious reduction of thermal noise by cooling with liquid helium to a temperature of 4.3 K, and the use of the Josephson junction SQUID as a low noise preamp, there was another technical innovation that helped the Stanford bar reach a new level of sensitivity. This was the introduction by Paik[26] of a resonant transducer, tuned to the same frequency as the bar's resonance, mounted on the end of the bar. Both Tyson and Garwin had used end-mounted transducers, but neither realized the advantages that would accrue to the tuned configuration—the ability to better "impedance-match" the mechanical excitation of the bar to the electrical system, thus increasing the coupling parameter β. (See the discussion above.) The Paik transducer represented a new generation in another sense—it made no use of the piezoelectric effect, but instead used the motion of the resonant proof mass in the transducer to modulate the value of an inductance in

the circuit that carried the persistent current through the Josephson junction.

As the first detector to operate at this new level of sensitivity, no coincidence observations were possible, so the first paper contains only the results of single-detector operation.[53] (The group at LSU, led by former Stanfordian W. O. Hamilton, was collaborating with the Stanford group, but was developing several subsystems independently, including an alternative transducer design.) The 1982 paper in *Astrophysical Journal Letters* included a histogram of excitations of the Stanford detector, showing that even without coincidences it set a new upper limit that, at least at large event rates (greater than of order 10^{-2} per day), was orders of magnitude more stringent than that achieved by the Munich group. An even better result was predicted once a second comparable detector would operate in coincidence.

The noise temperature of 20 mK was certainly a milestone, but doesn't entirely characterize the performance of the bar as a detector of rare events. The histogram of excitations recorded during the 74 days of data presented in the paper show a substantial excess of large excitations, beyond what would be expected from purely Gaussian statistics. The cause was unclear, but one possible explanation was acoustic emission within the bar from sudden stress relaxations. Without coincident operation with a comparable detector, gravitational wave pulses could not be ruled out either.

It wasn't until 1986 that coincident operation of all three cryogenic detectors started in the 1970s (Stanford, LSU, and Rome) was finally achieved. The results of that run were less than spectacular, because none of the detectors was operating as well as it might. Indeed, the event rate-event strength plot that characterized this coincidence run was hardly better than the single-detector plot from the Stanford 1981 solo paper.[24]

The problems with the LSU and Rome detectors were soon sorted out; the rms noise levels in these detectors have now fallen below 10^{-18}. Meanwhile, the Stanford bar met an untimely demise when it was irreparably damaged in the Loma Prieta earthquake of 1989. The LSU-Rome axis has carried out coincident observations since 1991. A first look gave a new upper limit on the flux of gravitational wave pulses that was presented in an otherwise unpublished conference report.[54] Another cryogenic detector that had been under development for some time, the niobium bar of Blair's group in Perth, recently achieved a comparable sensitivity. Coincidence observations continue as this review is being written.

The 1986 coincidence run was a consummation of years of work, whose occurence had been devoutly wished for by many friends of the field for some time. Aside from the fact that it may have been somewhat too late (from the point of view of Stanford,

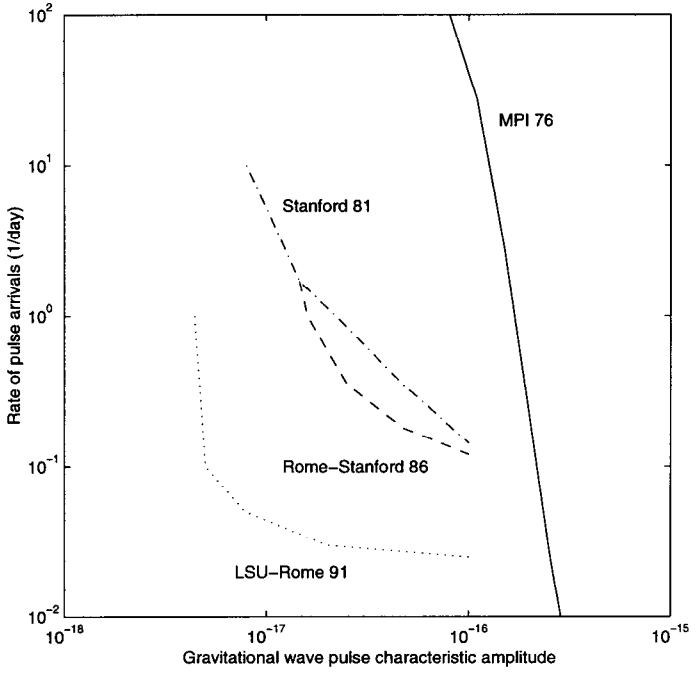

Fig. 3. Upper limits set by various experiments on the rate of gravitational wave impulse arrivals, as a function of the characteristic amplitude of the impulse.

whose detector wasn't working as well as in 1981) or somewhat too early (from the point of view of LSU or Rome, who had not yet shaken all of the bugs out of their systems), there was another accidental side effect of its timing. That was the complete coordination of the time when all three systems went off the air to fix the problems that running together had made obvious. This is the reason that none of the state-of-the-art detectors was on the air on February 23, 1987, when Supernova 1987A appeared. The closest observed supernova in centuries was a chance no one would have chosen to miss, although in fairness at a distance of order 50 kpc it is unlikely, according to standard estimates of the gravitational luminosity, that it would have been seen.

There were, however, non-state-of-the-art gravitational wave detectors observing at the time. Weber has kept a room temperature bar in operation nearly continuously since the '70s, as has the Rome group. An unusual chain of reasoning was constructed, involving a suspect time for the supernova collapse, an unorthodox signature for the gravitational wave event, *ad hoc* assumptions about neutrino physics, and tremendous gravitational luminosity, but leading to a claim of significant detections of a large flux of gravitational wave pulses.[55] This claim has attracted much less attention than did the original claims of Weber in the early 1970s. A serious effort has been made to demonstrate that the statistical significance of the analysis has been overstated, due to construction of the signature to match the data stream.[56]

6 History of Interferometers

6.1 The Work of Gertsenshtein and Pustovoit

Almost as soon as Weber had begun work on the first gravitational wave detector of the resonant-mass style, the idea arose to use interferometry to sense the motions induced by a gravitational wave. Weber and a student, Robert Forward, considered the idea in 1964.[10] We will discuss below how Forward later went about implementing the idea. But the first discussion of the idea is actually due to two Soviet physicists, M. E. Gertsenshtein and V. I. Pustovoit. They wrote in 1962[57] a criticism of Weber's 1960 *Physical Review* article, claiming (incorrectly) that resonant gravitational wave detectors would be very insensitive. Then, they make a remarkable statement justified only by intuition, that "Since the reception of gravitational waves is a relativistic effect, one should expect that the use of an ultrarelativistic body—light—can lead to a more effective indication of the field of the gravitational wave."

Gertsenshtein and Pustovoit followed up this imaginative leap by noting that a Michelson interferometer has the appropriate symmetry to be sensitive to the strain pattern produced by gravitational waves. They give a simple and clear derivation of the arm length difference caused by a wave of amplitude h. Next, they note that L. L. Bernstein had with ordinary light measured a path length differences of 10^{-11} cm in a 1 sec integration time. The newly invented laser, they claim, would "make it possible to decrease this factor by at least three orders of magnitude." (The concept of shot noise never appears explicitly here, so it is not clear what power levels are being anticipated.) They assume that one might make an interferometer with arm length of 10 m, thus leading to a sensitivity estimate of $10^{-14}/\sqrt{\text{Hz}}$ for "ordinary" light, or as good as $10^{-17}/\sqrt{\text{Hz}}$ for a laser-illuminated interferometer. This, Gertsenshtein and Pustovoit claim, is 10^7 to 10^{10} times better (it isn't clear whether they mean in amplitude or in power) than what would be possible with a Weber-style detector. Putting aside their unjustified pessimism about resonant-mass detectors, their arguments about interferometric sensing are right on the mark, even conservative.

For improvements beyond the quoted level, they make suggestions that are somewhat misguided. They say that observation time could be lengthened beyond 1 sec, which would be obvious for some sources (such as "monochromatic sinusoidal signals" or signals of long period) and hopeless for short bursts. Their other suggestion is to use "known methods for the separation of a weak signal from the noise background"; this suggestion is curious because known methods appear to be already built into their estimates that are referenced to a specific observing time. The other lack that is obvious in hindsight is any mention of mechanical noise sources. Still, the gist of the idea of interferometric detection of gravitational waves is clearly present, as is a demonstration that the idea can have interesting sensitivity.

6.2 The Origins of Today's Interferometric Detectors

For a variety of reasons, not least of which must have been the fact that it was written too early (before Weber's work had progressed beyond design studies), the proposal of Gertsenshtein and Pustovoit had little influence. The activity that began the by-now flourishing field of interferometric gravitational wave detection started independently in the West. In fact, it began semi-independently at several places in the United States at around the same time. The roots of this work can be seen in a pair of papers, written in 1971-2, by two teams linked in an unusual collaboration that is acknowledged in

the bodies of the papers, although not in the author lists. The first to be published was that of the Hughes Research Lab team, whose most committed member was Robert L. Forward, the former Weber student mentioned above. Later to appear, and not in a refereed journal, was the work of Rainer Weiss, an MIT physicist who had spent an influential postdoctoral stint with Robert H. Dicke at Princeton. Linking the two groups was someone who never published anything on the subject under his own name, but whose activity is mentioned in both papers—Philip K. Chapman, who had earned a doctorate in Instrumentation at MIT's Department of Aeronautics and Astronautics before joining NASA as a scientist-astronaut.

6.2.1 Interferometer Studies at Hughes Research Lab

An account of the idea for an interferometric detector of gravitational waves, and of the performance of an early-model prototype, is found in the 1971 paper of Moss, Miller, and Forward.[10] The authors cite a program to develop "long wideband" gravitational wave detectors that had started at Hughes in 1966, around the time of Weber's first account of a working resonant detector. The motivations for a wideband detector were 1) to allow detailed meaurement of waveforms which would in turn give insight into the nature of the sources, 2) "to allow the phasing of spaced antennas to form a phased array" (in other words, to allow good temporal resolution so that the direction of the wave can be determined by arrival time differences), and 3) to allow matched filters to be used to optimize the signal to noise ratio of a complex waveform "in addition to the use of standard narrowband frequency filtering for sinusoidal signals, which is the natural filtering action of a resonant antenna." The motivation for the use of a long detector is the larger test mass displacement, which, all else being equal, should directly translate into improved signal to noise ratio.

The authors credit the original idea for this way to achieve a long wideband detector to P. K. Chapman, and go on to state that "Our work has benefited from many discussions with Dr. Chapman as well as R. Weiss, who is involved in the design and construction of his own design at MIT."

The interferometer described by Moss *et al.* was "constructed to set experimental limits on the various noise sources in the laser transducer." It is a classic one-bounce Michelson interferometer, in which both output beams are detected "in a balanced bridge to reduce sensitivity to laser amplitude noise." The operating point for this arrangement was equal photocurrents from the photodetectors at the two output ports of the interferometer. (This is to be distinguished from the use of a photodetector at a single output port of the interferometer that is dithered about the dark fringe. See our discussion of this alternative below.) The interferometer is to be held at this balanced operating point by "slowly acting servo loops... so that the effects of laser amplitude and phase noise are minimized." The flat mirrors were rigidly mounted to an optical table, which was in turn supported on air-filled rubber tubes to give a resonant frequency of 2 Hz. (Other isolation schemes for the rigid interferometer were tried without success, causing the authors to lament that "vibration isolation is still an art rather than a science.") One of the mirrors was mounted on piezoelectric elements, which provided control of the operating point as well as a means of calibration.

The main result presented in the paper is the noise level that was achieved in this prototype interferometer, equivalent to a mirror displacement sensitivity of 1.3×10^{-14} $\mathrm{m}/\sqrt{\mathrm{Hz}}$ at a signal frequency of 5 kHz. This was about a factor of $\sqrt{2}$ larger than the calculated shot noise sensitivity, which the authors state is consistent with other indications that "the sensitivity limits were set by acoustic and ground noise." This noise level was "to date... the smallest vibrational displacement directly measured with a laser." No translation of the sensitivity into strain units was given, either directly or by specification of the arm length. This is perhaps appropriate, since the rigid mirror mounts made this test instrument ill-suited for actually searching for gravitational waves.

The last section of the paper lists the improvements intended to follow this initial work. Firstly, a more powerful laser was proposed; at the then impressive power level of 75 mW, the displacement sensitivity due to shot noise would be "close to that obtained in the present resonant antennas" that were at the date of writing appearing to give significant detections. A final paragraph listed the other proposed improvements: mirrors attached to masses that were large (to reduce thermal noise) and independently suspended from vibration isolation mounts, placed in a vacuum system whose initial length of several meters could be extended "to several kilometers by adding additional evacuated tubes." This section can be read as a telegraphic summary of the plans described at greater length by Weiss in his report written the following year.

6.2.2 The Vision of Rainer Weiss

The other paper that gave birth to the massive worldwide effort to detect gravitational waves using interferometers, Rainer Weiss' 1972 "Electromagnetically Coupled Broadband Gravitational Antenna," appeared only as an unpublished research progress report

of the organization at MIT that administered the umbrella research grant supporting his work.[11] Weber's claimed detection of gravitational waves was very much on Weiss' mind in 1972, reported as possibly correct but with the recognition that the energy flux the waves appeared to carry would dominate the luminosity of the Galaxy. Weiss states that he had been inspired by a 1956 paper by F. A. E. Pirani (that discussed the identification of measurable quantities in general relativity)[9] to consider the possibility that measurements of the light travel time between freely-falling test masses would make the best probes of spacetime structure. He further states that he had realized several years prior to writing (while teaching an undergraduate seminar) that the newly developed lasers could turn Pirani's *gedanken* experiment into a practical measurement strategy. Weiss also notes that the idea "has been independently discovered by Dr. Philip Chapman of the National Aeronautics and Space Administration, Houston."

Many of the ideas that appear in the breathless final paragraph of Moss *et al.* are elaborated at substantially greater length in Weiss' report, which should be considered the first serious design study of the concept of interferometric gravitational wave detection. After the review of Weber's claims, Weiss continues with a clear summary of the physical meaning of gravitational waves in general relativity, and an examination of the possible strength of gravitational waves from the then newly discovered pulsars. He then gives a summary of the key ideas of the proposed system:

- a Michelson interferometer used as a sensor of "differential strain induced in the arms,"
- operated "on a fixed fringe by a servo system" in a modulated system very much in the tradition of Dicke's improved Eötvös experiment,[58]
- "mirrors and beam splitter mounted on horizontal seismometer suspensions" that "must have resonant frequencies far below the frequencies in the gravitational wave" and "a high Q,"
- arms that "can be made as large as is consistent with the condition that the travel time of light in the arm is less than one-half the period of the gravitational wave," in part by being arranged as "optical delay lines"of the style described by Herriott.

Weiss is quite clear about the advantage that accrues from the last point. He says

> This points out the principal feature of electromagnetically coupled antennas relative to acoustically coupled ones such as bars; that an electromagnetic antenna can be longer than its acoustic counterpart in the ratio of the speed of light to the speed of sound in materials, a factor of 10^5. Since it is not the strain but rather the differential displacement that is measured in these gravitational antennas, the proposed antenna can offer a distinct advantage in sensitivity relative to detecting both broadband and single-frequency gravitational radiation. A significant improvement in thermal noise can also be realized.

This last sentence points out one of the key insights of this report, expanded upon at much greater length in the remainder of the text. As a sensitive mechanical measurement, the interferometric detection of gravitational waves is prey to a host of mechanical noise sources whose strengths need to be minimized if success is to be achieved. By far the largest section of the paper is devoted to estimates of the magnitudes of a long list of noise sources of various kinds. They include: amplitude noise in the laser (the only place where the work of the Hughes group is cited, as an example of a shot noise limited measurement), phase noise in the laser, mechanical thermal noise, radiation pressure noise, seismic noise, thermal gradient ("radiometer effect") noise, cosmic ray impacts, "gravitational-gradient" noise, and fluctuating forces from electric and magnetic fields. This looks almost (with a few omissions) like the list of noise sources that contemporary workers are grappling with as they strive to make the new kilometer scale interferometers work; by contrast, the other earlier treatments of the subject look myopic and unbalanced. And this insight is what led to the recognition that interferometers of the greatest practical length, with the resulting dilution of displacement noise terms as compared with a strain signal, would be the way to achieve the promise of good gravitational wave sensitivity, and would be worth the substantial investments needed to build them.

6.3 Interferometer as an Active Null Instrument

The agreement between Weiss and the Hughes group on the basic features of an interferometric detector must have something to do with the fact that they and Chapman were engaged in a remote three-way collaboration. But the fact that the key features of the design remain current to this day (with a few important additions) is evidence that they responded thoughtfully to an inherent logic of experimental design. Interferometric gravitational wave detection represents an extreme example of the application of design principles of wide validity in experimental physics. It is worthwhile to examine those principles here.

6.3.1 How to Maximize the Signal to Noise Ratio

Firstly, it is important to recognize where, in the spectrum of physics experiments, this one falls. To successfully detect gravitational waves, it will be necessary to attain AC strain sensitivity that is completely unprecedented. The concept of sensitivity is the key one—the signal to noise ratio for small strains is (essentially) the only figure of merit of interest here. Precision is primary, while accuracy of calibration or absence of other kinds of systematic errors definitely takes a back seat at this stage in the development of the field. Also, it is important to remember that one is perfectly content to measure signals only above some cut-off frequency; no absolute measurements of lengths or even of differences in length between two interferometer arms are necessary.

In experiments where precision is the primary desideratum, certain general principles apply. In particular, there are two fundamental strategies for maximizing a signal to noise ratio: one can make the response of the system large, and one can make the noise small. To make the response large, one can try to "capture" the largest possible effect from an external source. Here we want to make the largest possible apparatus, since relative displacements of two masses caused by a gravitational wave are proportional to the separation of the masses. This strategy is quite common—large telescopes can be more sensitive than small telescopes, for example. Another example is the improvement Michelson and Morley achieved in 1887 over Michelson's solo result of 1881, achieved by increasing the expected ether drift fringe shift through the addition of mirrors to lengthen the interferometer's optical path length.[59]

Another way to make a large response is to arrange for the external influence to drive an indicator that changes dramatically in response to a small effect. The implementation of that strategy here is to illuminate the interferometer with visible light, whose wavelength of order 1 μm sets the scale for motions that change the output port from dark to bright. This strategy too is common, as in such simple choices as making the indicator needle on an ammeter as narrow as practicable, or constructing a galvanometer with a fine fiber so that it will swing as much as possible or in using the longest possible lever arm for its optical lever.

Not all of the measures listed above are guaranteed to improve the signal to noise ratio; that depends on the nature of the noise. But one always improves the signal to noise ratio by reducing the magnitude of the noise. The noise sources in mechanical experiments can be loosely grouped in two classes. One class is noise in the measurement of the response of the test system. For interferometers, this is the shot noise in the fringe readout, or whatever other effect swamps it (excess amplifier noise, for example). In resonant mass detectors this class is represented by noise in the preamplifier that responds to the transducer output, or by excess transducer noise such as Johnson noise. We saw above that there may be quantum mechanical limits to the reduction of this kind of noise.

The other class of noise sources are those that also affect the test system in a way that mimics the effect being sought. This includes all of the noise forces on the test masses, like seismic noise and thermal noise. (This is the class of noise effects usually called, when it wouldn't cause confusion with the principle of an interferometer's operation, "interference"). Over a large range of frequencies, these are the dominant limits to sensitivity of a gravitational wave interferometer. Where that is true, measurement strategies that maximize the strength of the external effect on the test system (such as, here, the physical separation of test masses) can be helpful, but those that just maximize the response of the measuring instrument to any external effect just magnify the response to the noise as well. Reducing the strength of these kinds of noise is always a good idea, whenever it is possible.

6.3.2 What to Do when $1/f$ Noise Dominates

The considerations listed above are mostly obvious enough to be considered common sense. But there are some subtle aspects to consider as well. The most important non-obvious fact to consider is that almost every noise source has a pronounced $1/f$ character to its spectrum, at least at low frequencies. A laser whose power stability is limited at high frequencies by fundamental processes like shot noise almost invariably will show dramatically enhanced levels of noise at low frequencies. And, in many situations even such a fundamental process as thermal noise shows a $1/f$ or steeper power spectrum, as we saw above. Furthermore, seismic noise almost invariably has a very steep displacement power spectrum.

The difficulties caused by $1/f$ noise can come in several different forms. Sometimes the difficulty is simply that the noise has a larger magnitude than the minimum level it might have (laser power noise in excess of shot noise, for example), or that the noise is just inconveniently large (such as seismic noise at any frequency!). A more subtle kind of difficulty is the large integrated magnitude of the noise at frequencies that are low compared with the signal frequency. Many measuring devices have only a limited dynamic range over which they respond linearly to external influences; it seems a shame

to waste it dealing with noise outside the band in which one expects to find signals.

Measures to deal with $1/f$ noise often dominate the design of a high-sensitivity experiment. No one explored these measures more systematically than did Robert H. Dicke, who was for a few years in the early 1960s Weiss's mentor. Dicke was moved to think deeply about these problems while working on the development of microwave radar at the Radiation Laboratory at MIT during World War II. Devices called radiometers, receivers that measure the total power emitted by a broadband (often thermal) source of microwaves, would have had a variety of uses, if they hadn't been rendered so insensitive by the large amount of $1/f$ noise in the RF preamps. Dicke invented what came to be called the "Dicke radiometer" specifically to solve this problem.[60] The heart of the scheme was a device to periodically (at 30 Hz in the original case) interrupt the flow of RF power from the antenna to the preamp, replacing it instead with a thermal source of radiation. At the "back end" of the instrument, the electronics were arranged to give a measure of the difference between the detected power from the antenna and from the reference load. The reason this defeats the $1/f$ noise in the amplifier is that the comparison between measure and reference is made rapidly enough that the preamp's output can't wander much in the interval. Or, described in the frequency domain, the signal has been translated from DC up to a high enough frequency that the preamp's noise is not dominated by excess noise with a $1/f$ character.

Dicke's invention had the immediate effect that microwave radiometry became practical even for sources with rather low antenna temperatures; this made a substantial contribution to the Rad Lab's mission[61] as well as to the practice of radio astronomy.[62] But the greatest impact came from Dicke's realization that this modulation technique would have broad applicability, wherever $1/f$ noise was a problem. This insight led him to invent the lock-in amplifier, a universal back end that can control the chopping of an experiment, calculate the difference in output between the "on" and "off" states, and average the result to further reduce the noise. By now, "lock-in amplification" (also referred to as "phase sensitive detection") has become a nearly universal practice in the fight against $1/f$ noise.

A second classic measurement carried out by Dicke illustrates further insights in the battle against $1/f$ noise. The test of the equivalence of inertial and gravitational mass carried out by Roll, Krotkov, and Dicke[58] is considered one of the great examples of a *null experiment*. As championed by Dicke,[63] this term refers to a measurement where an answer of zero carries tremendous meaning. Precise equivalence of inertial and gravitational mass (or in other words a zero value for their difference) means that gravity can be described by a metric theory.

Null experiments play a special role for experimentalists as well as theorists, because an instrument that reads zero is immune to many of the sorts of problems that plague non-null measurements. Among these are calibration drifts and limited dynamic range of an instrument (whether from noise or from non-linear response.) Of course, turning a theoretical zero into an idea for an instrument that yields a zero output takes deep insight. One could argue that the torsion balance used in the improved Eötvös experiment, whose motion would track the Sun's if the aluminum and gold masses on opposite sides had differing ratios of inertial to gravitational mass, is among the most elegant instruments ever invented.

Maintaining the integrity of a null measurement takes insight that goes beyond the design of the front end of the experiment. For example, it would be a good idea for the null position of the test masses to be arranged to correspond to a null response from the sensor. Then, one can ignore (to first order) fluctuations in the drive level of the sensor (such as the light power in the optical lever), since zero is still zero even if it is multiplied by, say, 1.01 instead of 1.00. There are a variety of ways to create a null output from an optical lever at one particular operating point. One way would be to use a matched pair of photodetectors, placed so that the light beam falls equally on each detector when the balance is at the null position; as the beam moves to follow the balance's motion, one photodetector receives more light while the other receives less, and a differential amplifier will reveal the motion. This method is essentially a DC technique.

Dicke's team implemented a clever variation that let them make use of the advantages of a lock-in amplifier. A narrow light beam fell on a single photodetector, after passing by a wire of comparable width that cast a shadow on the photodetector. The wire was caused to vibrate from side to side by driving a current through it at the frequency of one of its "violin" resonances; as it did so, its shadow also moved from side to side across the light beam. If the beam were centered on the wire's position, then the light received by the photodetector would increase equally due to the wire's vibration to the left or the right. But if the beam were off center, then one direction of wire vibration lets more light pass than the other. So in the centered case the photocurrent varies only at twice the frequency of the wire's vibration, while in the off-center case the current contains a component at the wire's vibration frequency, whose amplitude and phase carries the information of the position of the light beam with respect to the wire. A lock-in amplifier converts the modulated signal into one at DC. The wire vibration can

easily be arranged to be at a frequency high enough to avoid $1/f$ noise.

Noise will always cause a sensitive instrument to depart from the precise null reading, and noise of a $1/f$ character will do so in an especially vexing way. Once it has drifted from the null, the instrument is once again sensitive to drive level fluctuations because its output has a non-zero value. The especially elegant feature of the Dicke torsion balance was the provision to apply a correction torque to hold it at the null position. This was accomplished by means of a servo loop that fed back a torque to null the output reading of the sensor. The greater the gain of this loop, the more tightly was the balance constrained near the null position, and the smaller was the sensitivity to light level fluctuations. Of course, the output has to be recalibrated for the effect of the loop, but the same information is present. One convenient place to read the output is to measure the control torque needed to hold the balance at null, which will just be equal to the external torque applied to the balance.

6.3.3 Application of these Principles in an Interferometer

Maximization of response in an interferometer is achieved by the obvious choices: placing the far mirrors as far away as possible from the beam splitter, and by using the shortest practicable wavelength for the illumination of the interferometer. Weiss also describes increasing the optical path length by use of a delay line that causes the light to make many trips through an arm; this is effective against sensing noise (like shot noise), but is just a wash for noise effects that cause actual mirror motions since N encounters with mirrors necessary import a factor N larger amount of these kinds of noise along with the extra signal.

Minimization of the noise starts with obvious choices as well: largest possible light power to make the shot noise small, and the minimization of the multitude of mechanical noises as discussed in Weiss' report. But it also involves replicating many of the features of the Roll *et al.* experiment to minimize the deleterious effects of $1/f$ noise of various kinds. This is the reason for the application of high frequency modulation of the fringe phase (by PZT transducer at Hughes, or by Pockels cell according to Weiss), for the arrangement of the measurement to give a null reading (by differential measurement with two photodetectors at the mid-point of a fringe in the Hughes case, and by modulation about the dark fringe at MIT), and by the provision for actively holding the instrument at the null state (by PZT again at Hughes, and by a combination of Pockels cell and force applied to test masses at MIT).

The fringe modulation and locking techniques mentioned just above have as their goal elimination of excess noise from low frequency fluctuations of the laser's output power. Other ways to make the instrument null are used to make it insensitive to other sorts of fluctuations. For example, laser wavelength fluctuations can be rendered harmless if the interferometer is operated at or near the "white light fringe," that is, with well-matched arm lengths. If the light travels through arms of equal length, then the phase relationship between them is hardly altered as the wavelength varies. But if the arms have a substantial difference in their lengths, wavelength fluctuations cause spurious relative phase shifts at the output, even without fluctuations in arm length difference. Note that this sets a different condition on declaring the instrument to be null—against laser power noise, it is the operating point within a fringe that matters, but for laser wavelength noise, it is the choice of which fringe on which to sit that is relevant.

6.4 Wrap-Up of the Hughes Program

A summary of the results eventually achieved by the Hughes group was reported in 1978 in a paper in *Physical Review D* whose sole author was R. L. Forward.[64] It represents a retrospective analysis of a completed experiment, somewhat in the same style as Kafka and Schnupp's paper of the same year. But there are also strong stylistic differences between the two papers—while Kafka and Schnupp want to make the strongest possible point with the data they analyzed (concerning whether Weber's events could be gravitational waves) with hardly a pause to describe the measurement apparatus, Forward's paper is primarily concerned with explicating the basic physics of the detector, and is somewhat cavalier about the observational data that is presented. The contrast is due in part, of course, to the distinction between publication about a mature technology (bars at room temperature) and one that was clearly immature, although with great promise. It is also a reflection of two facts about the Hughes interferometer as a scientific instrument: it was not as sensitive to bursts as were the bars of 1972, and its data stream was also much harder to analyze because of its broadband nature.

The first section of the 1978 paper is a detailed derivation of the antenna pattern (sensitivity versus angle) of an interferometer. Next comes a quite detailed description of the apparatus, with a strong emphasis on the optical aspects of the interferometer that determine the noise above 1 kHz: circuit diagrams of the photodiode biasing network and of the 1-20 kHz bandpass filter, part numbers for the photodiodes and the

front-end amplifier, and a painstaking derivation of the shot noise. Mechanical aspects of the interferometer, which mainly determine performance at lower frequencies, get shorter shrift: test mass suspensions are described in a single paragraph, as neoprene and brass stacks of "the desired height" with "typical frequency of 10 Hz," without any discussion of the mechanical transfer function or of the thermal noise of the suspension. The three paragraph section devoted to the "isolation system" gives information on both seismic isolation tables and the vacuum system enclosing the interferometer, and includes the following remark, almost in passing: "The vacuum system and isolation tables were designed so that after an initial checkout and operation with 2-m sections of aluminum irrigation pipe (8.5 m total interferometer pathlength), those sections could be replaced with longer sections (up to 1 km) with a substantial increase in interferometer-gravitational radiation-strain sensitivity for the same photon-noise-limited displacement sensitivity."

A careful discussion of the calibration of the instrument and of its linearity is provided, although without including any but the most cursory details about the servo system (whose actuator was a PZT stack on which one of the mirrors was mounted) used to keep the interferometer in lock. One presumes that ignoring the behavior of the servo was justifiable on the assumption that its bandwidth was smaller than 1 kHz. Indeed, given the strategic decision only to consider the output of the interferometer at frequencies above 1 kHz, most of the omissions that strike a modern eye as surprising can be seen to make sense.

The discussion of the operation of the interferometer as a gravitational wave detector begins with a paragraph that will evoke much sympathy from present-day readers. It repeats the "ultimate plan" of operation at a remote site with long arms, but concludes with the remark, "The funding for this next move proved to be unavailable so we concluded the program by operating the system as it was, despite the high level of acoustic, electromagnetic, and vibrational noise from the other activities in the building." Operation was evidently difficult, since as the Abstract notes, "The laser interferometer was operated as a detector for gravitational radiation for 150 h during the nights and weekends from the period 4 October through 3 December 1972," a duty cycle of a bit over 10%. Environmental noise was a serious problem, and was taken seriously: a set of monitors of seismic, acoustic, optical, and electrical noises was installed, and a measure of their outputs was recorded along with the interferometer output.

Part of what made taking data so difficult was the decision to take advantage of the high bandwidth available; although the band below 1 kHz was abandoned as useless because of high noise levels, the upper frequency cut-off was taken to be 20 kHz. This choice was never discussed in the paper—one might have expected some sort of argument on astrophysical grounds that such high frequencies might contain signals, but it is just as likely that the cut-off was chosen to match the bandwidth of the "high quality stereo tape recorder" that was used as the primary data storage medium. Dealing with this much data was a tremendous burden, given the state of computer technology in the early '70s. In fact, the data processing was performed almost entirely by listening to the audio tape—one section of the paper is called "Calibration of Ear." (One 10 msec digitized chunk of data is shown in the paper, both in the time and the frequency domain.)

This method of data analysis was a clever solution to a vexing problem, and indeed continues to be a model for qualitative analysis and debugging of interferometers today. But it showed its weaknesses in what might otherwise have been the most interesting section of the paper, "Comparison of Data with Other Observers." Here, Forward looks for coincidences between the unexplained events in his data set (not coincident with environmental signals in the monitor channel) and events in the resonant mass detectors that were in operation at the same time, at Frascati, Glasgow, and the Maryland group's detectors at College Park and Argonne. In every case, Forward found no event in his detector at the time of a candidate event from another detector. He notes ruefully that "The one 'distinctive signal' reported by the Glasgow group occurred at 13 h 07 min 29 sec GMT 5 September 1972, which was prior to the start of the Malibu data collection period."

The data were of course most interesting for their comparison to the results reported by Forward's former mentor Weber, since the latter was continuing to report coincident events between his various detectors. Forward notes that there were seven time blocks during which unexplained events in the interferometer occurred in close proximity to Weber coincidences. However, he further states, "Both raw power and derivative power-squared digitized data plots digitized to 0.1-sec accuracy were obtained from the Maryland group and compared with the 0.2-sec accuracy Malibu data. None of the audible Malibu signals fell within 0.6 sec of a Maryland-Argonne coincidence."

Fair enough, but what can be concluded from this lack of coincidences? Not much, according to Forward, since "It is difficult to compare the relative detection capabilities of the various antennas since their amplitude sensitivities, bandwidths, and signal processing techniques differ widely." He goes on to state that "at the time one of the bar-antenna systems produced an event or coincidence corresponding to a gravitational-

radiation signal with an amplitude of 0.1 fm/m [10^{-16}] due to spectral components in a narrow band around the bar resonance, the amplitude of the gravitational-radiation spectral components in the entire band from 1-20 kHz was definitely less than 10 fm/m and was probably less than 1 fm/m."

6.5 System Designs for More Sensitive Interferometers

6.5.1 The Magnitude of the Challenge

Forward's paper describing the state of the art of interferometric gravitational wave detectors in 1972 appeared in 1978. It was not until ten years later still that the next improvement in the state of the art was considered significant enough by its authors to warrant another comparable paper in the *Physical Review*. It is worth understanding what factors might have contributed to this slow pace of progress. Certainly the collapse of the credibility of Weber's "events" and the consequent redirecting of the effort at the much smaller signals predicted by astrophysical theory removed a lot of the motivation for trying to achieve incremental improvements in sensitivity. Instead, ultimate success came to be seen to require heroic improvements; neither the 10^{-16} of the room temperature bars nor the 10^{-18} sensitivity of the cryogenic bars would guarantee that gravitational wave astronomy could be established. It looked like frequent signals weren't likely to appear with strengths in excess of 10^{-21}, and perhaps not even much above 10^{-22}. If that were truly the case, then every possible advantage that could be squeezed out of the ideas detailed in Weiss' report would be required. And to achieve them, a great deal more effort was required than could be obtained from the Hughes interferometer, with its sensitivity in the range of 10^{-14} to 10^{-15}interferometer's arms from 2 meters to 1 km would hardly have begun to meet the need.

A sober look at the prospects for the field pushed its practitioners to even greater ambitions than simple improvement of sensitivity at or above 1 kHz. Much of the hope for detectable signals near 1 kHz had come to be focused on the radiation from the "bounce" at the end of the gravitational collapse of a stellar core at the onset of a supernova of Type II. But the theoretical predictions of the strength of such events were very uncertain. If one wanted to maximize the potential for discoveries, one had to imagine building instruments sensitive to the widest possible varieties of signals. And, since very few of the imaginable signals had frequencies above 1 kHz, the best way to improve one's chances was to improve the sensitivity to low frequency signals. This meant minimizing the magnitudes of many of the noise sources that Weiss had listed, a task that the Hughes group had chosen (for sensible reasons) to defer.

- Improved isolation from seismic noise is straightforward in principle, but very demanding in practice. The essential idea was employed by Weber: a cascade of mass-spring oscillators can provide a very steep slope to the frequency dependence of the isolation, making it acceptable for frequencies higher (by of order a decade or more) than the characteristic resonance frequency. It is a real trick to move the whole set of resonances to low enough frequencies (a few Hz) to extend the useful band down as low as 10 Hz or so.
- On the assumption that seismic noise can be controlled, another difficult noise source looms at low frequencies. The thermal noise of the test mass about its equilibrium position can become the dominant noise source, unless very specific measures are undertaken. In place of Forward's rubber mounts for the test masses, one needs to use what Weiss described as "horizontal seismometer suspensions." By this he meant suspensions that had two attributes: low resonant frequency and high Q. The latter was to be achieved by an arrangement whereby most of the restoring force on the test mass comes from gravity (which is nearly dissipationless), as in a pendulum. His system diagram is marked with the compliant directions for the seismometer suspensions, on the assumption that they would be relatively rigid in the orthogonal directions. Present thinking has moved to simple pendulums, partly because of worries about alignment but mostly because the rigid members of single d.o.f. seismometer suspensions tend to have internal resonant modes at inconveniently low frequencies.
- Shot noise minimization needs the whole bag of tricks, including a laser whose power was rated in tens of Watts (not tens of milliWatts), and an optical path length comparable to the gravitational wavelength. The latter would require Forward's desired kilometer-scale separation plus folding of the optical path, such as by the delay line described in Weiss' report. The Herriott delay line has served well in meter-scale prototypes, but most of the large projects have adopted long Fabry-Perot cavities, proposed for this purpose by Drever. (See the next section.) These have the great advantage of allowing the use of the smallest possible test masses, and taking up correspondingly small cross sections in the vacuum pipes. But their operation is substantially trickier than corner reflectors or delay lines, since each Fabry-Perot cavity is itself an interferometer that only performs like a beam-folding element when it is locked to the laser wavelength, using a servo of some

subtlety. Fabry-Perot cavities also appear to be less subject to excess noise from light scattered into unanticipated paths from mirror imperfections, a problem not suspected by either Weiss or Forward.

- Achieving the high sensitivities to which we now aspire requires vacuum of a quality much better than the Hughes interferometer. Pressures of 10^{-6} torr or better are required. The vacuum pipes are themselves much larger in diameter, due partly to the great care needed to keep scattered light effects at low levels. Scattered light also demands that baffles be properly placed in the interior of the pipes.

So it was probably going to take more than adding a few kilometers of irrigation pipe to the Hughes interferometer to detect gravitational waves with an interferometer. The realization that all of these features would be necessary was daunting, and caused the character of work on interferometers to change. Instead of quick demonstrations, it was considered necessary to try to engineer the variety of subsystems that high sensitivity would require. Instead of a device that Forward could honestly describe as a "gravitational-radiation experiment," workers conceived of their apparatus as "prototype gravitational-wave detectors."

6.5.2 Ron Drever's Bag of Tricks

Ronald W. P. Drever was one of the leaders of the generation of experimenters who followed Weber, only to find no signals that matched his claims. Rather than build a faithful copy of Weber's original bar, he chose to follow the path invented by Aplin (and publicized by Gibbons and Hawking) of the split bar, which maximized the bandwidth of the detector. When it became clear that much greater sensitivity would likely be required, he (like the German group) chose to switch to work on interferometers. His work in this period is again marked by an enthusiastic exploration of clever ideas. It is not marked, however, with many conventional papers in refereed journals. Instead, his most stimulating work is to be found in conference proceedings and lectures at physics summer schools.

Several of Drever's most important contributions are described in the text of the lectures he gave at the NATO Advanced Study Institute on Gravitational Waves held at the Les Houches Center of Physics in 1982.[65] Cast as an overview of the interferometric method of gravitational wave detection, it is dominated by an account of three crucial improvements on the basic scheme of Weiss, Forward *et al.* Each of these variations has come to play an important role in the design of the large detectors now under construction.

The Introduction gives an astoundingly brief account of the history of the field:

> An obvious way one might consider detecting gravity waves is through the changes in separation of free test particles, and the idea of using optical interferometers for observing this has certainly occurred to many physicists: indeed one might wonder why so few searches for gravity waves have been made this way.

The work of the Hughes group is mentioned in passing as demonstrating that a simple gravitational wave interferometer could achieve the shot noise limit. Weiss's work is referred to later as having contributed the idea of the delay line as an "important practical method for improving photon-noise limited sensitivity."

Drever goes on to describe the optimization of the parameters of a delay line, from the point of view of shot noise reduction. He then remarks on a "practical difficulty" that "became apparent in early experiments at Munich and at Glasgow—the potentially serious effect of incoherent scattering of light at the multireflection mirrors or elsewhere in the system." The interference between scattered light and light following the intended paths (which is non-stationary because the path followed by the scattered light can vary in length both on long and short time scales) proved to be a very troubling noise source in delay lines. The German group, Drever notes, proposed a way of modulating the laser light that would minimize the problem. Drever then suggests that "another approach would be to make the path traveled by scattered light equal to that of the main beam, and this may in fact be achieved if another type of optical system, a Fabry-Perot cavity, is used instead of a Michelson interferometer with many discrete reflections in each arm."

The basic idea was that light traveling between parallel mirrors can be, in effect, trapped for many round trips, until it is either absorbed, scattered, or leaked out by transmission through one of the mirrors. Thus, such a cavity can play the same role as a delay line with its many spatially separate reflections. The classic Fabry-Perot cavity used flat mirrors, usually equivalent to one another, usually closely spaced compared with their diameters or with the diameter of the beam of light, and usually operated in transmission (that is, with the interesting light emerging from the mirror opposite to the one into which the light was injected). What Drever proposed was rather different: a pair of small mirrors (no larger than necessary to keep diffraction losses small), spaced

apart by kilometers. The distant mirror has as nearly perfect a reflectivity as possible; a finite transmission is used on the near mirror, which functions both as an input and an output coupler for the light. Thus modified, a Fabry-Perot cavity can serve as an arm for a Michelson interferometer.

Drever is explicit about both the advantages and the drawbacks of this beam-folding scheme.

> The diameter of the cavity mirrors can be considerably smaller than that of delay-line mirrors.... This reduces the diameter of the vacuum pipe required, and also may make it easier to keep mechanical resonances in the mirrors and their mountings high compared with the frequency of the gravity waves, thus minimizing thermal noise. The Fabry-Perot system has however, some obvious disadvantages too—particularly the requirement for the very precise control of the wavelength of the laser and of the lengths of the cavities. Indeed with long cavities of the high finesse desirable here exceptional short-term wavelength stability is required from the laser.

The heart of the difficulty is that, unlike a delay line, a Fabry-Perot cavity stores light because it is in itself an interferometer—the trapping of the light for many round trips comes about only by careful adjustment of the phases of the superposed beams. This can only occur when the wavelength of the light and the length of the cavity are in resonance, that is, matched so that an integer number of waves fits into the cavity. Very near the resonance condition, the phase of the output light varies with mirror separation in the same way as the light that has traveled through a delay line. To achieve this condition, the light and the arm have to be locked together by a servo system. Drever's lecture goes on to describe the style of servo required, one that he and his group developed in conjuction with John Hall's group at the Joint Institute for Laboratory Astrophysics in Boulder, Colorado.[66] This servo design has its roots in an analogous microwave device developed by Robert Pound.[67]

While the essence of the difficulty was thus solved, in practice the use of Fabry-Perot cavities has additional complications. One is due to the fact that when a cavity is not very close to resonance, the phase of the output light has almost no dependence at all on the separation of the mirrors, thus making it very hard to generate the sort of signal necessary to acquire the lock on resonance in the first place. An additional level of complication comes when the arm cavities are assembled into a complete Michelson interferometer, since the interferometers within the interferometer need to be separately controlled without degrading the function of the main instrument. Solving these sorts of problems robustly has proven to be challenging work.

As a stopgap measure until those challenges could be met, Drever proposed a kind of interferometer that functioned without the light from the two arms being recombined at the beam splitter for the comparison between their phases. In the context of an ordinary Michelson interferometer this may seem impossible; but, since Fabry-Perot cavities are themselves interferometers, they can each be used to make an independent measurement of the difference between the wavelength of the light and the length of the cavity. A laser illuminates the two orthogonal arms of an interferometer containing Fabry-Perot cavities. Arm 1 is read out by the Pound-Drever-Hall method to generate an error signal reflecting the mismatch between the laser light and the length of the arm. This error signal is used in a servo loop to cause the wavelength of the laser to resonate with Arm 1. The other half of the laser's light is directed by the main beam splitter to Arm 2. There, the mismatch between the light and the arm generates another error signal, reflecting the difference in length (modulo N wavelengths) between Arm 2 and Arm 1. Since a fluctuating arm length difference is the signature of a gravitational wave, this second error signal constitutes the scientific output of the interferometer. (It also of course contains the various noise sources that cause or mimic arm length differences, but in that sense it is no different from the dark fringe output of a more conventional interferometer.) Drever included the use of that error signal being used to close a second servo loop that forces the length of Arm 2 to follow the wavelength of the light. This is necessary to keep the arm at a functional operating point; it means that the error signal has to be calibrated to take the servo action into account, which sounds more complicated at the heuristic level than it actually is in practice.

The scheme described in the previous paragraph formed the basis for almost all of the work on Fabry-Perot-based gravitational wave interferometers until well into the 1990s. But none of its proponents ever expected it to play more than a stopgap role. This is mainly because, without recombination of the light from the two arms to generate "dark" and "bright" output ports, the system cannot be used as the basis of what came to be known as *power recycling*, described for the first time in this lecture, featured there as one of the "possibilities for future enhancement in sensitivity."

Drever introduces the idea of recycling (modestly referred to as a "possibility for more efficient use of light") in the context of a delay-line Michelson interferometer, for pedagogical simplicity. The key idea is as follows. If an interferometer has long arms and if it is constructed from mirrors with high enough reflectivity, then the light exiting

from the bright port may be nearly as bright as the light entering the interferometer from the laser. (This insight represents a profoundly different "take" on the issue than can be found in Weiss' work; he instead worried about optimizing the shot noise versus number of bounces on the assumption, good for short arms and poor mirrors, that substantial losses would eventually occur.) The light exiting the bright port is every bit as good as "fresh" light from the laser, so it seems a shame to waste it. Drever's proposal is to arrange by an appropriate set of mirrors to redirect the used light into the interferometer, in coherent superposition with light arriving directly from the laser. (This has to be done using a beam splitter or other partially reflecting mirror of a carefully chosen reflectivity.) This arrangement has in effect made the whole interferometer into a single Fabry-Perot resonant cavity, whose back mirror is the Michelson interferometer, and whose input/output coupler is the partially-reflecting recycling mirror.

In principle, the advantages that could be achieved with this technique are quite large. Drever quotes rms shot noise in a search for 1 msec pulses of 10^{-22}, far superior to what could be achieved without recycling. He also gives a diagram showing how the technique could be applied to an interferometer whose arms were made of Fabry-Perot cavities. The components necessary to sense and control the various internal degrees of freedom are drawn in with dashed lines, as an indication of the provisional nature of the design. In fact, more subtle schemes have had to be developed to implement such as system. But, given the quality of the mirrors available today (and the lack of commensurate progress in the power levels available from stabilized lasers), power recycling has been adopted as an essential feature of every large interferometer under construction today.

The other "possibility" described here is one "for enhancing sensitivity for periodic signals." This one is again introduced in the pedagogically simpler delay line interferometer. And again, the aim is to find a way to make use of the fact that, with good mirrors, the light would not be significantly attenuated after it has spent one half of a gravitational wave period in an interferometer arm. A periodic gravitational wave persists (by definition) for much longer than one half period; why not find a way to accumulate a phase shift on the interferometer's light for a much longer interval? The scheme proposed here does just that, by arranging for light that exits one arm after one half cycle of the gravitational wave to enter the other arm, where it stays for another half cycle. The light changes arms at the same time that the gravitational wave changes sign, at least for the signal frequency that matches the length of the interferometer. A partially reflecting mirror governs how long the light repeats this cycle before finally exiting the interferometer. As with power recycling, Drever goes on to show how a similar effect can be achieved in an interferometer that uses Fabry-Perot cavities.

It has been shown recently that the scheme can actually be implemented in a much more elegant way, using a single partially reflecting mirror at the nominally dark port. In analogy with power recycling, this scheme (called *signal recycling*) can be thought of as forming a single large Fabry-Perot resonant cavity out of the interferometer, this one resonant at the frequency of the signal sidebands on the laser light that have been created by the action of the gravitational wave.[68] This version of the idea will almost certainly also find application in the next generation of large interferometers.

6.6 The Garching 30-Meter Prototype Gravitational-Wave Detector

The 1988 paper to which we referred above was the account by the group at the Max-Planck-Institut für Quantenoptik, the successor to the bar group of the early '70s. Shoemaker *et al.*[69] provided a beautifully detailed account of the best-characterized interferometer prototype yet built. It can be thought of as the work that brought to fruition, on the meter scale at least, the ideas embodied in Weiss's 1972 design study. Through the '70s and '80s, a number of groups (including Weiss's at MIT, Drever's at Glasgow and at Caltech, and Brillet's at Orsay) worked in parallel with the MPQ group to develop prototypes of kilometer-scale working interferometric detectors.[70] The MPQ paper makes a nice example, though, since it is an especially complete account of a well-functioning instrument. So for pedagogical purposes we let it here stand for the large body of work done worldwide through the 1980s.

The interferometer described here had test masses 30 meters from the beam splitter; light made 45 round trips, for a total light travel time in an arm of 9 μs. The folding of the optical path was achieved with a Herriott delay line. The interferometer was illuminated with an Argon-ion laser at $\lambda = 514.5$ nm, capable of supplying up to 0.23 W to the photodetector (at a bright fringe) after all optical losses in the interferometer are included. The test masses consisted of simple glass mirrors with a radius of curvature 31.6 m; they were suspended from single-wire slings of free length 0.72 m, giving a resonant frequency of about 0.6 Hz. Each of these was in turn suspended from a metal plate hung from coil springs. This upper level of the suspension not only added isolation along the optic axis, but gave isolation in the other degrees of freedom that might cross-couple into the sensitive direction.

The many compliant degrees of freedom of such a system needed damping, but damping of a sort that would not add substantial amounts of noise, in particular thermal noise. The solution was a set of optical shadow sensors that detected the positions of small vanes attached to the mirrors; the outputs of these sensors, suitably filtered, drove currents through coils that were in turn positioned near magnets integrally mounted with the vanes. This is a very robust kind of servo, and it can be made sufficiently noiseless, at least at intermediate and high frequencies. In the Garching 30-meter interferometer, 16 degrees of freedom were damped using servos of this kind.

The Garching group paid careful attention to the influence of fluctuations in laser power, wavelength, position, and angle. Laser power fluctuations are dealt with primarily by implementation of the modulated dark-fringe servo system. Sensitivity to variations in the input beam's transverse position and injection angle was minimized by using an optical fiber as a spatial filter for the laser, an idea the authors credit to Weiss. Frequency fluctuations enter in two ways:

- Mismatches in the curvature of the mirrors cause the two interferometer arms to differ in length by an amount ΔL, when the mirrors are spaced so as to give the same number of round trips N through the arms. The spectral density of effective arm length noise $x(f)$ due to a frequency fluctuation spectrum $\delta\nu(f)$ is

$$x(f) = \frac{\Delta L}{N}\frac{\delta\nu(f)}{\nu}.$$

- Light that scatters out of the intended path can nevertheless find its way to the beam splitter again, where it interferes with the rest of the light. Although good mirror surfaces and coatings minimize the fraction of the light scattered, the very large mismatches in path length that can result made this a comparable mechanism for conversion of laser frequency noise into apparent mirror motion.

In order to make laser frequency noise small enough, the Garching group stabilized the laser using a combination of two servo loops. In the first loop, a rigid Fabry-Perot resonant cavity serves as a length reference; the light's wavelength is held to resonance in the cavity, by inspection of the transmitted light intensity. A second error signal is derived by interfering the light that exits the bright port of the interferometer (whose phase depends on the average of the lengths of the two arms) with some of the new light entering. Feedback was applied to a mirror at the end of the laser cavity, to a Pockels cell within the laser cavity, and to the common mode positions of the two end mirrors of the interferometer.

The noise spectrum of the system was in reasonable agreement with a noise budget prepared from estimates of the noise sources described above. The rms noise in a 1 kHz bandwidth near 1 kHz was about 3×10^{-18}, only a factor of three poorer than the best that had been achieved by a resonant-mass detector. This was one of the great triumphs of the German work. The other was the robustness of the rather elaborate active system that this interferometer had become, of order two dozen servo loops. It typically stayed in lock for 30 minutes to an hour, and upon losing lock would shortly reacquire lock automatically.

The 30-meter interferometer was run for 100 hours in March 1989, in coincidence with the ten-meter interferometer at Glasgow that had achieved comparable sensitivity. Even then, the enthusiasm for looking for gravitational waves at "low" sensitivity was such that an analysis of the results of the run was not published until 1996.[71]

6.7 Designs for Kilometer-Class Interferometers

As noted above, laboratory work on interferometers was almost from the beginning considered an engineering exercise preparatory to the construction of instruments with arms of kilometer scale. With several such devices now under construction, it is worth reviewing their distinctive features. Here, even more so than for the other cases we have been discussing, the refereed literature is a poor source of information, and so are conference proceedings. For most projects the only detailed descriptions are those contained in funding proposals. (The one redeeming feature of this form of publication is that, since the reviewers of such documents were typically not expected to be experts in the field, they contain an abundance of carefully written tutorial material, and well-reasoned justifications for most design choices.)

The three largest approved projects today, (LIGO,[72] VIRGO,[73] and GEO[74]) all went through similar parallel processes of design study, proposal, and now construction. This was a fruitful period, with a rich interchange of ideas. For pedagogical purposes, we choose to focus in this review on a single line of development, that of the U.S. LIGO Project.

6.7.1 The "Blue Book"

In almost the same sense as the early table-top interferometers were prototypes of larger instruments, so too did the proposals for kilometer-scale interferometers have a prototype. This was the report called "A Study of a Long Baseline Gravitational Wave An-

tenna System," submitted to the U.S. National Science Foundation in October 1983.[75] (It has since its presentation been called the "Blue Book" because of the color of the cheap paper cover in which it was bound.) It was prepared primarily by Weiss and two colleagues at MIT (Paul S. Linsay and the present author), as the product of a planning exercise funded by the NSF starting in 1981. The report also contained a section by Stan Whitcomb of Caltech on Fabry-Perot systems (as a partial counter to Weiss' emphasis on Herriott delay lines), as well as extensive sections written by industrial consultants from Stone & Webster Engineering Corporation and from Arthur D. Little, Inc. These latter contributors were essential, because this document contains, for the first time anywhere, an extensive discussion of the engineering details specific to the problems of the construction and siting of a large interferometer. The report was presented, by both Weiss's MIT group and that of Drever at Caltech, at a meeting of the NSF's Advisory Council for Physics late in 1983. While not a formal proposal, it served as a sort of "white paper," suggesting the directions that subsequent proposals might (and in large measure did) take.

The first half of the report is devoted to the physics of gravitational wave interferometers. This section reads much like Weiss' 1972 design study, except that many issues only touched on briefly in the first paper are here discussed at substantially greater length. In the 11 years that elapsed between the two documents, there had been real progress on several fronts. There are chapters on sources of gravitational waves, the basic physics of the response of a free-mass interferometer to a gravitational wave, a discussion of beam-folding schemes and a summary of the current prototype interferometers, and another extensive discussion of noise sources. The report is bracketed by an introductory section outlining a history of the field to 1983 and by a pair of appendices, one of which compares the quantum limits of bars and interferometers and the other showing why the interferometer beams must travel through an evacuated space instead of through optical fibers.

The main emphasis of the Blue Book was less a discussion of physics *per se* than it was a consideration of the practical aspects of the experiment as an engineering and construction project. The completely new material appears in the second half of the Blue Book, in the chapters summarizing the work of the industrial consultants. Weiss believed that the only significant impediment to achieving astrophysically interesting sensitivity was the expense of building an interferometer with long arms (the issue that had brought the Hughes group's progress to a halt). The industrial study was undertaken with the aim of identifying what design trade-offs would allow for a large system to be built at minimum cost, and to establish a rough estimate of that cost (along with cost scaling laws) so that the NSF could consider whether it might be feasible to proceed with a full-scale project.

Before such an engineering exercise could be meaningful, though, it was necessary to define what was meant by "full-scale." The Blue Book approaches this question by first modeling the total noise budget as a function of frequency, then evaluating the model as a function of arm lengths ranging from 50 meters (not much longer than the Caltech prototype) to 50 km. The design space embodied in this model was then explored in a process guided by three principles:

- "The antenna should not be so small that the fundamental limits of performance cannot be attained with realistic estimates of technical capability." This was taken to mean that the length ought to be long enough that one could achieve shot noise limited performance for laser power of 100 W, without being limited instead by displacement noise sources, over a band of interesting frequencies. The length resulting from this criterion strongly depended on whether one took that band to begin around 1 kHz (in which case $L = 500$ m was adequate), 100 Hz (where $L = 5$ km was only approaching the required length), or lower still (in which case even $L = 50$ km would not suffice). Evidently, this strictly physics-based criterion was too elastic to be definitive.
- "The scale of the system should be large enough so that further improvement of the performance by a significant factor requires cost increments by a substantial factor." In other words, the system should be long enough so that the cost is not dominated by the length-independent costs of the remote installation.
- "Within reason no choice in external parameters of the present antenna design should preclude future internal design changes which, with advances in technology, will substantially improve performance." This was a justification for investing in a large-diameter beam tube, and for making sure that the vacuum system could achieve pressures as low as 10^{-8} torr.

In an iterative process, rough application of these principles was used to set the scope of options explored by the industrial consultants. Then at the end of the process, the principles were used again to select a preferred design. Arm lengths as long as 10 km were explored, and tube diameters as large as 48 inches. An extensive site survey was also carried out by the consultants. It was aimed at establishing that sites existed that were suitable for a trenched installation (which put stringent requirements

on flatness of the ground) of a 5 km interferometer. The survey covered federal land across the United States, and a study of maps of all land in the Northeastern United States, along with North Carolina, Colorado, and Nebraska. Thirteen "suitable" sites were identified. Evaluation criteria also included land use (specifically that the site not be crossed by roads, railroads, or oil and gas pipelines), earthquake risk, drainage, and accessibility.

The site survey also attempted to identify possibilities of locating an interferometer in a subsurface mine, which would give a more stable thermal environment and perhaps also reduced seismic noise (if it were located deep enough, and if it were inactive). No mines were found in the United States with two straight orthogonal tunnels even 2 km in length.

The conclusion of the exercise was a "proposed design" with the following features:

- Two interferometer installations separated by "continental" distances.
- Interferometer arm length of $L = 5$ km.
- Beam tubes of 48-inch diameter made of aluminum (chosen for an expected cost savings over stainless steel) pumped by a combination of Roots-blowers for roughing and ion-pumps for achieving and maintaining the high vacuum. A delay line interferometer would require a diameter of almost the proposed size. Drever's beam-interchange scheme for improved narrow-band sensitivity was also listed as one justification for preferring large tubes, as was the possibility of multiple interferometers (presumably based on Fabry-Perot cavities) side by side.
- The proposed installation method was to enclose the tube in a 7' by 12' cover constructed of a "multi-plate pipe-arch," in turn installed four feet below grade in a trench that was subsequently back-filled with soil.

The total estimated cost for such a system was given as $58M.

Note that there were no specific recommendations for the design of the interferometers themselves, beyond the "straw man" used for estimating the noise budget.

The Blue Book was received respectfully by the NSF's Advisory Committee for Physics. As a result, the MIT and Caltech research groups were encouraged to combine their forces to develop a complete specific design. Subsequently, both groups received funding with the eventual goal of a joint proposal for construction of a large interferometer system.

6.7.2 The LIGO Proposal of December 1987

By 1987, substantial progress had been made on lab-scale interferometers by research groups around the world. And, encouraged by the NSF's reception of the Blue Book, more thinking had gone into the best way to construct and exploit large interferometers. Much of this progress is evident in the proposal submitted to the U.S. National Science Foundation in December of 1987 by a formal Caltech-MIT collaboration that had adopted the name of LIGO, for Laser Interferometer Gravitational wave Observatory.[76] Since September 1987 it has been led by Rochus E. ("Robbie") Vogt as Project Director, with Drever and Weiss as science team leaders. The proposal requested funds for a three-year program of R&D and engineering studies, the outcome of which was intended to be another proposal (to be submitted in 1989) requesting authorization to build a pair of 4-km long interferometers.

Prototype interferometers were functioning at respectable sensitivities, after years of assembly, debugging, analysis, and redesign. The Caltech 40-meter interferometer was the showpiece of the proposal. It employed high-finesse Fabry-Perot cavities, arranged in the simplified non-recombined configuration for ease of testing. An impressive graph shows the improvement in strain sensitivity since its first operation in May 1983, by a factor of over 10^3 in amplitude. In that interval, ultra-low loss "supermirrors" were installed, first on an early optical-bench style of test mass and then on separated compact test masses (eventually ones made of fused silica), and a variety of improvements were made to the Argon laser and to the locking servos. The noise spectrum above 1 kHz was nearly white, with a level of $h(f) \approx 2 \times 10^{-19}/\sqrt{\text{Hz}}$. This was consistent with the expected level of shot noise.

Results were also presented from the table-top (1.5 meter arm length) prototype interferometer at MIT. It employed Herriott delay lines of 56 bounces between conventional high quality mirrors that were clamped to aluminum test masses. Unlike the Caltech instrument which could not function without sophisticated frequency stabilization of its laser, MIT used an unstabilized Argon laser to which phase noise was actually added to help suppress scattered light. Pointing, damping, and slow feedback were accomplished with electrostatic actuators. Strain sensitivity could of course not compete with the much longer Caltech instrument, but even the displacement noise was nearly an order of magnitude worse, given as 4.6×10^{-17} m$/\sqrt{\text{Hz}}$, for frequencies above 4 kHz. That level was a factor of two in excess of the expected shot noise in the 60 mW of light, diagnosed as insufficiently suppressed noise from scattered light. At lower fre-

quencies acoustic noise drove the interferometer via a variety of coupling paths through the injection optics as well as the test mass suspensions.

The proposal records substantial progress toward design of a full-scale interferometer. It states that the collaboration had adopted the Fabry-Perot beam-folding system. A preliminary design is presented in an appendix of the proposal. It envisioned use of 5 to 6 W of light at 514 nm from an Argon laser employed in a power recycled configuration. An elaborate schematic diagram gave a hint of the complexity of the servos necessary to control the large number degrees of freedom that need to be kept locked for such an instrument to function. These include lengths of the arm cavities, the separation of their input mirrors from the beam splitter, the location of the power recycling mirror, and the lengths of various "mode cleaning" resonant cavities used for spatial filtering of the laser beam. In addition to these lengths, control of a number of angular degrees of freedom also needs to be included. Four separate RF modulation frequencies are specified to drive these servos. Special features are designed into the main cavity locking servo so that the phase modulation can be injected with a small Pockels cell without the inevitable losses dominating the performance of the recycling system.

Another appendix describes an alternate optical configuration based on Herriott delay lines. It employed 86 cm diameter silicon test masses of 450 kg. The simplicity of the servos was listed as one of its major advantages. A "closed-path" variation of this design was also presented, in which light leaving one arm is injected into the other. This is like a single-interchange version of Drever's system for improving sensitivity to periodic waves. Here it was employed mainly to relax the tolerances on matching the curvature of the large mirrors. (The virtues of this design have recently been explored again by the Stanford group.[77])

On the engineering and site issues, there had also been some progress since the Blue Book study, mostly made by engineers at Caltech's Jet Propulsion Laboratory, but this was not considered complete enough to highlight in the proposal. Instead, one of the first proposed tasks was to complete a preliminary engineering design. Nevertheless, a mature understanding had been achieved of what LIGO ought to *be*. This insight was expressed in a list of "Essential Features of the LIGO":

1. "Two widely separated sites under common management." Two sites had been a feature of Weiss' earliest thinking, to allow coincidence observations to search for transient signals. The new feature was the commitment to truly have them managed as a single entity, "to guarantee that two receivers of nearly equal sensitivity are on line simultaneously at two sites, with a high live time."
2. "Arm lengths of order 4 kilometers at each site," a slight scaling back of the 5 km considered previously, but still long enough to strongly dilute the effects of displacement noise.
3. "The ability to operate simultaneously several receiver systems at each site." In a way, this was the most ambitious feature of the LIGO concept. In part it grew out of a kind of conservatism that was not clearly spelled out, but that was nevertheless real. The early LIGO interferometers, if they were not to be extremely risky extrapolations from known technology, were unlikely to have sufficient sensitivity to be assured of detecting astrophysical signals. Even if that weren't so, the project would have had to wrestle with the competition between time devoted to observation and time devoted to improving the performance of the instrument. This competition had bedeviled workers on resonant-mass detectors. The key new idea for LIGO was that the precious commodity, an evacuated beam pipe, might be available with abundant cross-sectional area since the Fabry-Perot geometry had been adopted. All that was required was an arrangement of tanks at the ends of the pipe to install the test masses of various interferometers, both operational and experimental. This actually called for substantial cleverness in developing an airlock system, so that installation and operation could take place with "a minimum of mutual interference."
4. "The capability for receivers of two different arm lengths." Drever urged the adoption of this feature, to allow a clean test of the gravitational origin of candidate signals, which should show up as the tidal signature that a longer interferometer sees twice the signal.
5. "A vacuum tube diameter of order 48 inches." This had the conservative justification that it would be necessary if one had to switch from Fabry-Perot cavities to delay lines, and the great benefit of allowing multiple Fabry-Perot interferometers, as mentioned above.
6. "The capability of a vacuum level of 10^{-8} torr." This would be needed, not for the first LIGO instrument, but to avoid having fluctuations in the index of refraction of the residual gas dominate shot noise in a more sensitive "advanced" receiver.
7. "A minimum lifetime of the facilities of 20 years." This was to be not just a one-shot discovery experiment, but a laboratory to exploit the gravitational wave

window in astronomy.

8. "Adequate support instrumentation."

The heritage of the Blue Book should be evident in the above list, but so too should be the progress in thinking beyond that point.

Because of a Federal budget crisis, this proposal was not funded. However, the two groups were encouraged to continue their work, and to submit a more complete proposal in a subsequent year.

6.7.3 The LIGO Proposal of December 1989

Many of the features only hinted at in the 1987 proposal are spelled out in much greater detail in the proposal for engineering design and construction of LIGO (now with a hyphen in Laser Interferometer Gravitational-Wave Observatory) that was submitted to the NSF in December 1989.[78] It fleshes out the design of a system that would embody the eight Essential Features of LIGO first described in the 1987 proposal. (The only differences are that the vacuum tube diameter is now specified as a "clear optical diameter of approximately 1 meter," and the vacuum spec is given as "10^{-9} torr of hydrogen and 10^{-10} of other gases.")

A single detector system would require three interferometers—a 4 km interferometer at each of two widely separated remote sites, plus a 2 km interferometer at one of the sites. This shorter interferometer played two related roles: a check that a candidate signal had the tidal signature of a gravitational wave, and the simpler but crucial requirement that a real signal should appear in all three interferometers. A calculation presented here shows that an accidental event rate of around 100/hour/interferometer can be tolerated without accidental three-way coincidences occurring more frequently than once in ten years, an improvement of about two orders of magnitude over what could be tolerated with only a single interferometer at each site.

The features described above are part of a plan that is aimed at accomplishing "three primary objectives":

- "observation," or a continuous "gravitational-wave watch,"
- "development," or "full functional testing of new and advanced interferometer-based detector concepts," and
- "special investigations" using detectors optimized for "particular phenomena."

These missions are "to be conducted without mutual interference."

It would take a substantial investment (of money, ideas, and energy of scientists) to accomplish all of these goals, and so for this reason full implementation of this strategy was to be accomplished in a series of phases.

- "Phase A, The Exploration/Discovery Phase," with one three-interferometer detector system, suitable for observation or development, but not both simultaneously.
- "Phase B, The Discovery/Observation Phase," with two three-interferometer detector systems, allowing "concurrent observation *and* development or specialized search."
- "Phase C, The Observatory Phase," room for three full detector systems, "allows concurrent observation, development, special investigations, and optimal access for the scientific community at large. It completes the LIGO evolution to its presently conceived full-design capability."

Because of the cost involved in elaborate vacuum chambers with airlocks, the 1989 proposal asked only for the funds to complete Phase A. The single important investment in the capability to upgrade to Phases B and C was the design of buildings large enough to accommodate all of the vacuum tanks that would be eventually required.

It should be emphasized that, to a large degree, this aggressive planning for an elaborate facility was a necessary consequence of a simple fact—that it looked difficult to build an interferometer that would have sufficient sensitivity to assure detection of gravitational waves. Hence the need to plan for ongoing interferometer development and specially optimized instruments. Of course, these activities would also be useful even if some signals proved easier to detect than expected, since carrying out gravitational wave astronomy would call for the highest achievable signal to noise ratios. For example, angular position errors are inversely proportional to the signal to noise ratio, and are as large as ten arcmin or more when the SNR = 10, even when observations are made with a three-detector U.S.-Europe network.

The 1989 proposal is much more explicit about the details of the design of the first interferometer. The design is based on the Fabry-Perot interferometer of the 1987 proposal's appendix. It has been fleshed out with specifications of laser power, finesse, test mass parameters, and vibration isolation performance, so that a specific noise budget could be presented. The 1989 proposal also contains a preliminary discussion of what sorts of improvements would be necessary to push the noise to levels low enough

to guarantee detection of signals. This includes laser power of 60 W recycled by a factor of 100, a much more aggressive vibration isolation system, and final pendulum suspensions with a quality factor of 10^9 carrying one-ton fused silica mirrors.

6.7.4 The Situation Today

Construction of LIGO was approved in 1991. By mid-1998 (the time of the writing of this review), construction of the two facilities in Hanford, WA and Livingston, LA was over three-quarters complete. The schedule calls for construction to be completed soon. Roughly speaking, 1999 is to be devoted to installation of the scientific equipment in the completed facilities, 2000 to shakedown of the interferometers, and 2001 to engineering activities to bring the performance up to the design specifications. Then, data will be collected during 2002-3. Beginning in 2004, upgrades to improve the performance will be carried out, interspersed with additional periods of observation.

The first instrument to be installed is expected to have a noise spectrum like that shown in Figure 4. The high frequency noise spectrum should be dominated by shot noise, as determined from an input power of 6 W, multiplied by a power recycling gain of 30. Thermal noise from the 1 Hz pendulum mode will dominate the intermediate frequency band; the oscillations of the 10 kg test masses should achieve a quality factor of 1.6×10^5. (Internal thermal noise will dominate the spectrum only in a narrow band, due to test mass modal quality factors of about 10^6.) Low frequency noise will be governed of course by seismic noise that passes through the multi-layer stack.

Performance of the VIRGO 3 km interferometer will be similar at medium and high frequencies. At low frequencies, seismic noise should be much lower in VIRGO than in LIGO, since a much more aggressive filter has been designed. This should allow the noise to be dominated by pendulum thermal noise down to 10 Hz or a bit lower.

The GEO 600 meter interferometer is not expected to reach quite such low levels, but it will be surprisingly close. To make up for the shorter length, advanced technologies (including signal recycling) will be pursued aggressively from an early date. Thus this instrument will play a dual role as part of the global network of interferometers and as a prototype for features that will later be incorporated into other interferometers.

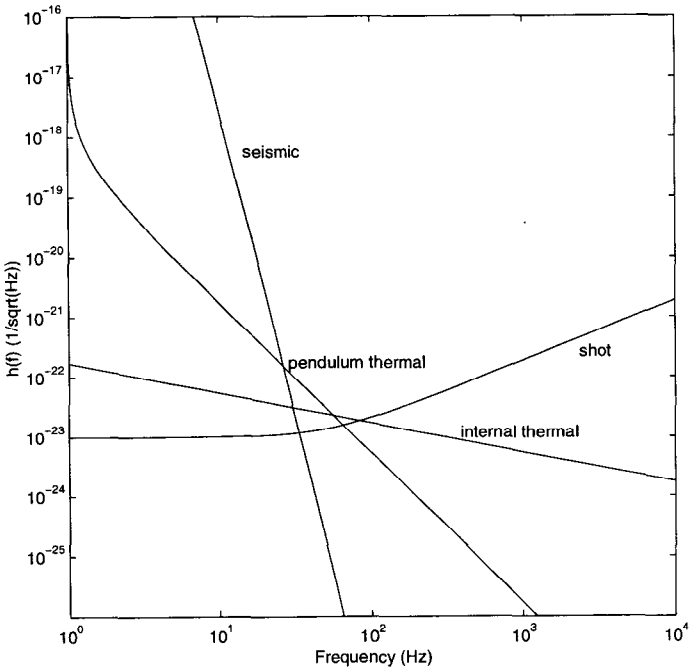

Fig. 4. An estimate of the noise spectrum of the LIGO I interferometers. The four most important noise sources are shown: seismic noise, pendulum mode thermal noise, thermal noise of internal vibrations of the mirror, and shot noise.

Summary

During recent years, the first generation of large-scale laser-interferometric gravitational wave (GW) detectors has been commissioned and is now in operation. This worldwide network of gravitational wave observatories collects the most GW-sensitive data to date.

The gravitational wave detector GEO 600 near Hannover, is the first large-scale instrument already now using second generation technology, such as electro-static actuators and signal recycling. The use of signal recycling allows to improve the sensitivity but at the cost of a significantly more complex detector. A new method was developed that allowed, for the first time, the realization of tuned signal recycling in a large interferometer. In Chapter 2 a comparison of tuned and detuned signal recycling operation is given and related problems are discussed. It is found that the combination of heterodyne readout and detuned signal recycling is unfavourable in many respects. This supports the decisions to operate the LCGT detector with tuned signal recycling, and advanced LIGO in detuned signal recycling, but with a homodyne readout. The concept of detuned signal recycling with a DC-readout scheme might actually also have advantages for GEO 600 as described in Chapter 6.

One of the main noise sources encountered during the commissioning of 1st generation detectors is stray light. The actual sensitivity of GEO 600 can already be degraded by stray light contributions of the order 10^{-20} W. Since second generation GW detectors will operate with significantly higher light powers, and aim for increased sensitivities, stray light could be even more problematic. Chapter 3 describes the experience that was gained by studying stray light in GEO 600. A guide is given to help avoid, identify and eliminate stray light noise.

GEO 600 is not only an excellent test facility for second generation technologies, but also provides sensitive data with a high duty cycle. Currently a peak strain sensitivity of $2.5 \cdot 10^{-22}/\sqrt{\mathrm{Hz}}$ is achieved. In order to allow the data from GEO 600 to be used for multi-detector analysis, a high calibration accuracy is required. In an attempt to validate the official calibration routines, photon pressure calibrators are used in GEO 600 and LIGO. As shown in Chapter 4, several problems have been encountered during the commissioning of the GEO photon pressure calibrator. In particular, at frequencies above 1 kHz, a large discrepancy between the official calibration and that derived from the photon pressure calibrator was observed. This can be explained by photon pressure induced test mass deformation.

In Chapter 5 a new statistical veto method is presented employing an amplitude consistency check. This technique allows the derivation of safe statistical vetoes from interferometer channels which can contain traces of GW signal. This veto was applied to S5 data of the GEO 600 detector and was found to give veto efficiencies between 5 % and 20 % and a use-percentage of up to 80 %. This new veto method can easily be applied to the data from other GW detectors.

Key words: *Gravitational wave detector, signal recycling, stray light, photon pressure calibrator, statistical veto, DC-readout*

Zusammenfassung

Die großen laser-interferometrischen Gravitationswellendetektoren (GWD) der ersten Generation haben ihren Betrieb aufgenommen und bilden ein weltweites Netzwerk von Gravitationswellen-Observatorien. Die aufgenommenen Daten haben die beste Empfindlichkeit, die bisher erreicht wurde.

Der Gravitationswellendetektor GEO 600 bei Hannover ist das erste große Instrument, das bereits jetzt Technologien der zweiten Generation einsetzt, wie z.B. elektrostatische Aktuatoren oder Signal-Recycling (SR). Der Gebrauch von SR erhöht die Empfindlichkeit des Interferometers, steigert aber gleichzeitig auch die Komplexität des Systems. Eine neue Methode wurde entwickelt, mit der es erstmals möglich ist, tuned SR in einem großen Interferometer zu realisieren. In Kapitel 2 werden detuned und tuned SR verglichen und die damit verbundenen Probleme diskutiert. Es zeigt sich, dass eine Kombination aus Heterodyndetektion und detuned SR in mehrfacher Hinsicht unvorteilhaft ist. Dies bestätigt die Entscheidung, LCGT im tuned SR modus und Advanced LIGO mit einer Homodyndetektion zu betreiben. Die Konfiguration, detuned SR mit Homodyndetektion, kann auch für GEO 600 von Vorteil sein (siehe Kapitel 6).

Eine der Hauptrauschquellen der GWD der ersten Generation stellt Streulicht dar. Die Empfindlichkeit von GEO 600 kann schon von Streulichtbeiträgen in der Größenordnung von 10^{-20} W limitiert werden. Da die Detektoren der zweiten Generation mit deutlich größeren Lichtleistungen und gleichzeitig besserer Empfindlichkeit betrieben werden, kann die Streulichtproblematik in Zukunft sogar noch verstärkt auftreten. Kapitel 3 beschreibt die Erfahrungen, die in GEO 600 mit Streulicht gemacht wurden. Es werden Methoden beschrieben, wie Streulicht gefunden und eliminiert, bzw. vermieden werden kann.

Mit GEO 600 können nicht nur Technologien der zweiten Generation hervorragend getestet werden, sondern GEO 600 nimmt auch Daten mit hoher Empfindlichkeit und großem Dutycycle auf. Aktuell wird eine Empfindlichkeit von $2.5 \cdot 10^{-22}/\sqrt{\text{Hz}}$ erreicht. Damit GEO-Daten für Multi-Detektor-Analysen eingesetzt werden können, ist eine hohe Kalibrationsgenauigkeit erforderlich. GEO 600 und LIGO versuchen, Strahlungsdruckkalibratoren zu entwickeln, um die offiziellen Kalibrationen zu überprüfen. Wie in Kapitel 4 dargestellt wird, treten dabei aber mehrere Probleme auf. Besonders bei Frequenzen oberhalb von 1 kHz wird eine große Abweichung der Strahlungsdruckkalibration von der offiziellen Kalibration gefunden, die durch eine vom Strahlungsdruck induzierte Verformung der Testmasse erklärt werden kann.

In Kapitel 5 wird eine neue Methode zur Gewinnung statistischer Vetos beschrieben, die einen Amplitudenschwellwert benutzt. Diese Technik erlaubt das Erstellen von zuverlässigen Vetos auch aus Interferometerkanälen, die Spuren von Gravitationswellensignalen enthalten können. Die Vetomethode wurde auf Daten vom GEO-Detektor mehrfach angewendet und hat sich als leistungsstark erwiesen.

Chapter 1.

Introduction

1.1. Detection of Gravitational waves

The existence of gravitational waves (GW) is a consequence of the General Theory of Relativity, which was discovered and published by Albert Einstein in 1916. Supernovae, coalescing compact binary systems and pulsars are only a few representatives of astrophysical source, which can emit gravitational waves. Gravitational waves are expected to cover a wide frequency range, starting at the lower end at about 10^{-17} Hz and going up to frequencies as high as a few kHz. The strength of even the strongest signals, for instance a supernova in our own galaxy, will be very small at the earth and only cause a relative length change of about 10^{-21}. A good overview of gravitational wave sources can be found in [Cutler/Thorne].

The first efforts towards detecting gravitational waves were carried out by Joseph Weber in the 1960s. He used large metal cylinders, so called bar detectors or resonant detectors, as antennas [Weber]. While Weber and his first followers used the bar detectors at room temperature, later experimenters cooled their bar detectors down to liquid Helium temperatures to suppress the intrinsic thermal noise. An overview of the present status of the resonant detectors can be found in [Astone02].

Indirect evidence of the existence of gravitational waves was supplied by R. A. Hulse and J. H. Taylor [Hulse], [Taylor]. They observed a pulsar, in the binary star system PSR 1913+16 over years, and found a continuous increase of its rotation frequency. The observed increase exactly matched the increase predicted from emission of gravitational waves. For this work, Hulse and Taylor were awarded the Nobel price in 1993.

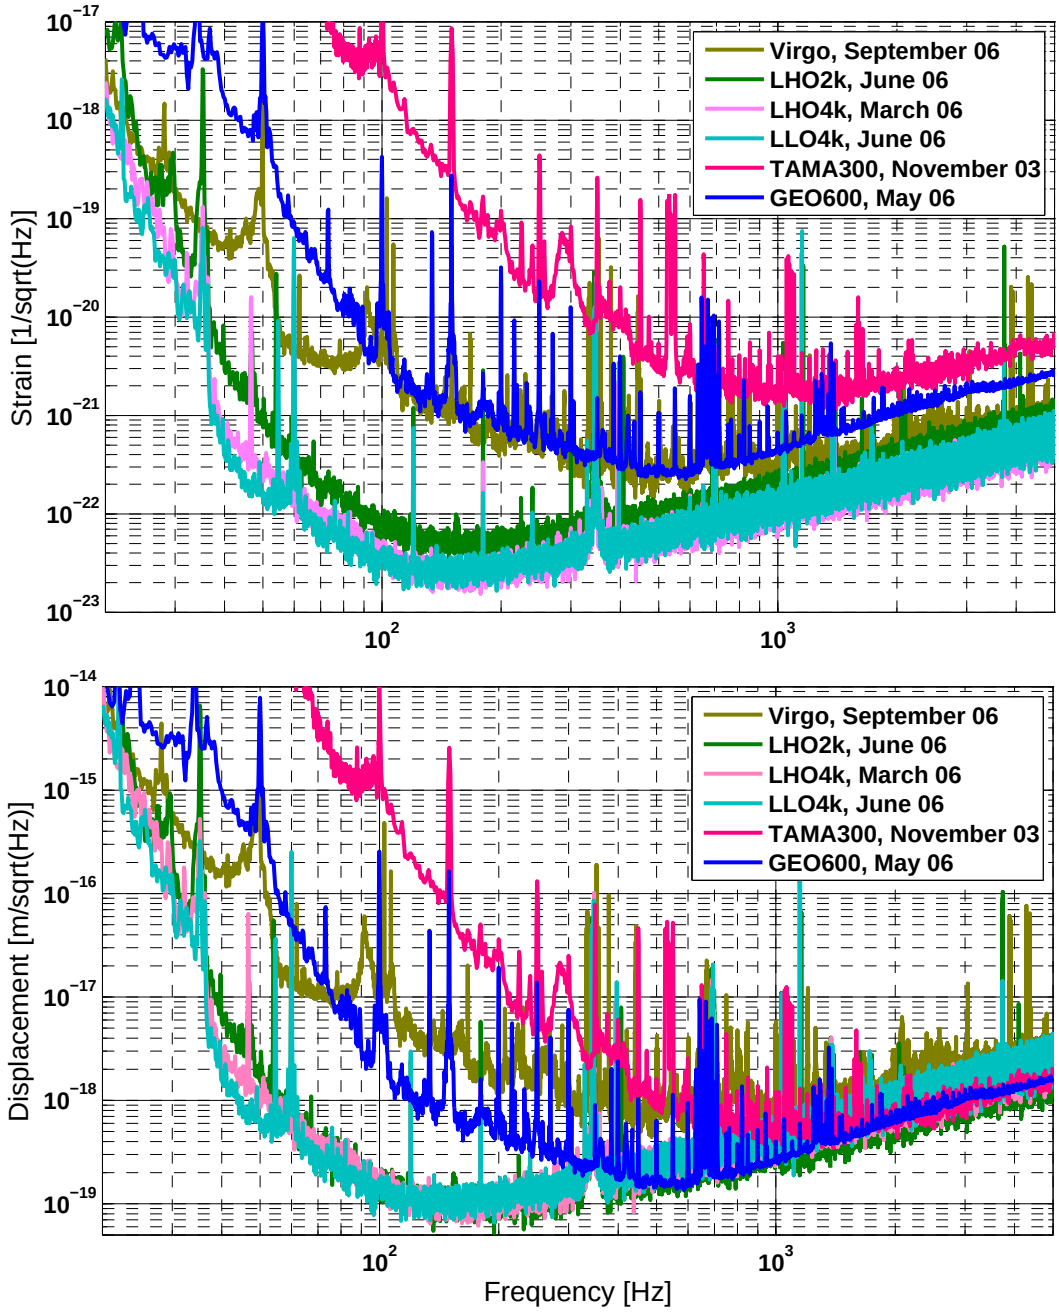

Figure 1.1.: Overview of the achieved sensitivities of the 6 large-scale laser-interferometric gravitational wave detectors. The upper subplot shows the strain sensitivities, while the lower plot depicts the corresponding displacement sensitivities, which are the sensitivities of the detectors to an absolute length change of the interferometer arms.

Today the direct search for gravitational waves concentrates on using large-scale laser interferometers, such as GEO 600. These extremely sensitive machines are based on kilometer long Michelson interferometers. Detailed descriptions of the measuring principle can be found [Rowan/Hough], [Saulson] and [Blair]. The currently operating generation of laser-interferometric GW detectors achieves sensitivities of the order $10^{-22}/\sqrt{\text{Hz}}$ and therefore it seems only to be a question of time until the first gravitational wave signal will be detected.

1.2. A world wide network of large-scale gravitational wave detectors

Currently six large-scale gravitational wave detectors are in operation. In the USA there are the three LIGO detectors [Waldman06]: One 4 km interferometer in Livingston (LLO), Louisiana and two detectors with arm lengths of 2 and 4 km in Hanford (LHO), Washington. An Italian-French Collaboration operates the 3 km long VIRGO detector [Acernese06]. The 300 m long Japananese detector TAMA300 is located in Tokio [Ando05]. Finally there is the 600 m long GEO 600 detector near Hannover, operated by a team of British and German scientists [Hild06c]. The sensitivities achieved by the detectors are shown in Figure 1.1.

Within the frame of LIGO Scientific Collaboration (LSC) GEO 600 and the three LIGO detectors have taken a huge amount of coincident data. These periods of simultaneous data taking are called *science runs*. The data of these 4 detectors are searched for gravitational wave signals by scientists of the LSC. Probably soon a memorandum of understanding (MOU) will be signed between the LSC and VIRGO collaboration. Then people will be able to analyze simultaneous data streams from the five most sensitive gravitational wave detectors built so far.

1.3. A brief description of the GE0 600 GW detector

The GEO 600 gravitational wave detector is a very complicated device, consisting of about 300 partly coupled control loops. The core of the detector comprises of about 30 optics, suspended by multi-stage vibration isolations and enclosed by an ultra high

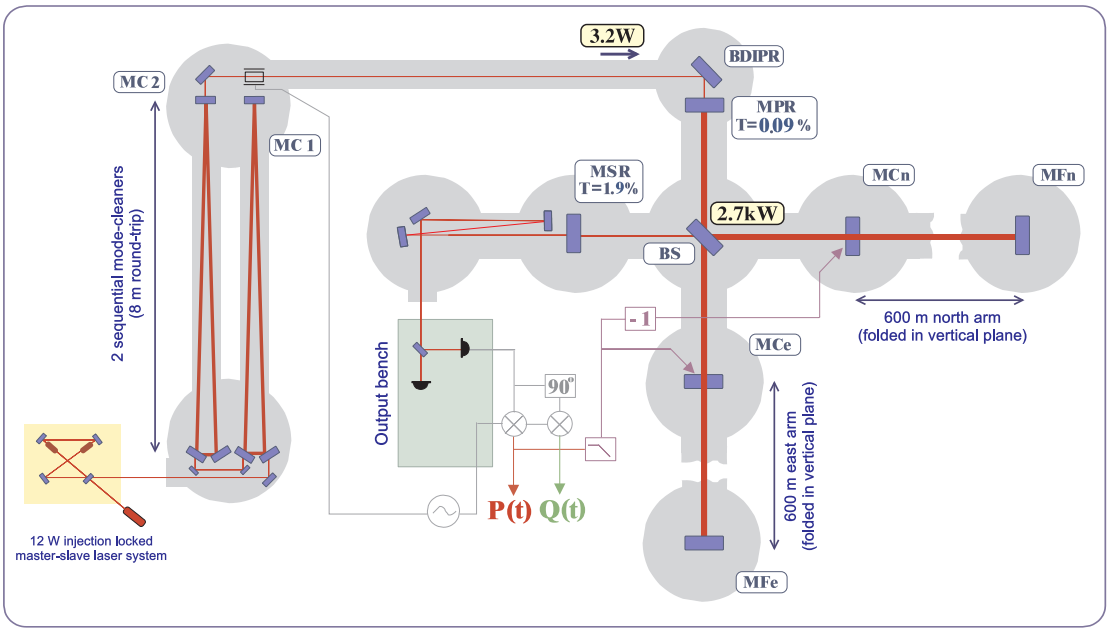

Figure 1.2.: The light of a 12 Watt master-slave laser system is injected into two sequential mode-cleaners, MC1 and MC2 of 8 and 8.1 meters round-trip length, and a finesse of 2700 and 1700, respectively. The stabilized and filtered light enters the main Michelson interferometer through the power-recycling mirror (MPR). The main interferometer consists of five optical components: the beam splitter (BS), the two end mirrors (MCe and MCn) and the two folding mirrors (MFe and MFn). In contrast to most of the other large scale interferometric gravitational-wave detectors GEO600 does not use Fabry-Perot resonators in the arms, but instead the simplest case of an optical delay line including one folding mirror per arm. The light containing potential gravitational-wave information leaves the Michelson interferometer at the antisymmetric port and the signal gets enhanced by usage of a second recycling mirror, the signal recycling mirror (MSR). The light passing the signal-recycling mirror is detected at the output bench, and the gravitational-wave information is derived from a RF-heterodyne method.

vacuum system of a volume of about 400 cubic meters. A simplified optical layout of the detector is shown in Figure 1.2. The alignment systems of GEO 600 automatically controls 38 angular degrees of freedom. At a frequency of 450 Hz a displacement sensitivity of $1.5 \cdot 10^{-19}\mathrm{m}/\sqrt{\mathrm{Hz}}$ and a strain sensitivity of better than $3 \cdot 10^{-22}/\sqrt{\mathrm{Hz}}$ are achieved. Figure 1.3 shows the improvement of the sensitivity from GEO 600 over the last few years. About 100 gigabytes of science data are collected and processed per day.

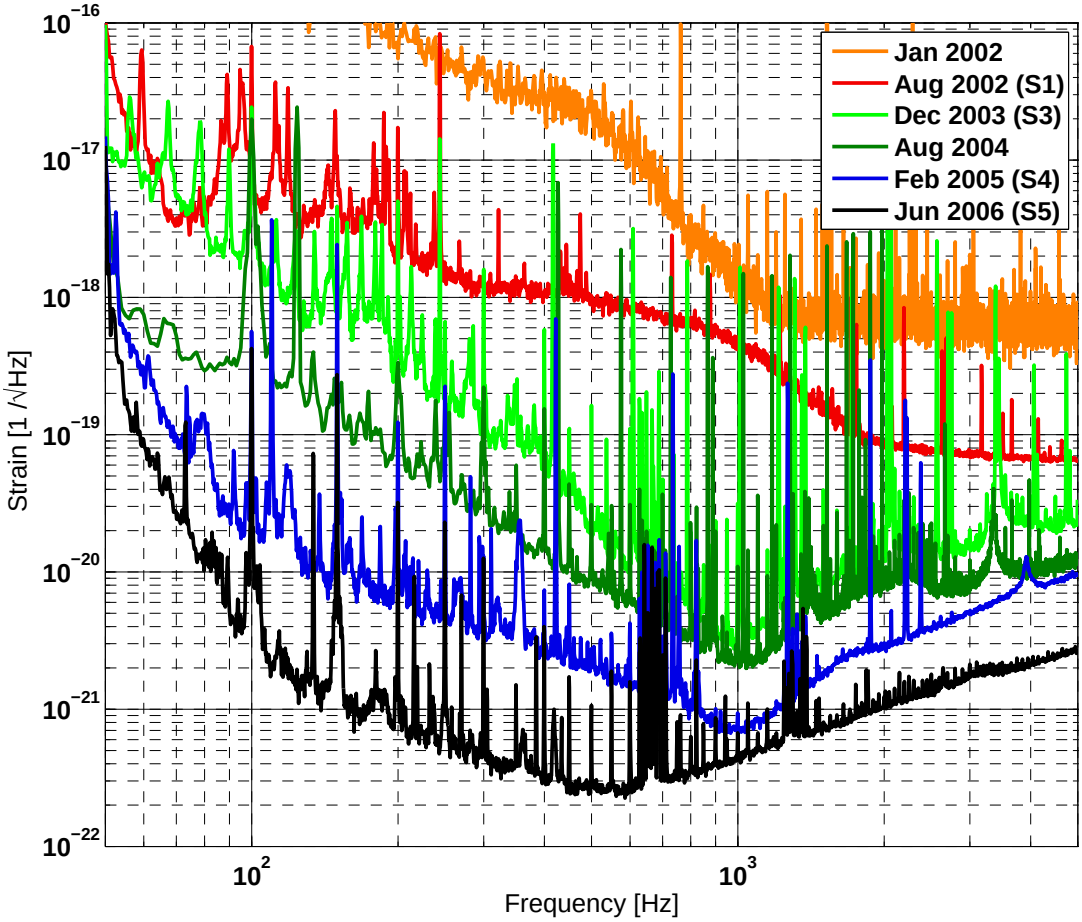

Figure 1.3.: Sensitivity improvement of GEO 600 over the last few years.

The preceding gives an impression of the complexity of GEO 600. A full description of GEO 600 would not fit into the frame of a single dissertation. Therefore the curious reader is asked to refer to the latest papers giving the status of GEO 600 [Willke04], [Grote05], [Lück06], [Hild06c] for a quick overview. More detailed descriptions of the most important subsystems of the GEO 600 detector can be found in the following five

dissertations: [Freise03], [Grote03], [Hewitson04a], [Gossler04] and [Smith06].

Chapter 2.

Demonstration and comparison of tuned and detuned signal recycling in a large-scale gravitational wave detector

2.1. Introduction

Placing a mirror (MSR in Figure 2.4) in the dark port of an interferometric gravitational wave detector can significantly increase its sensitivity in a certain frequency band. This technique, called signal recycling (SR), was proposed by Brian Meers [Meers] and first demonstrated in a table top experiment by Strain and Meers [Strain91]. The combination of power and signal recycling, called dual recycling, was realized 1998 in a fully suspended interferometer at the Garching prototype [Heinzel98]. The GEO 600 interferometer is the first and so far only large scale gravitational wave detector using signal recycling. However, nearly all projects plan to use signal recycling in their next generation of instruments, like for example Advanced LIGO [Giaime] or the Japanese LCGT project [Kuroda06].

The use of signal recycling allows a frequency dependent shaping of the detector response function, which is defined as the transfer function from to differential arm length changes to the output of the detector. The bandwidth of the signal recycling resonance is determined by the reflectivity of the signal recycling mirror. A high reflectivity gives a large increase of the response function in a narrow band (narrow-band operation), while a moderate reflectivity yields a medium improvement of the response function over a broader frequency range (broadband operation). Figure 2.1 shows exemplary the

shot noise limit of the GEO 600 detector for three different transmittances of the signal recycling mirror.

The frequency of maximum response, also called tuning frequency, is determined by the length of the signal recycling cavity and can be chosen by a change of the microscopic position of the signal recycling mirror. In this thesis we will refer to *tuned* signal recycling as the case when one of the resonances of the signal recycling cavity is centered at the frequency of the carrier, in contrast to *detuned* signal recycling where the signal recycling resonance is shifted to a frequency different from the carrier. The difference between the frequency of the signal recycling resonance and the carrier frequency is referred to as the detuning frequency. In Figure 2.2 the shot noise limit of GEO 600 is shown for various tuning frequencies.

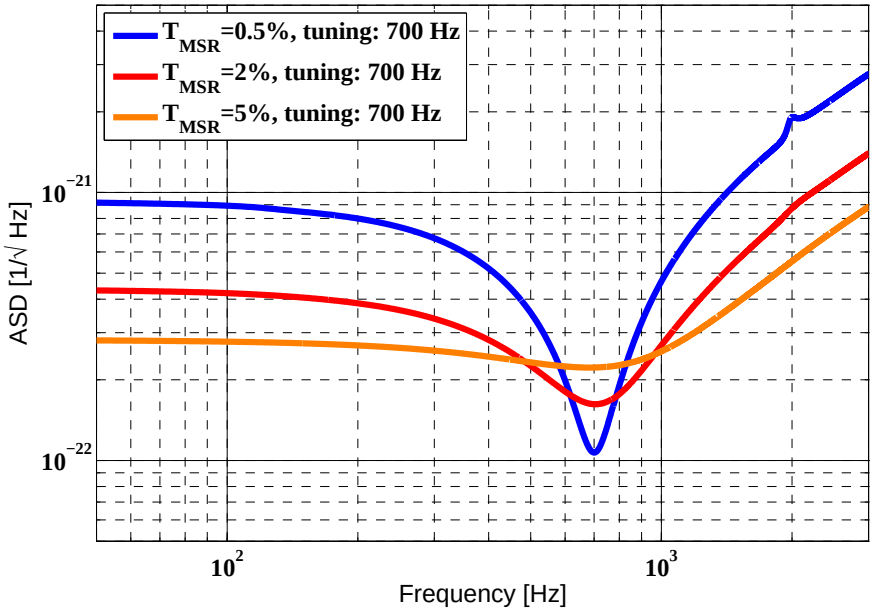

Figure 2.1.: Shot noise limit of GEO 600 for different transmittances of the signal recycling mirror.

Until recently, the GEO 600 detector has been operated with detuned signal recycling in order to shift the peak sensitivity to frequencies between 350 and 1000 Hz [Hild06c]. This was done to optimize the science contribution of the GEO 600 detector to the LSC (LIGO Scientific Collaboration) detector network. However, the use of detuned signal recycling brings some disadvantages. In contrast to a Michelson interferometer having

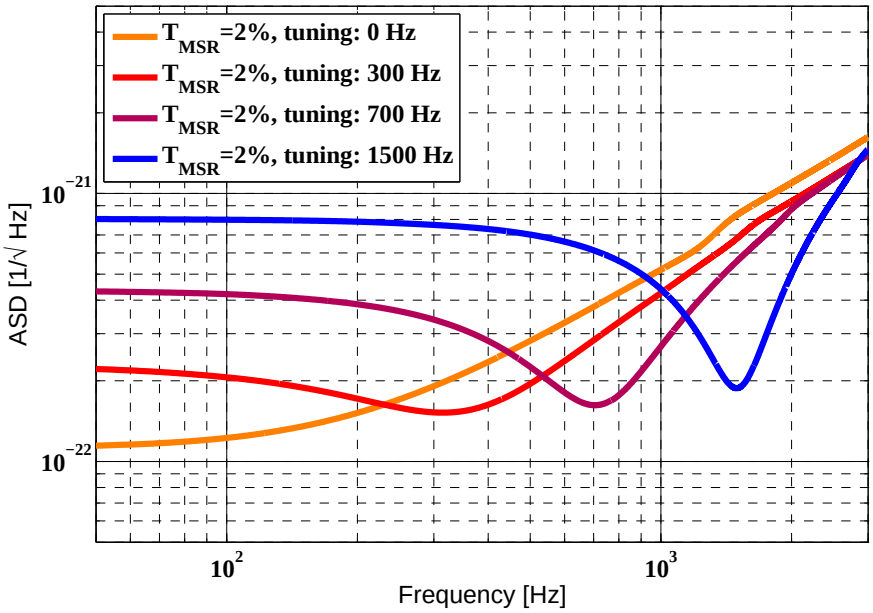

Figure 2.2.: Shot noise limit of GEO 600 for different tunings of the signal recycling cavity.

only power recycling, the signal recycling cavity changes amplitude and phase of almost any light component present at the dark port, for instance the gravitational wave signal sidebands or the radio frequency (RF) sidebands used for detector control.

Figure 2.3 gives a qualitative overview of the light fields in the signal recycling cavity for tuned and detuned operation. In the tuned case, the differential arm length information can be derived completely from demodulation of the photo current detected at the dark port in the in-phase quadrature (in the following referred to as P quadrature). In the detuned signal recycling case this information is in a frequency-dependent way spread over both quadratures, P and Q (out-of-phase quadrature) and both have to be analyzed to obtain the best signal-to-shotnoise ratio. A detailed description of this effect and its consequences for the calibration of the instrument can be found in [Hewitson04] and [Hewitson05].

Furthermore, the asymmetry of the RF control sidebands at the dark port causes a strong amplitude modulation of the light on the main photo detector, containing no gravitational wave signal. However, this strong RF amplitude modulation was found to

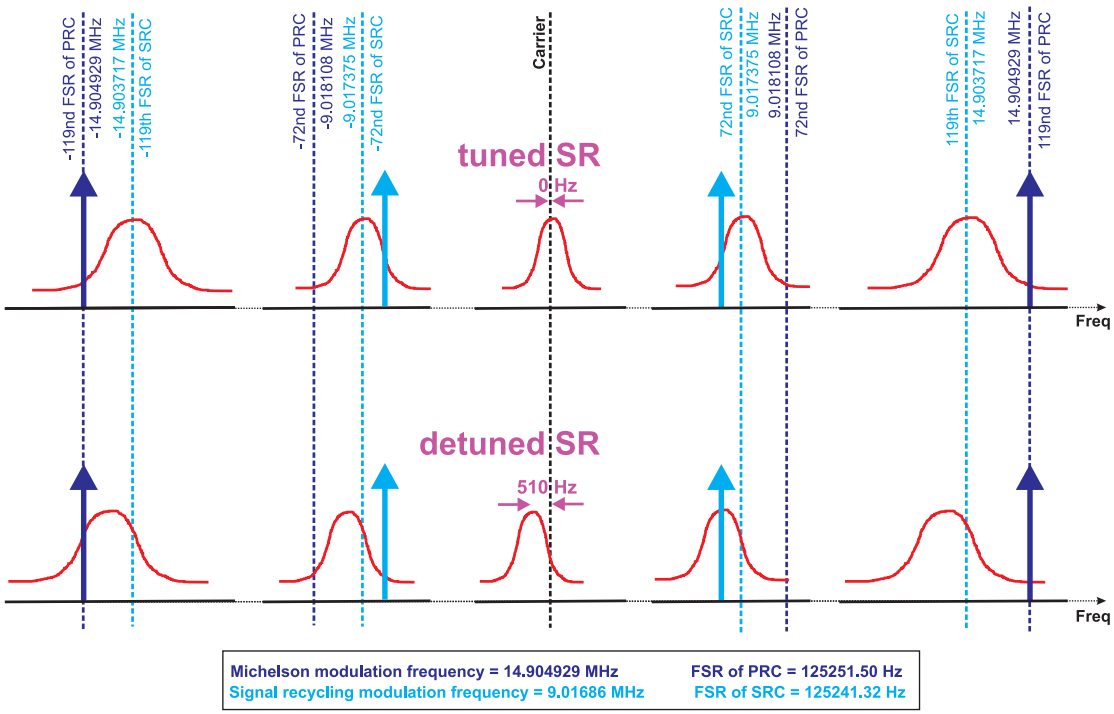

Figure 2.3.: Overview of the resonance conditions for the carrier (black dashed line), Michelson control sidebands (dark blue arrows) and signal recycling control sidebands (light blue arrows) inside the signal recycling cavity. The resonance conditions are shown for tuned and detuned (510 Hz) signal recycling in the upper and lower subplot, respectively. The comb of equidistant resonances of the signal recycling cavity (SRC) is indicated by the red Airy peaks. Due to the Schnupp asymmetry the shape of the resonance gets wider for frequencies far off the carrier. The gravitational wave signal is located around the carrier. The frequency of the Michelson modulation was chosen to be close to resonant in the 119th free spectral range (FSR) of the power recycling cavity (PRC). In detuned signal recycling the two Michelson sidebands see different resonance conditions inside the SRC: The lower sideband is nearly resonant, while the upper one is nearly off resonance. When going from detuned to tuned signal recycling using the method described in this thesis the frequency of all sidebands stays the same, but the comb of signal recycling resonances (red curves) is shifted by 510 Hz towards higher frequencies. In the tuned case the sidebands used for the Michelson control are balanced as well as the ones used for signal recycling control.

be a potential source of saturation of the main photo detector [Grote].[1]

It was also observed in the detuned case that various noise sources, for instance oscillator phase noise and laser power noise, couple to the gravitational wave channel in a more complex way than one would expect from simple models. A suspected cause for this are the imbalances of the sidebands in the interferometer and at the dark port.

An illustrative example of the complexity of the noise couplings in an interferometer with detuned signal recycling can be found found on the CD-ROM (Multimedia Appendix) at the end of this thesis. The time lapse video shows the evolution of the sensitivity of GEO 600 during an experiment in which a single parameter of the detector, namely the radius of curvature of MFE, was changed by about 1 %. The black trace indicates a reference sensitivity, while the blue trace represents the actual sensitivity.

The facts given above made it highly desirable for us to directly compare tuned and detuned signal recycling operation in GEO 600. In section 2.2 we describe the GEO control scheme implemented for detuned signal recycling, while in section 2.3 we introduce a new technique, which allows the operation of tuned signal recycling. In Sections 2.4-2.6 important aspects of tuned and detuned signal recycling (510 Hz) are compared: Section 2.4 shows measurements of the optical gain, in Section 2.5 a comparison of the size of the amplitude modulation at the main photodiode is given. In section 2.6 exemplary measurements of some noise coupling transfer functions to the gravitational wave channel are shown. Finally the sensitivity is compared for detuned and tuned signal recycling in Section 2.7 as well as for positive and negative detunings in Section 2.8.

2.2. Control scheme for signal recycling in GEO 600

The signal used to control the microscopic position of the signal recycling mirror (MSR) is derived from a radio frequency modulation/demodulation technique. Figure 2.4 shows a simplified diagram of the control of two degrees of freedom, the Michelson differential arm length and the length of the signal recycling cavity in blue and green respectively.

[1] At the LIGO detectors an additional feedback loop (called *I-servo*) is used which reduces the part of the RF signal that is not suppressed by the interferometer control loop. This is done by adding an appropriate RF-signal, essentially a sine wave at the modulation frequency, with correct amplitude and phase, directly to the PD-resonant circuit, thereby cancelling the RF-signal (at this frequency) in one quadrature [Sigg04].

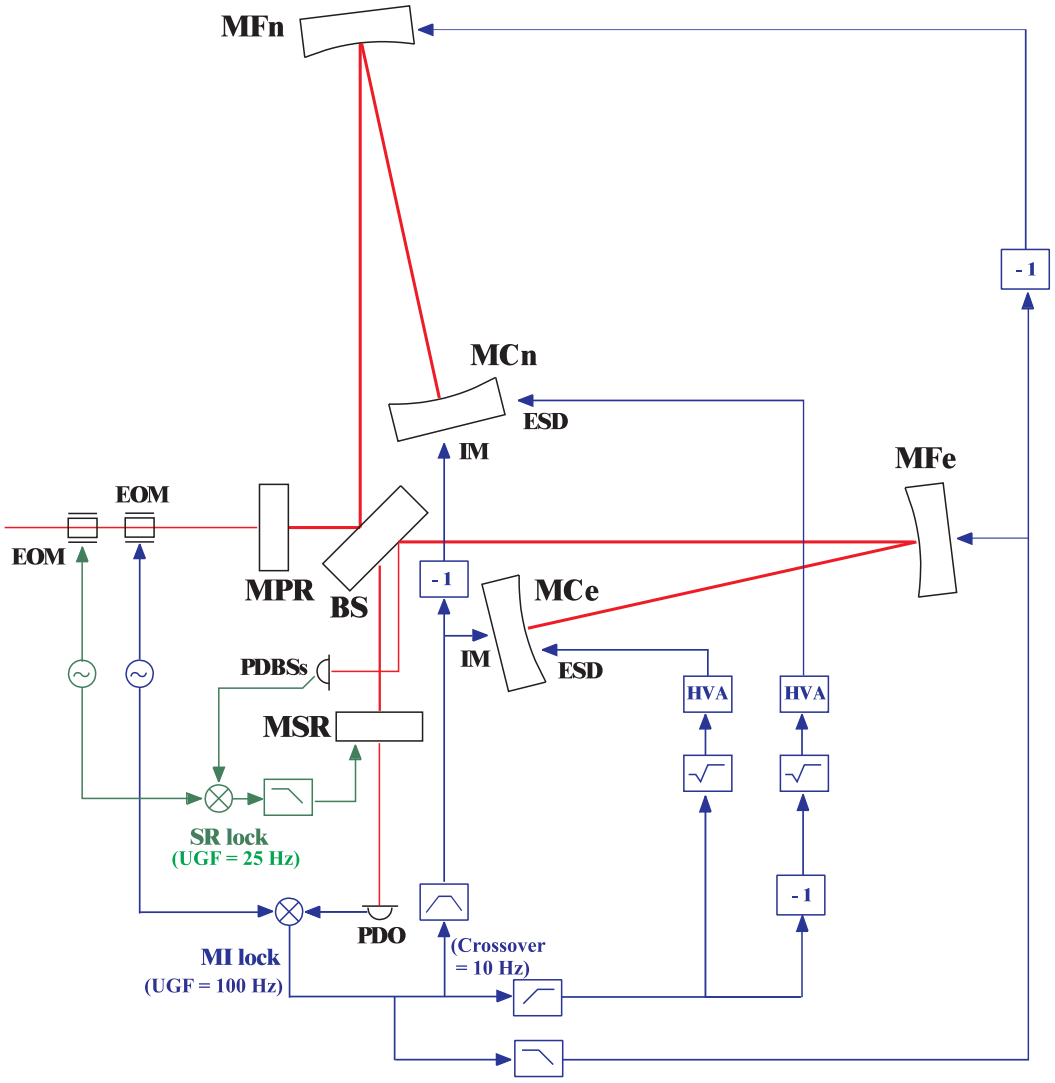

Figure 2.4.: Simplified control scheme for two longitudinal degrees of freedom of GEO 600. Shown are the Michelson differential loop and the signal recycling loop in blue and green, respectively. The control signals used for lock acquisition are not shown in the diagram.

Two sets of phase modulation sidebands are created in front of the power recycling mirror (MPR in Figure 2.4). Due to a asymmetry in interferometer arms of several cm (Schnupp asymmetry), a fraction of these sidebands leaves the interferometer at the dark port [Schnupp]. The error signal for controlling the differential arm length of the Michelson interferometer is derived from the photodiode PDO placed at the dark port of the interferometer. For the sensing of the signal recycling loop a pick-off beam from one of the interferometer arms is used (photodiode PDBSs, sensing the beam reflected at the beam splitter AR coated side).

For various reasons (described in detail in [Grote03]) it was so far not possible to realize lock acquisition for the tuned configuration of GEO 600. Therefore a procedure was developed to acquire lock at a high detuning (a few kHz) and then gradually tune the signal recycling cavity to lower frequencies. This so-called tuning process is done by changing the radio frequency of the signal recycling modulation and other relevant parameters [Grote05].

Figure 2.5 shows the error signal of the signal recycling loop for different modulation frequencies versus the position of the signal recycling mirror. These simulations were done using the FINESSE software [Freise04]. In the case of detuned signal recycling, the error signal structure shows three zero crossings. The two outer ones are referred to as the lower and upper sidebands corresponding to a negative or positive detuning, while the zero crossing in the center corresponds to the tuned case. So far the zero crossing corresponding to the upper sideband was chosen to be the nominal operating point. If the modulation frequency is increased, the zero crossings from the lower and upper signal recycling sideband are shifted towards the zero crossing corresponding to tuned signal recycling, i.e. the whole error signal structure gets squeezed, but keeps roughly its shape. As the signal recycling mirror is locked to the position at which the upper sideband crosses zero, the position of the mirror is shifted corresponding to the change of the modulation frequency of the SR control sideband. This tuning technique works for tunings as low as about 300 Hz.

As indicated in the second subplot of Figure 2.5, for tunings below 300 Hz the error signal structure is not only squeezed, but also changes its shape significantly. The slopes of the error signals of the upper and lower sideband become asymmetric around their zero crossings. For the extreme condition of a modulation frequency corresponding to the tuned case the zero crossings of the sidebands vanish completely. For frequencies

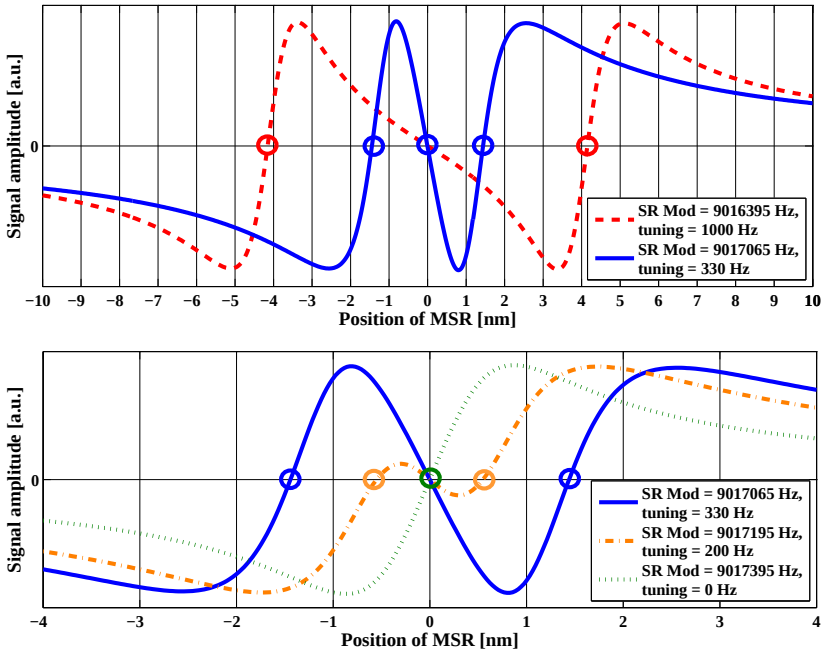

Figure 2.5.: Signal recycling error signals derived from an RF modulation demodulation technique versus microscopic position of the signal recycling mirror. The error signal is plotted for various modulation frequencies corresponding to detunings of the signal recycling cavity between 1000 Hz and 0 Hz. By increasing the modulation frequency the structure gets more and more narrow.

corresponding to tunings between 300 and 0 Hz in the presence of electronic or seismic noise, the error signals cannot be used for a stable control of the signal recycling mirror. Their range with a constant slope is too small to hold the mirror in a defined position, given that the control bandwidth of the signal recycling loop is limited. Therefore reaching the tuned case in small steps seems not a promising technique here.

2.3. A new method for locking tuned signal recycling

One possible way to reach the tuned case is to start from the lowest stable tuning, then make the microscopic position of the signal recycling mirror 'jump' over the region where the control signals are not valid, and 'catch' it again at the tuned state, where reasonable control signals can be derived. This can be done without changing the signal recycling modulation frequency by jumping from the zero crossing corresponding to the upper sideband to the zero crossing corresponding to the tuned case.

We realized this jumping by pushing the signal recycling mirror in the direction corresponding to a smaller detuning frequency and stopping it near the zero crossing of the tuned case. In order to not disturb the other control loops, for example the loop controlling the differential arm length of the Michelson interferometer, the signal recycling mirror has to be pushed over the region of non-valid error signals quickly.

In detail the procedure works as follows: We start from a modulation frequency corresponding to a tuning of about 350 Hz where the signal recycling mirror is locked at the position corresponding to the zero crossing of the error signal around the upper sideband. Then we switch off the signal recycling control loop to be able to push the signal recycling mirror away from its operating point. At the same time we start pushing the signal recycling mirror as hard as the coil-magnet actuators allow. After 4 milliseconds of pushing, the mirror has covered half the distance between the zero crossing of the upper sideband and the one from tuned case which is in this case a distance of 0.7 nm. Then the sign of the force applied to mirror is inverted to decelerate the mirror in 4 milliseconds from maximum speed to a velocity near zero when the mirror finally reaches the tuned position. After these 8 milliseconds the signal recycling feedback loop is closed again, but with opposite polarity, to account for the different sign of the slope around the zero crossing of tuned signal recycling.[2] The duration of this procedure is short

[2] Another possibility would be to change the modulation frequency while the mirror is being pushed,

enough, to not significantly disturb other control loops.

Using this technique it was also possible to jump twice the distance (about 3 nm) with the signal recycling mirror, and thereby go from the zero crossing of the upper sideband to that of the lower sideband, which turns out to be an equally stable operating point.

2.3.1. Simulation of the control parameters for tuned signal recycling

When jumping from detuned to tuned signal recycling a few control parameters need to be adjusted to account for the different operating point of the signal recycling mirror. The gain of the signal recycling loop needs to be adjusted for the different slope of the error signal. Furthermore in the case of tuned signal recycling the pole of the signal recycling cavity for carrier light is shifted towards lower frequencies, thus all signals generated from the dark port need to be adapted.

Figure 2.6 shows the results of simulations, done using the Finesse software [Freise04], for the longitudinal gains of the Michelson (upper set of subplots) and signal recycling (lower set of subplots) longitudinal error signals. In tuned signal recycling operation the Michelson error signal has at low frequencies about 9.5 dB and around the unity gain frequency (100 Hz) about 7.8 dB higher gain. Due to the shifted signal recycling cavity pole around the unity gain frequency about 30 degrees of phase are lost in tuned signal recycling operation compared to detuned operation. For tuned signal recycling operation this is compensated by switching an additional differentiator into the loop controlling the Michelson differential arm length and adjusting the overall gain of the loop.

The gain of the signal recycling error signal is about 2 dB higher in tuned case for all frequencies within the control bandwidth of 50 Hz. The phase is for all frequencies of interest 180 degrees different between tuned and detuned operation, i.e. the sign is swapped as indicated in Figure 2.5. A simple change of the overall loop gain of 2 dB is sufficient for stable operation of tuned signal recycling.

and then to keep the sign of the control loop.

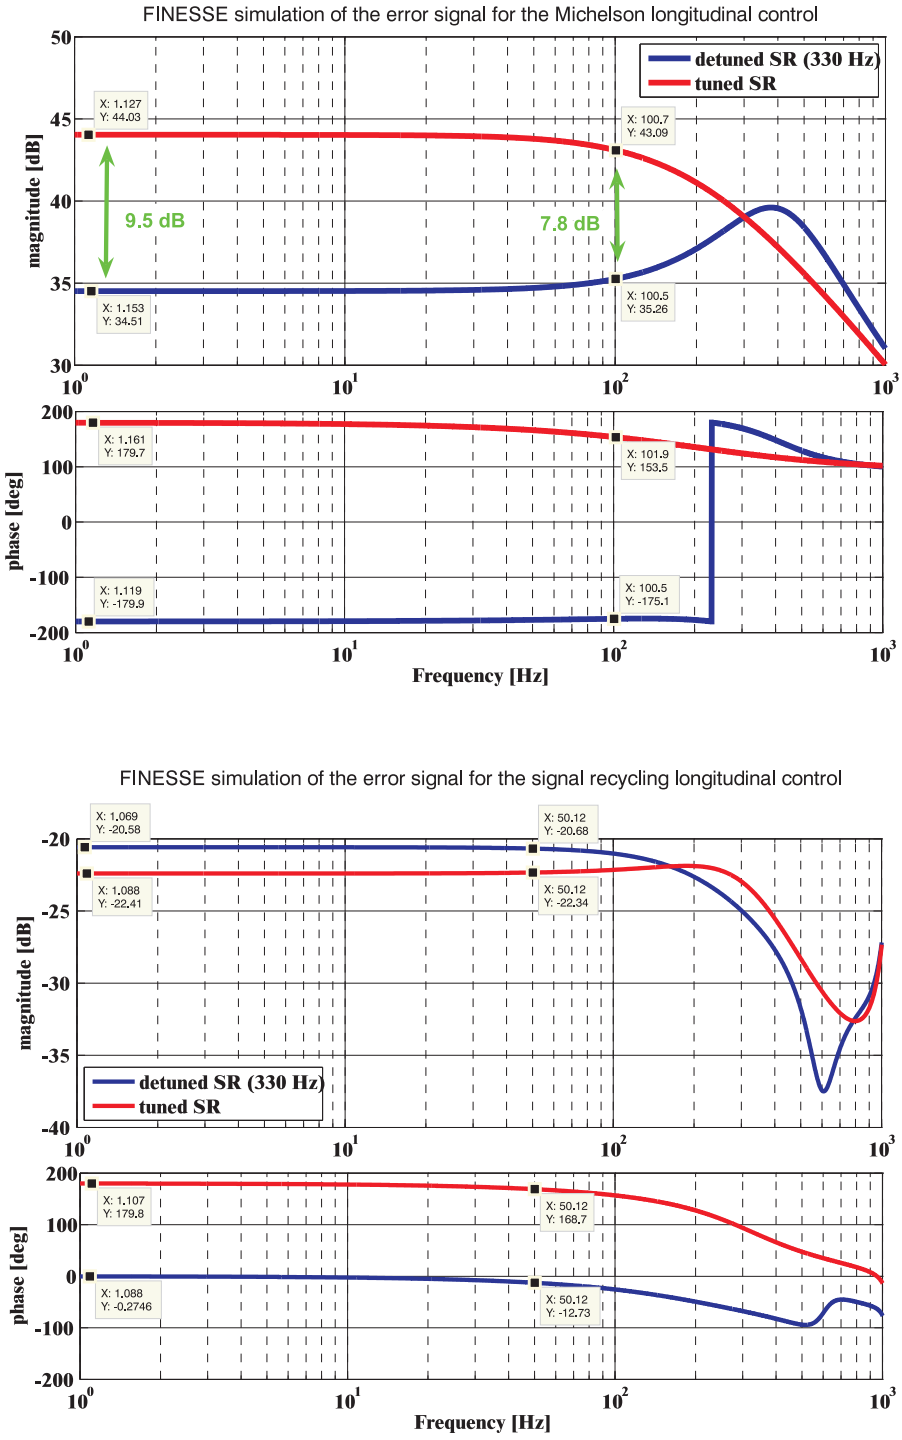

Figure 2.6.: Simulations of the error signal gain for the longitudinal control of the Michelson differential armlength (upper pair of plots) and the longitudinal control loop of the signal recycling mirror (lower pair of plots). The Michelson control loop has an unity gain frequency of about 100 Hz. The signal recycling control loop has unity gain frequencies of about 50 Hz in acquisition mode and 25 Hz in low-noise run mode.

2.3.2. Calibration of the actuator strength

In order to increase the accuracy of the jumping process it is desirable to calibrate the applied force to the signal recycling mirror in order to be able push the mirror as accurate as possible to its new operating point.

The idea of the calibration process is to use the known distance of the two positions of the signal recycling mirror for detuned and tuned operation. Starting from position P_{start} corresponding to detuned operation the mirror is pushed for Δt milliseconds with a force F_p towards the tuned operation point. Afterwards the mirror is decelerated by again Δt milliseconds, but with opposite force $-F_p$. At the end of this process the mirror reaches the position P_{end} and should, in absence of any disturbance, hang still again. We now vary Δt and F_p in order to stop the exactly at the position corresponding to tuned operating point. This position is in particular suitable as it corresponds to a zero crossing of the error signal.

Using the maximum force that can be driven by the coil driver electronics we get the following calibration of the actuator. The maximal acceleration a_{push} amounts to:

$$a_{\text{push}} = 1.53 \cdot 10^{-4} \frac{\text{m}}{\text{sec}^2} \tag{2.1}$$

2.4. Measurements of optical gain

The response function of the Michelson differential error signal to differential arm length fluctuations, the so called optical gain *G_opt*, is frequency dependent. In the case of detuned signal recycling the signal is also inherently spread between the two orthogonally demodulated signal quadratures, P and Q.

Figure 2.7 shows a simplified diagram of the loop controlling the differential arm length of the Michelson. The optical gain of the P quadrature can be described by the following expression

$$G_opt(P) = \frac{\text{EP-P} \cdot \text{P-dw}}{\text{FB} \cdot \text{FB-dw}} \cdot \frac{1}{\text{ESD}} \cdot \frac{1}{\text{HVA-dw}} \tag{2.2}$$

where EP-P (LSC_MID_EP-P_HP) is the error signal from the P quadrature recorded in the data acquisition system (DAQS) and FB (LSC_MID_FB-MCEMCN) is the record of

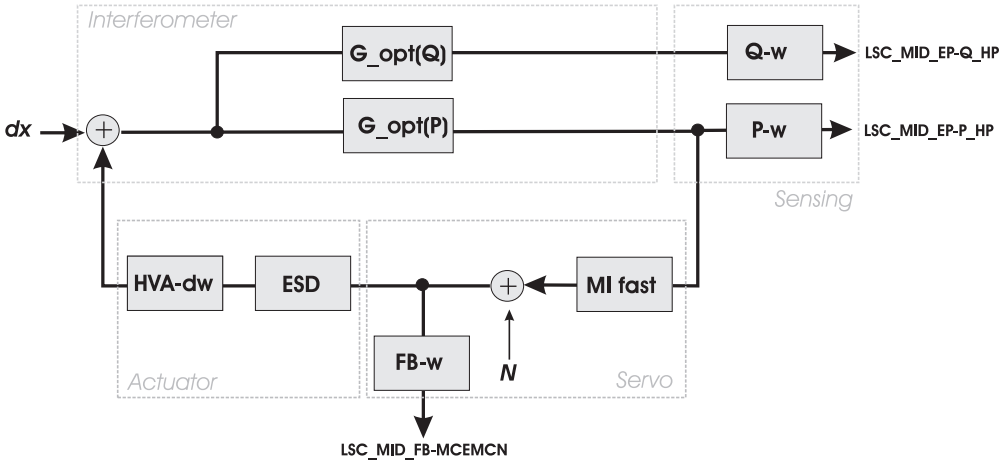

Figure 2.7.: A simplified diagram of the loop controlling the differential arm length of the Michelson. The diagram contains only components important for calibration and measuring the optical gains *G_opt* from the two orthogonal signal quadratures P and Q. Abbreviations used: MI fast = electronics of the servo, FB-w = whitening filter of feedback signal, ESD = high voltage amplifier (HVA) and electro static drives, HVA-dw = HVA dewhitening filter, P-w = whitening filter for P signal, P-w = whitening filter for Q signal, N = noise injected (for optical gain and loop transfer function measurements), dx = mirror displacement.

the feedback. ESD and HVA-dw represent the responses of the actuators, FB-dw is the response of the feedback whitening filter and P-dw is the inverse of the P error signal whitening filter.

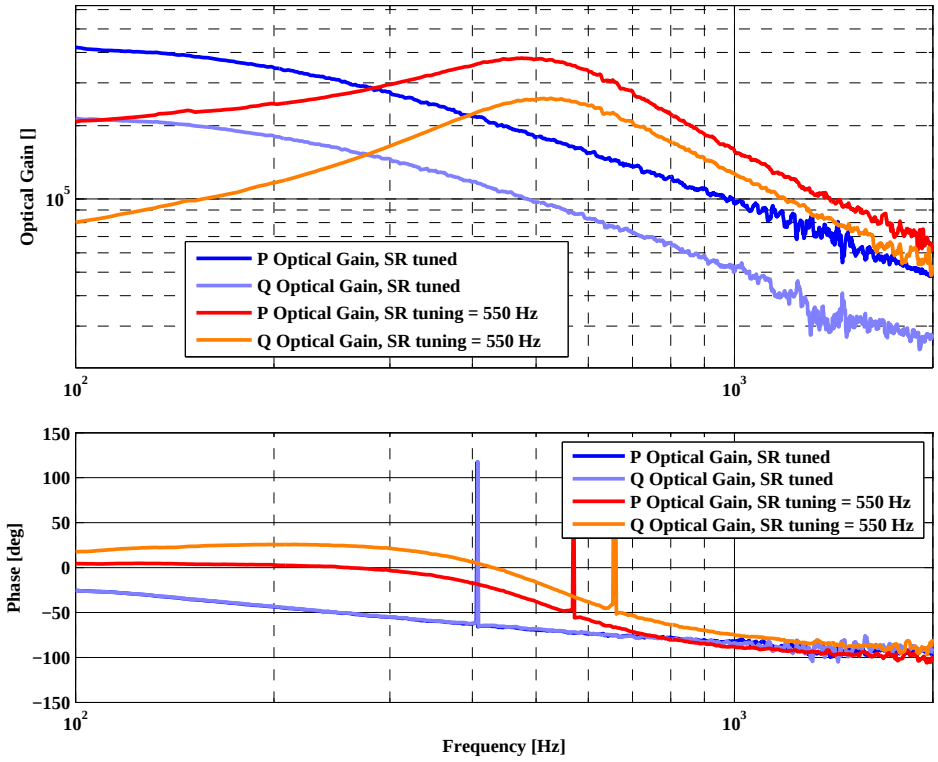

Figure 2.8.: Measurement of the optical gains for tuned and detuned signal recycling for the two orthogonal quadratures P and Q. For the tuned case the demodulation phase was not optimized. Therefore the the differential armlength signal is still clearly present in the optical gain of the Q-signal.

Figure 2.8 shows measurements of the optical gains for detuned and tuned signal recycling for the two quadratures. In the detuned case the optical gain shows a maximum at the frequency of the signal recycling detuning. The width of the maximum is given by the bandwidth of the signal recycling cavity, which is about 700 Hz for the currently installed signal recycling mirror with a transmission of about 2%. In the tuned case the maximum of the optical gain is centered around 0 Hz and the bandwidth of the response function is decreased to 350 Hz.

2.5. Reduction of the RF amplitude modulation

In detuned signal recycling the RF sidebands from the Schnupp modulation which originally represented a pure phase modulation get partly converted to amplitude modulation inside the signal recycling cavity. The light hitting the main photo diode at the dark port shows strong amplitude modulation at the frequency of the Michelson control sidebands, which are in case of GEO 600 at a frequency of about 15 MHz.

Some of our observations indicated that the strong amplitude modulation (in detuned SR) together with a high averaged photo current might cause saturation effects and nonlinearities in the photodiode. A detailed description of these problems can be found in [Grote]. However, it is important to mention that most of the spurious effects depend on the size of the RF amplitude modulation. Therefore it would be desirable to reduce the size of the amplitude modulation.

In the case of tuned signal recycling we have been able to reduce the rms of the signal in the Q quadrature, which is a good measure of the size of the amplitude modulation, by a factor of 12 compared to detuned operation.

2.6. Comparison of noise transfer functions for tuned and detuned signal recycling

Measurements of the transfer functions from various technical noise sources to the error signal of the differential arm length servo (and hence the gravitational wave channel) during detuned operation indicate complex couplings [Smith06]. Many of the measured transfer functions contain resonances and notch structures that could not be explained completely even by a complex frequency domain model of the interferometer [Malec06].

Asymmetry of the radio frequency sidebands in the detuned case was suspected to be the origin for some of the complexity observed in the noise couplings. To investigate this we performed measurements for four important technical noise sources for tuned and detuned signal recycling in order to check whether the couplings get simpler and perhaps less significant for tuned signal recycling.

- *Oscillator phase noise (OPN)*: The two sets of upper plots in Figure 2.9 show the measurements of the coupling from oscillator phase noise (of the modulation

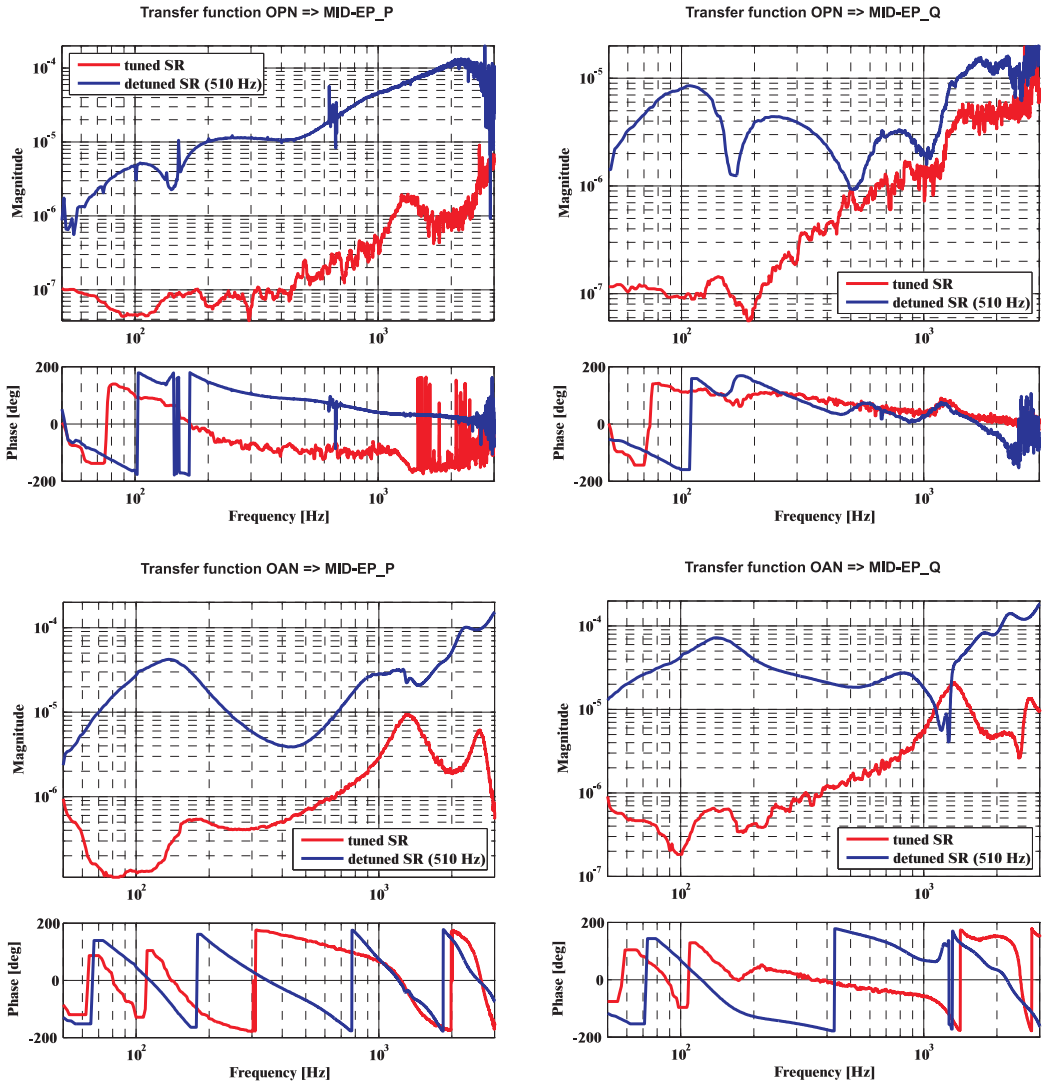

Figure 2.9.: Measurements of the transfer functions from oscillator phase noise (OPN) and oscillator amplitude noise (OAN) to the error signal of the differential arm length servo. The red trace represents tuned signal recycling, while blue indicates a detuning of 510 Hz. The magnitudes of transfer functions are normalized by magnitudes of the optical gains from Figure 2.8, which allows for a direct comparison of the transfer functions regarding the strain sensitivity of the detector.

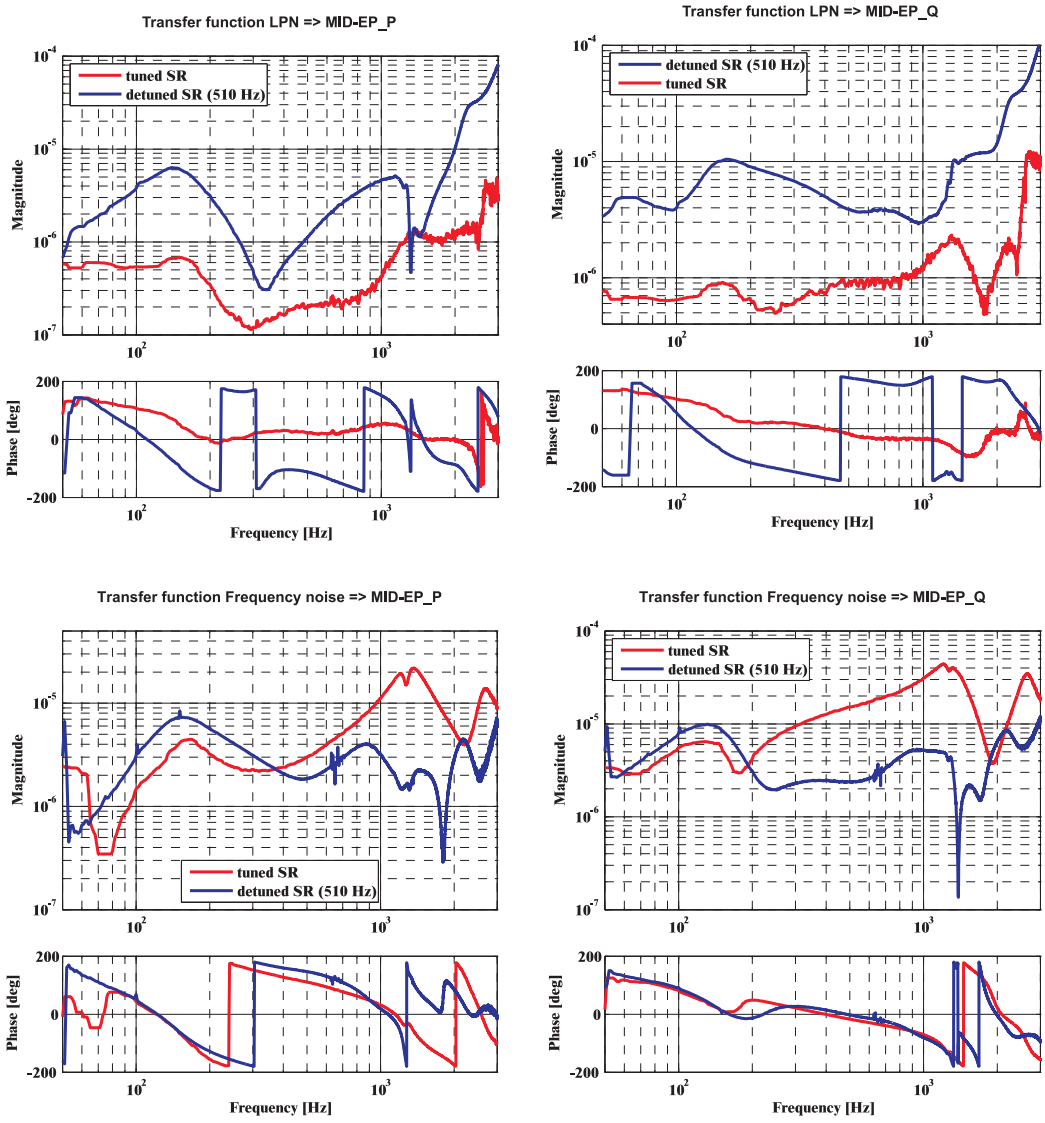

Figure 2.10.: Measurements of the transfer functions from laser frequency noise and laser power noise to the error signal of the differential arm length servo. The red trace represents tuned signal recycling, while blue indicates a detuning of 510 Hz. The magnitudes of transfer functions are normalized by magnitudes of the optical gains from Figure 2.8, which allows for a direct comparison of the transfer functions regarding the strain sensitivity of the detector.

used for creating control signals for the differential arm length of the Michelson interferometer and the local oscillator signal) to differential arm length. In the P quadrature the coupling in the tuned case is dramatically reduced over a wide frequency range by about two orders of magnitude. This can be explained by the reduction of the rms of the signal in the Q quadrature, (see section 2.5). The coupling of OPN to the Q quadrature is for frequencies below 500 Hz significantly decreased by up to a factor of 100 at 100 Hz. A detailed description of potential coupling mechanisms can be found in [Smith06].

- *Oscillator amplitude noise (OAN)*: The two sets of lower plots in Figure 2.9 show the measurements of the coupling from oscillator amplitude noise (of the modulatior used for creating control signals for the differential arm length of the Michelson interferometer) to differential arm length. The amplitude noise in the EOM path is eventually imparted on the carrier and control sidebands and couples to the detector output via asymmetries in the interferometer, as explained in [Malec06]. Again the coupling into both quadratures is strongly suppressed in tuned signal recycling due to more balanced sideband conditions at the dark-port.

- *Laser power noise (LPN)*: The two sets of upper plots in Figure 2.10 show the measurements of the coupling from laser power noise to differential arm length. The coupling to both quadratures is decreased on average by about a factor of 5 to 10 over the frequencies of interested. In addition at least in the P quadrature the structure of the coupling got slightly simpler. The strongly pronounced notch structure around 1.5 kHz vanishes for tuned signal recycling.

- *Laser frequency noise*: The two sets of lower plots in Figure 2.10 show the measurements of the coupling from laser frequency noise to differential arm length. At low frequencies we observed a moderate reduction of the coupling in the tuned case, while for higher frequencies the coupling is significantly increased. On the other hand the very distinct notch structures between 1 and 2 kHz seem to vanish completely.

2.7. Calibrated detector sensitivity for tuned signal recycling

Even though the performed investigations on comparing tuned and detuned signal recycling focus on the different propagation of optical sidebands through the interferometer,

the curious reader should get a chance to look at the GW sensitivity for tuned and detuned signal recycling, too.

The calibration of the detuned detector is done continuously using a time-domain method. A detailed description can be found in [Hewitson04] and [Hewitson05]. In order to calibrate the new case of tuned signal recycling operation we used a frequency domain method. With the aid of the closed loop transfer function ($CLTF$) the differential displacement dx (see Figure 2.7) can be expressed by:

$$dx = \frac{\text{EP-P} \cdot \text{P-dw}}{G_opt(P) \cdot CLTF}. \tag{2.3}$$

To convert the displacement dx to strain sensitivity we have to divide dx by the optical arm length of GEO 600:

$$HP = \frac{dx}{1200\,\text{m}} \tag{2.4}$$

The calibration of the orthogonal quadrature Q is done analogous.

Figure 2.11 shows the calibrated sensitivities of the two output quadrature signals. By going to tuned signal recycling no improvement in the calibrated P signal is observed. As shot noise is the main contribution to the noise level of GEO 600 for frequencies above 500 Hz, the sensitivity got worse in that frequency range when going to tuned signal recycling. At low frequencies we observed no increase in sensitivity because in that frequency range the shot noise is masked by the noise contributions of several technical noise sources.

For the sensitivity derived from the Q signal the situation is different: Between 90 and 200 Hz an improvement is achieved for tuned signal recycling operation. On the other hand, above 300 Hz the sensitivity is worse by about a factor of 2.

This is only a preliminary result as not much time during the science run could be spend to optimize the detector for tuned signal recycling operation yet.

2.8. Comparison of detuned signal recycling for upper and lower operating point

From the sensitivity point of view it might also be interesting to compare the sensitivities of the detector for locking the signal recycling mirror either at the position corresponding

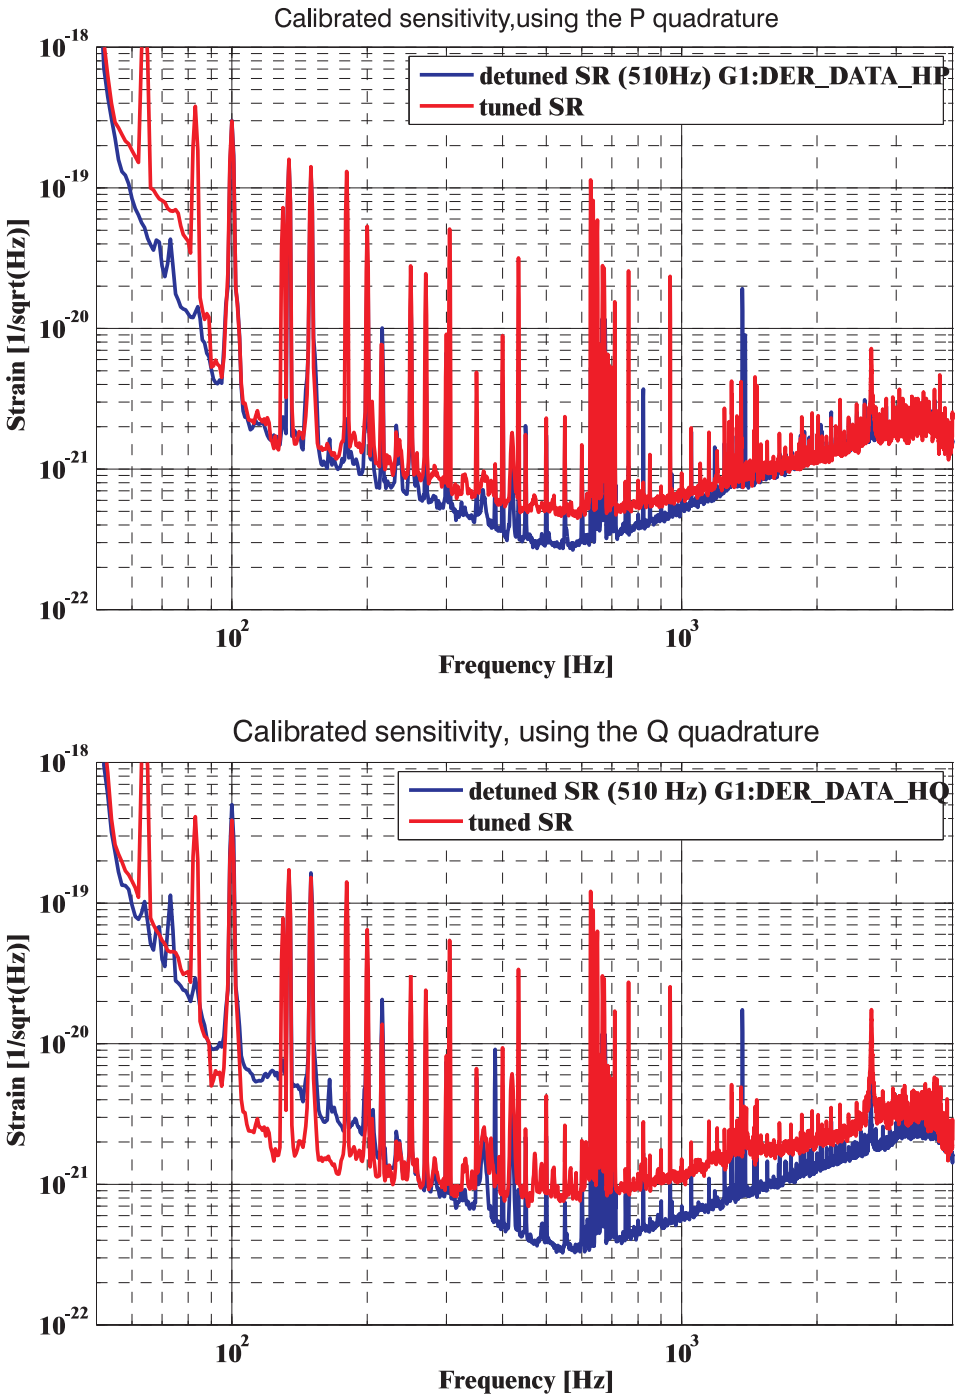

Figure 2.11.: Comparison of the sensitivity of GEO 600 for tuned and detuned signal recycling operation. The upper plot shows the calibration derived from using the in-phase signal (P), while the lower plot is derived from using the out-of-phase signal (Q).

to the lower sideband crossing or the position corresponding to the upper sideband crossing. In principle there should be no difference between the two cases: By going from the upper sideband lock to the lower sideband lock all the imbalances of the light fields in the dark-port are preserved. In the lower subplot of Figure 2.3 the resonance condition is plotted for a positive signal recycling detuning of 510 Hz. How does this picture change when going to the opposite detuning of -510 Hz. As the signal recycling mirror is locked in that case to the zero crossing of the lower signal recycling sideband, the comb of signal recycling resonances is shifted by 1020 Hz to the right, thus the -72nd signal recycling resonance is centered around lower signal recycling sideband. Consequently the complete picture in the lower plot of Figure 2.3 is just mirrored at the carrier frequency.

Light field	lower MI SB	lower SR SB	carrier	upper SR	sideband
SR tuning = +510 Hz	-702 Hz	+1020 Hz	+510 Hz	0 Hz	+1722 Hz
SR tuning = -510 Hz	-1722 Hz	0 Hz	-510 Hz	-1020 Hz	+702 Hz

Table 2.1.: A summary of the resonance condition of the important light fields at the dark-port for a positive and negative detuning of the signal recycling cavity. The given values indicate the distance of the light field from the center of the nearest resonance peak.

Table 2.1 gives an overview of the resonance condition of the light fields of interest inside the dual recycled interferometer. Provided that any kind of technical noise is impressed equally onto the lower and the upper sideband of each, MI and SR modulation, the detected signals at the dark-port, which orignate from the beat of the two sidebands with the carrier field, should be equivalent for positive and negative detuning. That is also the reason why all the gains of the control loops can stay the same for both cases and no adjustments of any control system is required.

Figure 2.12 shows a measurement of the sensitivity for a positive (blue trace) and a negative (red trace) detuning of the signal recycling cavity of 510 Hz. Apart from a few line features an astoundingly agreement is found.

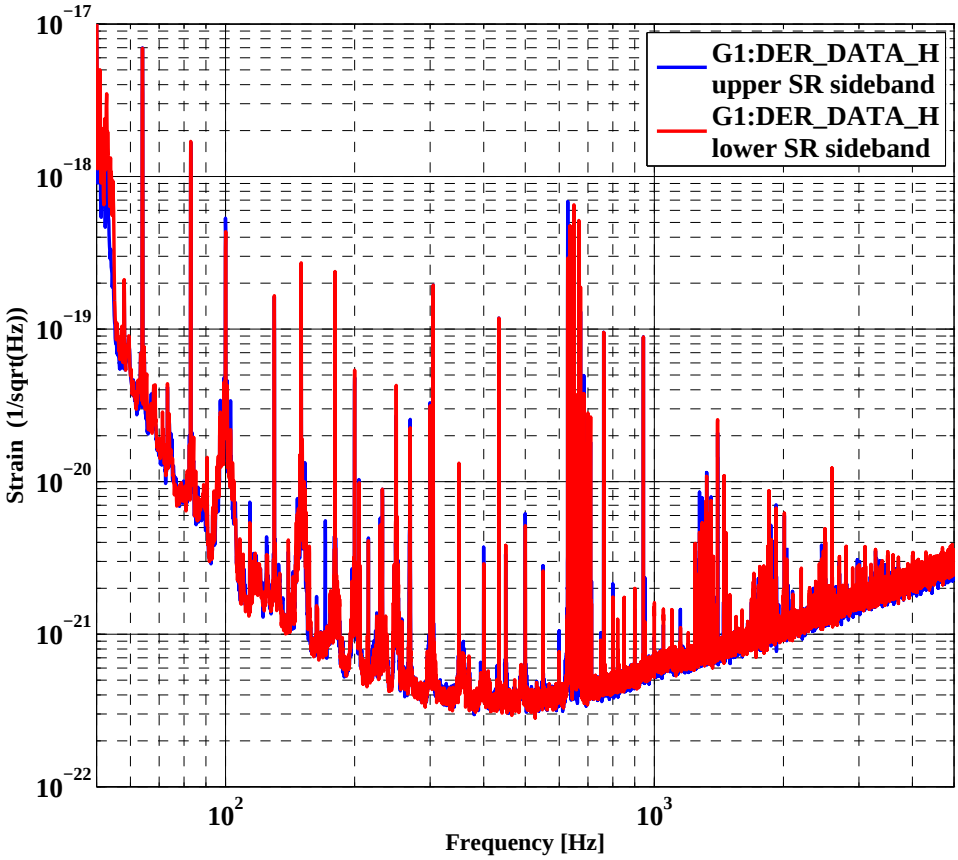

Figure 2.12.: Comparison of the sensitivity of GEO 600 for two different operating points of detuned signal recycling. The blue trace corresponds to a nominal tuning frequency of +510 Hz, while the red trace represents a negative detuning frequency of −510 Hz.

2.9. Summary

We developed and demonstrated a new technique for rapidly changing the signal recycled GEO 600 gravitational wave detector from the detuned to the tuned operating state. With this method, the signal recycling mirror is shifted accurately between two positions within milliseconds. This allowed for jumping with the signal recycling mirror from a position corresponding to a positive detuning of 510 Hz to a position corresponding to the tuned case and also from a positive detuning of 510 Hz to the corresponding negative detuning of −510 Hz. The method is generally applicable and only limited by the strength of the actuators used for longitudinal control of the signal recycling mirror.

A comparison of tuned and detuned (510 Hz) signal recycling was given. The measurements of the optical gain for the tuned case show that the maximum in the signal response is shifted to DC. In the tuned case the rms of the signal in the Q quadrature is reduced by a factor of 12. The measurement of various noise couplings to the gravitational wave channels were performed for tuned and detuned signal recycling. The transfer functions are shown to be significantly different. For most of the noise sources (except laser frequency noise) we found the magnitude of couplings being strongly decreased in tuned signal recycling. Furthermore in the tuned case the complexity of transfer functions seems to be, at least for some couplings, slightly reduced.

In the future we will try to improve the simulations of the noise couplings in order to reproduce the measured results. A deeper understanding of the complex noise couplings, originating from imbalanced sidebands, is not only important for commissioning of the current interferometers, but also essential for the design of next generation gravitational wave detectors.

Chapter 3.

Scattered light problems in interferometric gravitational wave detectors

3.1. Introduction

Stray light problems have been encountered during the commissioning of all currently operating large scale gravitational wave detectors. The underlying principle of all these interferometers is to make an extremely sensitive phase measurement. Therefore even tiny stray light contributions with a different or varying phase will harm the measurement. The currently achieved sensitivity of GEO 600 can already be spoiled by stray light of the order 10^{-20} W (!).[1]

A well-known manifestation of stray light noise is the so called *scattering shoulder* which has been observed in many detectors independent of their topology, as shown in Figure 3.1. A shoulder was observed in the VIRGO and LIGO instruments, which are power recycled Michelson interferometers with arm cavities, as well as in the folded arm GEO 600 configuration with and without signal recycling.

Stray light problems have already been observed in former interferometers like the 30 m-prototype in Garching. However, there the scattering was caused by the core optics of

[1] GEO 600 currently reaches a displacement sensitivity of $3 \cdot 10^{-19}\mathrm{m}/\sqrt{\mathrm{Hz}}$ for an end mirror (MCe, MCn), which corresponds to an accuracy of the phase readout of, $\phi = 4\pi \cdot 3 \cdot 10^{-19}\mathrm{m}/\sqrt{\mathrm{Hz}}/\lambda \approx 3.5 \cdot 10^{-12}\mathrm{rad}/\sqrt{\mathrm{Hz}}$. If we now assume the carrier light inside the Michelson interferometer to be represented by E_C with the amplitude A_C, we can calculate which minimal amplitude, A_S, of a potential stray light field E_S is required in order to shift the phase of the total field $E_T = E_C + E_S$ by ϕ. Assuming E_C and E_S to be 90 degrees out of phase we get $A_S = A_C \cdot tan(\phi)$. With the actual intra cavity power $A_C = 2.7\,\mathrm{kW}$ we get minimal stray light power of $A_S^2 \approx 3 \cdot 10^{-20}$ W.

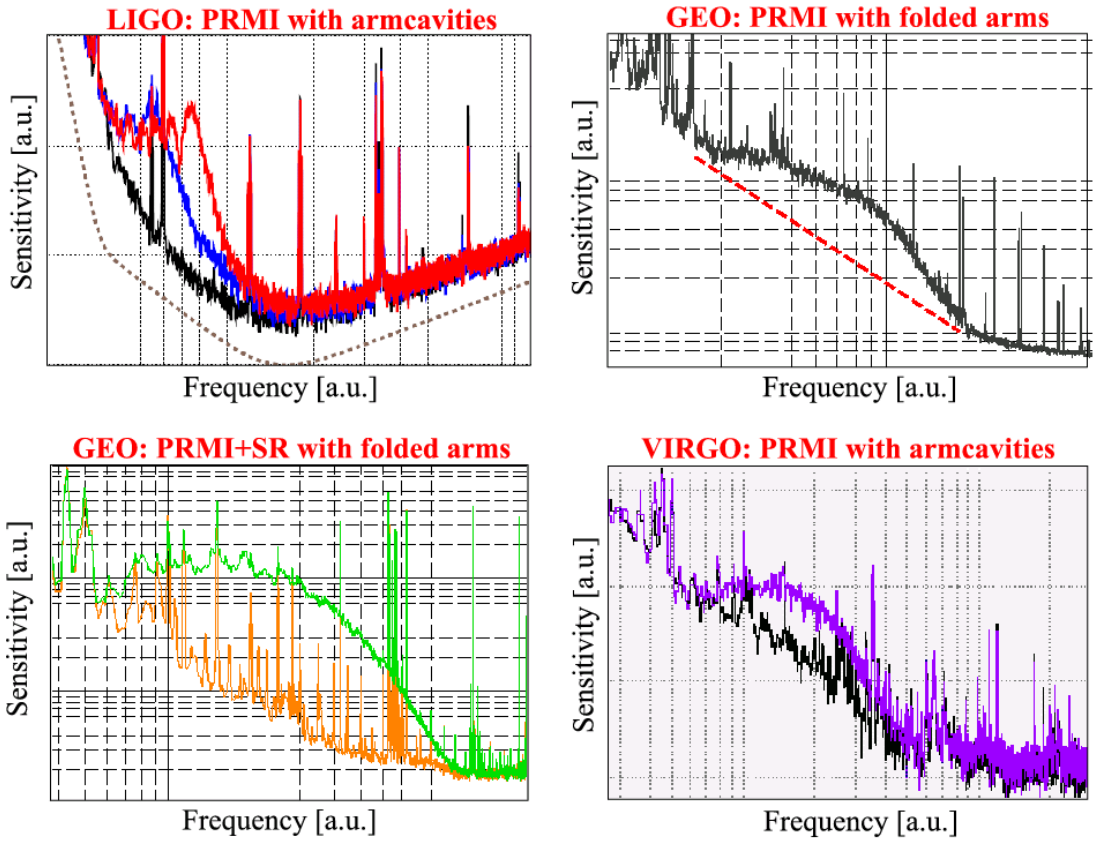

Figure 3.1.: In all interferometric gravitational wave detectors stray light is showing up in shape of a scattering shoulder. *UPPER LEFT PLOT:* Stray light shoulder in the LIGO Livingston detector, which is a power recycled Michelson interferometer of 4 km arm length using arm cavities [LIGO05]. *UPPER RIGHT PLOT:* Stray light shoulder in the GEO 600 detector, which was at the time shown here a power recycled Michelson interferometer using single folded arms of 600 m length. *LOWER LEFT PLOT:* Stray light shoulder in the dual recycled GEO 600 detector, which is a power and signal recycled Michelson interferometer with 600 m long folded arms. *LOWER RIGHT PLOT:* Stray light shoulder in the VIRGO detector, which is a power recycled Michelson interferometer of 3 km arm length using arm cavities [ILIAS06]. All four subplots have logarithmic x and y-axis.

the interferometer, i.e. the Herriot delay lines [Winkler]. The effect scattered light interacting with the walls of the vacuum vessel is theoretical described in [Vinet96]. In more recent times in the Japanese Tama300 detector stray light reflecting from the vacuum tubes was experimentally observed and characterized [Takahaschi04].

Learned from the experience collected in the prototypes, both the core optics and the beam tube of GEO 600 have been designed with great care with respect to stray light. So far there was no indication for stray light problems related to either the tube or the main optics.

The scattered light contributions observed in GEO 600 seem to originate from auxiliary beam paths where light is intentionally coupled out of the main interferometer for the purpose of sensing of the angular and longitudinal degrees of freedom. If some light from these paths is scattered back towards the interferometer it can reenter the main interferometer beam path. This light has, depending on the optical path length outside the interferometer, a shifted phase that varies in time with respect to the original light and is detected as noise in the output.

This chapter describes the experience with scattered light in the GEO 600 detector from the last two years. Powerful tools for observation, identification and elimination of stray light limiting the sensitivity of the GEO 600 detector have been developed and will be presented in this chapter.

3.2. Controlled stray light injections

This section describes experiments done with the goal to verify the general understanding of the stray lights effects observed in GEO 600. This is done by controlled generation of stray light in auxiliary beam pathes outside the vacuum system. For the experiments shown in this section the auxiliary path behind MFn and the one on the SR bench (a beam originating from a reflection on the AR coated side of the beam splitter) are used (see Appendix D for an optical layout of GEO 600).

3.2.1. How to produce stray light sowing up in H at 1 kHz

The scattering noise shoulders observed in GEO 600 extend to high frequencies of up to about 1 kHz (see for example Figure 3.6). In order to generate stray light effects inside

the GW detector at a frequency of 1 kHz one can image two ways:

- **The "high frequency small amplitude" scenario:** An optical component moving with a frequency of 1 kHz only needs to move by a fraction of the laser wavelength, in our case a micron. In presence of acoustical and seismic excitation most optical components, mounted in a standard way onto any optical table, show some movement at high frequencies, i.e. their resonance frequencies.
- **The "low frequency large amplitude" scenario:** An optical component moving with a very low frequency but with an large amplitude. Even though all suspension in GEO 600 are damped at their resonance frequencies they show a significant movement at low frequencies. Suppose a suspended optic with a resonance frequency of 1 Hz moves with an amplitude of 0.25 mm, then this will, as it will be shown in Equation 3.2.3, generate stray light with a phase shift of $2000 \cdot \pi$ showing up at 1 kHz in the sensitivity.

These two scenarios are extremes and of course an intermediate state, for example an component moving with an amplitude of 10 microns and a frequency of 25 Hz, would also be able to produce a stray light component showing up at a frequency of 1 kHz in the sensitivity. Often the stray light noise originates from number different vibrations at different frequencies. If for example the excess stray light is originating from a beam director on an optical table the surface of the mirror will at least to some amount vibrate with all kind of frequencies corresponding to the resonance frequencies of the optical table, the mirror mount and the mirror itself. Since the movement of the beam director has to be measured with respect to the main interferometer, which is moving up to several tens of microns at frequencies around 1 Hz in addition to the small amplitude high frequency movement we get also a low frequency large amplitude component.[2]

3.2.2. A device for controlled stray light generation

It is desirable to prove whether the scattered light we find in the GEO 600 detector can really be described fully by the picture of a moving optical component. This can be done by placing a scattering surface in an auxiliary beam path and moving the surface of the

[2] A third mechanism for stray light noise generation is known, but was so far not observed in GEO 600: Laser frequency noise in combination with stray light that travels a different path length with respect to the main beam can create stray light noise even without any moving component.

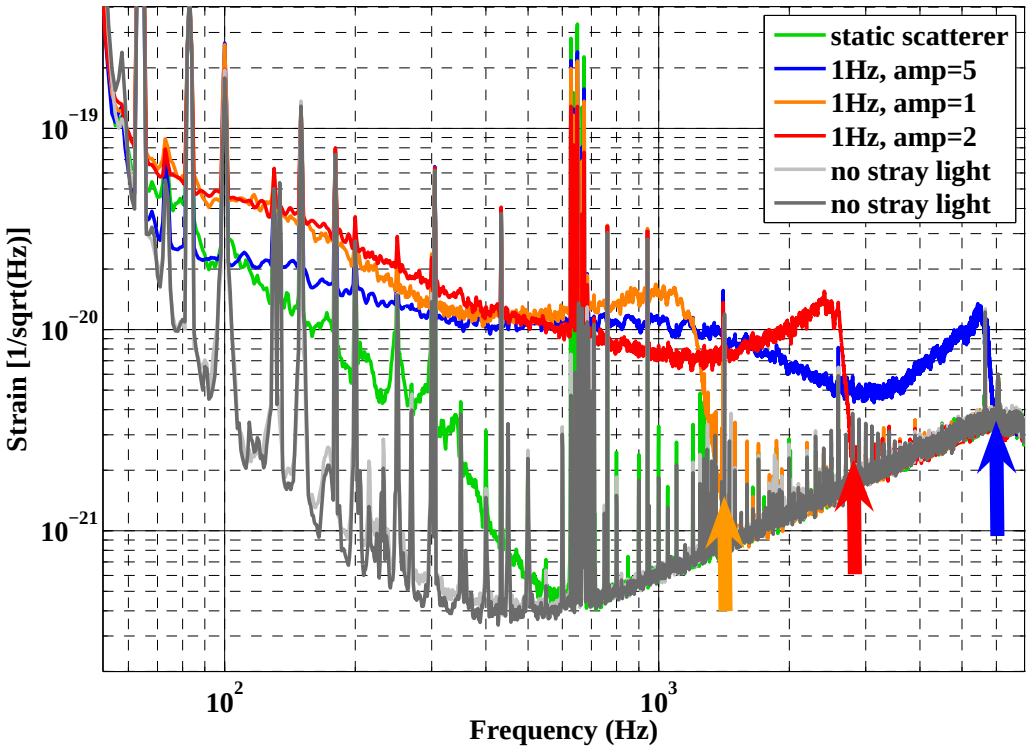

Figure 3.2.: Controlled forced scattering at the signal recycling bench: driving the stray light source with a triangular voltage of 1 Hz and amplitudes in the millimeter range. The two gray traces show the reference sensitivity for no stray light present. The green curve represents the scattered light contribution to the sensitivity for the speaker being installed but not driven with any signal. We see the usual scattering shoulder originating from the relative movement of the interferometer and the acoustically excited speaker diaphragm. The traces in orange, red and blue indicate the speaker driven with 1 Hz and different amplitudes. The cutoff frequency of the orange shoulder is around 1.3 kHz which corresponds to an amplitude of the movement of about 0.35 mm of the cone surface. When the amplitude of the triangular is increased by a factor of 2 (red trace) the cutoff frequency is doubled to 2.6 kHz as well. When the amplitude is further increased to a factor of 5 a cutoff frequency of about 5.5 kHz is observed which corresponds to a peak to peak movement of the scattering source of nearly 1.5 mm. This is already quite a large amplitude for the speaker and is probably the reason for the non-linearity of the observed cutoff frequency. Overall this experiment confirms our present understanding of the low frequency large amplitude scenario.

stray light source in a controlled way. We realized such a controllable scattering source

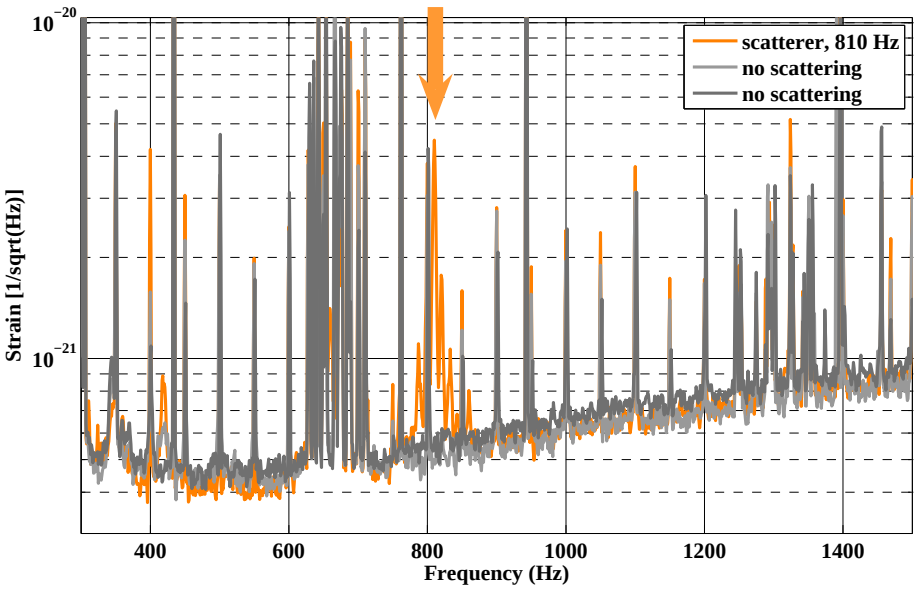

Figure 3.3.: Controlled forced scattering from the beam path transmitted through MFn: The two gray traces show reference spectra without any scattered light contribution. The orange curve represents a time when the stray light source (speaker) was driven with 810 Hz and an amplitude of less than a laser wavelength. A noise peak at 810 Hz surrounded by a strong sideband structure is observed.

by using an commercial low-cost loudspeaker driven by a commercial audio amplifier. In order to increase the backscattering amplitude on the one hand and to reduce the risk of thermal damage of the speaker caused by absorption of the laser light on the other hand we chose a speaker with a rough and silvery metal diaphragm (anodised aluminium). In addition we used the bare speaker without any housing to reduce the sound emission of the speaker. A speaker with high compliance was chosen to allow a total travel of several millimeters. The scattering efficiency was maximized by positioning the surface of the speaker close to a beam waist (see Section 3.6). The speaker was fixed into a strong metal frame with a mount to allow a rigid connection to the optical table.

3.2.3. Low frequency large amplitude scenario

First we want to verify that a low frequency movement of the speaker cone with a large amplitude produces a smooth scattering shoulder. Figure 3.2 shows the corresponding measurement, where the speaker was driven with triangular voltage of a frequency of 1 Hz. Shown are calibrated strain sensitivities for two reference times without any stray light contribution (gray), a reference for the static scattering source, where the speaker was installed but not driven (green) and three times when the speaker was driven in a controlled way with amplitudes in the mm-range. The static speaker already produces a strong scattering shoulder originating from the relative movement of the speaker surface and the suspended main interferometer. The cutoff frequency, f_{cutoff}, can roughly be estimated by the following relation

$$f_{\text{cutoff}} \approx 4 \cdot f_{\text{sp}} \cdot \frac{A_{\text{sp}}}{\lambda_{\text{laser}}}, \tag{3.1}$$

where f_{sp} is the frequency of the signal the speaker is driven by, A_{sp} is the peak to peak amplitude of the diaphragm and λ_{laser} is the wavelength of the laser. The factor 4 originates from a factor of 2, accounting for the fact that the light hitting the speaker and being reflected travels twice the distance the diaphragm moves, and a second factor of 2, originating from the fact that during a single period of the triangular signal 2 times the peak-peak movement is covered. For the measurement corresponding to the red trace of Figure 3.2 an amplitude twice as large as for the measurement corresponding to the orange trace was chosen. In good agreement the cutoff frequency of the red trace, 2.6 kHz, is found to be twice as large as the cutoff frequency of the orange curve, 1.3 kHz. However, caused by the non linear response of the speaker for large amplitudes, we find for the blue trace instead of the expected cutoff frequency of 6.5 kHz only 5.5 kHz. However, overall it can be stated that our understanding of the low frequency large amplitude scenario is confirmed by this measurement.

3.2.4. High frequency low amplitude scenario

The next measurement was done to prove the high frequency low amplitude scenario. The speaker was driven by a triangular signal with a frequency of 810 Hz and an amplitude much smaller than one laser wavelength[3]. Figure 3.3 shows this measurement

[3] That the amplitude was much smaller than the laser wavelength could be determined by the fact that no additional line in sensitivity was observed at 1620 Hz.

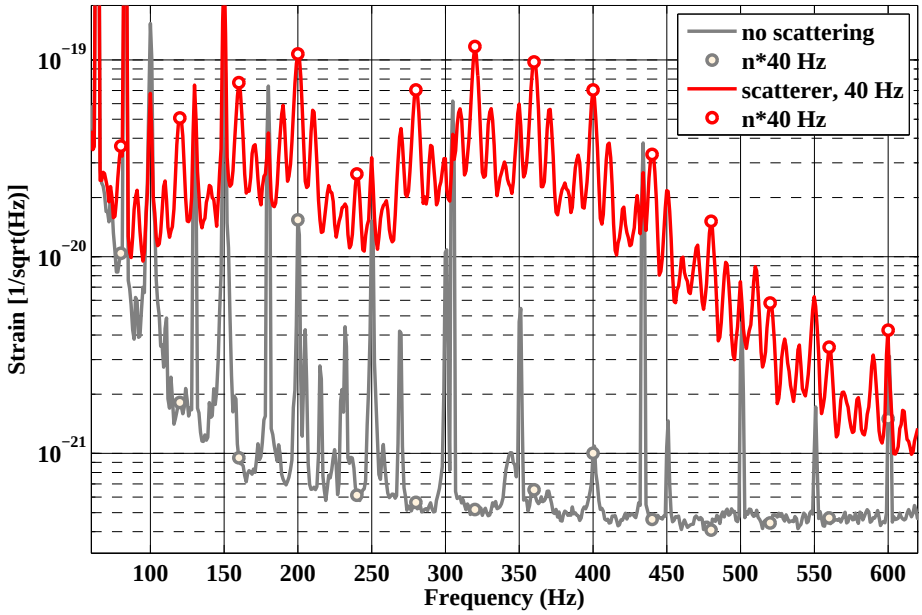

Figure 3.4.: Scattered light injection by controlled movement of the speaker surfaces. A triangle with a frequency of 40 Hz and an amplitude of a few ten microns.

in detail. The two gray traces represent reference spectra in the absence of any stray light contribution. The orange curve represents the time of the stray light injection. A large noise peak is generated with a strong sideband structure around it. The dominat sideband frequencies are 10 and 23 Hz with amplitudes of 50 and 25 % of the center peak, respectively. The sideband structure represents the up-converted low frequency movement of the speaker relative to the main interferometer. Comparisons of measurements for stray light injections at different frequency have shown identical sideband structures for all frequencies. The same is also true for measurements of injections with amplitudes of a few laser wavelengths, thus the first few harmonic frequencies with their sideband structures could be observed.

3.2.5. Combination of the two scenarios

Figure 3.4 shows a measurement where the speaker was driven with a frequency of 40 Hz and an amplitude of several tens of microns. As expected we find a comb of harmonics of 40 Hz (red circles). Each line of a frequency n*40 Hz is surrounded by the same

sideband structure that was already observed in Figure 3.3. That is why each line is accompanied by 10 Hz sidebands. Altogether this excitation of the speaker diaphragm gives a scattering shoulder containing strong peaks at all harmonic frequencies of 40 Hz. As we will see later (Section 3.7) this stray light injection shows some similarities to an observed stray light phenomen called *ripple noise*.

3.2.6. Summary of the stray light injections

We found a simple and very efficient way to generate stray light in an controlled way by using the cone of a loudspeaker as scattering surface. By carrying out stray light injections with various amplitudes and frequencies we found the excess noise in the sensitivity originating from stray light to qualitatively match our expectations. This means that we understand the basic principle of scattered light problems and there seems no "magic" about them.

3.3. Indications for a stray light limited sensitivity

During the commissioning of a gravitational wave detector one of the main problems regarding stray light is to find out whether the current detector sensitivity is in any frequency band limited by stray light effects. The tiny amounts of stray light that can already limit the sensitivity of GEO 600 are hardly detectable by independent sensors.

Therefore the most promising method to identify whether there is any stray light contribution is to use the specific signature of the stray light in the sensitivity of the GW detector. In GEO we found stray light always to show up in the sensitivity with three specific characteristics:

- **Non-stationarity on short time scales:** The noise originating from stray light is in many cases found to be highly non-stationary on second's time scales. In contrast to most of the technical noise, for instance feedback or electrical noises, and most of the fundamental noise, for instance thermal noise or shot noise, which are rather stationary. Figure 3.5 shows spectrograms of the uncalibrated error signal of the differential arm length servo for a time without any contribution from stray light and a time of intentionally increased scattered light contribution. The stray light shows up as strongly varying broadband excess noise. Not only the size of

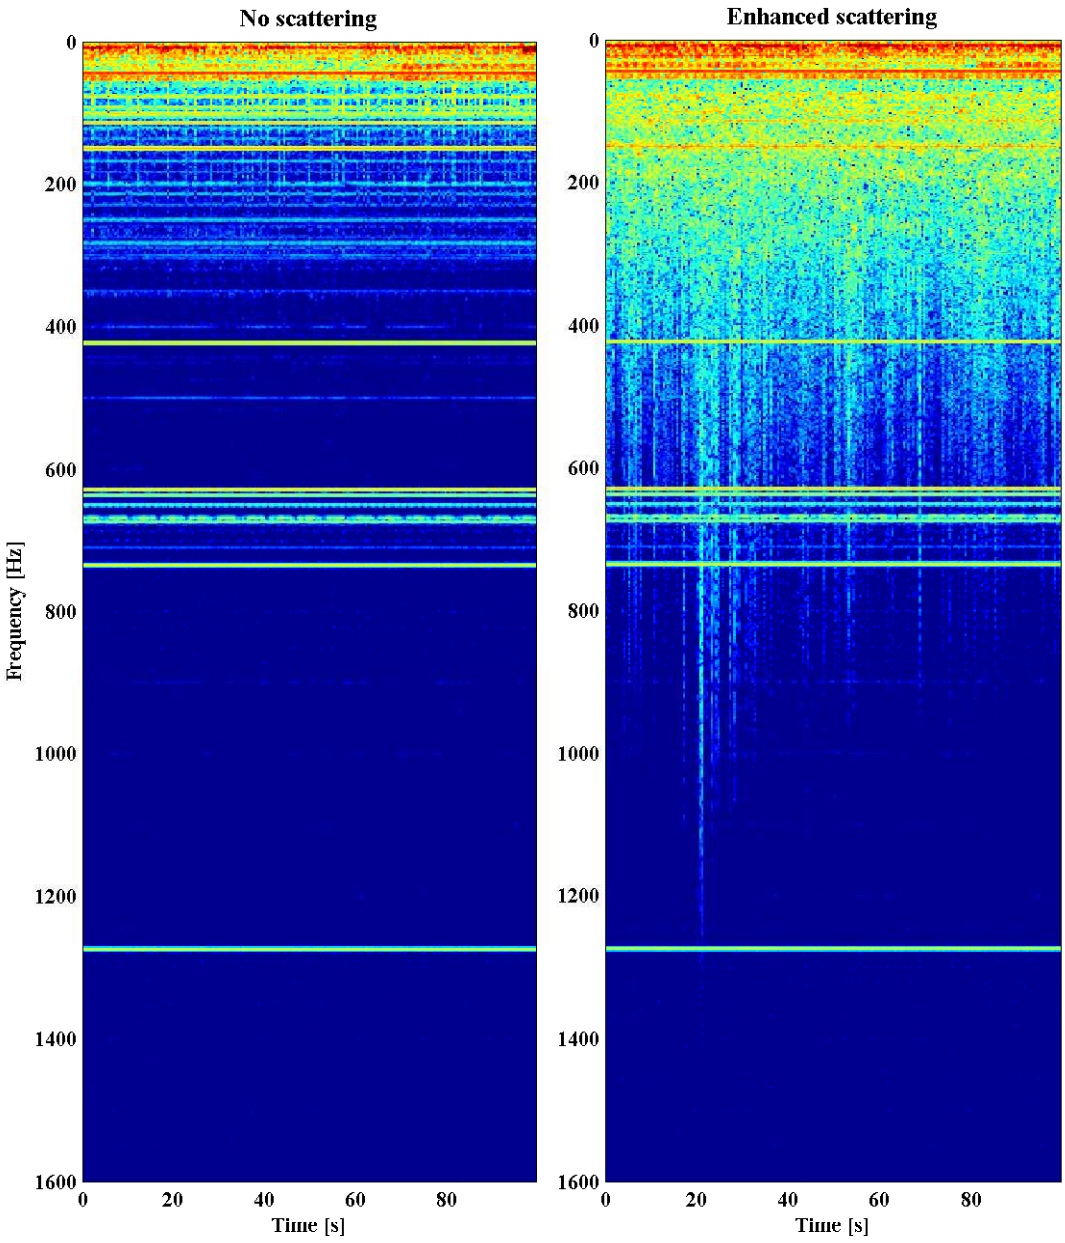

Figure 3.5.: Spectrograms of the uncalibrated error signal (P quadrature) of the differential arm length servo. The left hand plot shows 100 seconds of "clean" data without enhanced scattered light limiting the sensitivity. For frequencies above a few hundred the sensitivity is reasonable stationary. The right plot show 100 seconds of data from a time when the scattering was intentionally enhanced. Over most of the detection band the sensitivity varies strongly on the time scale of a second.

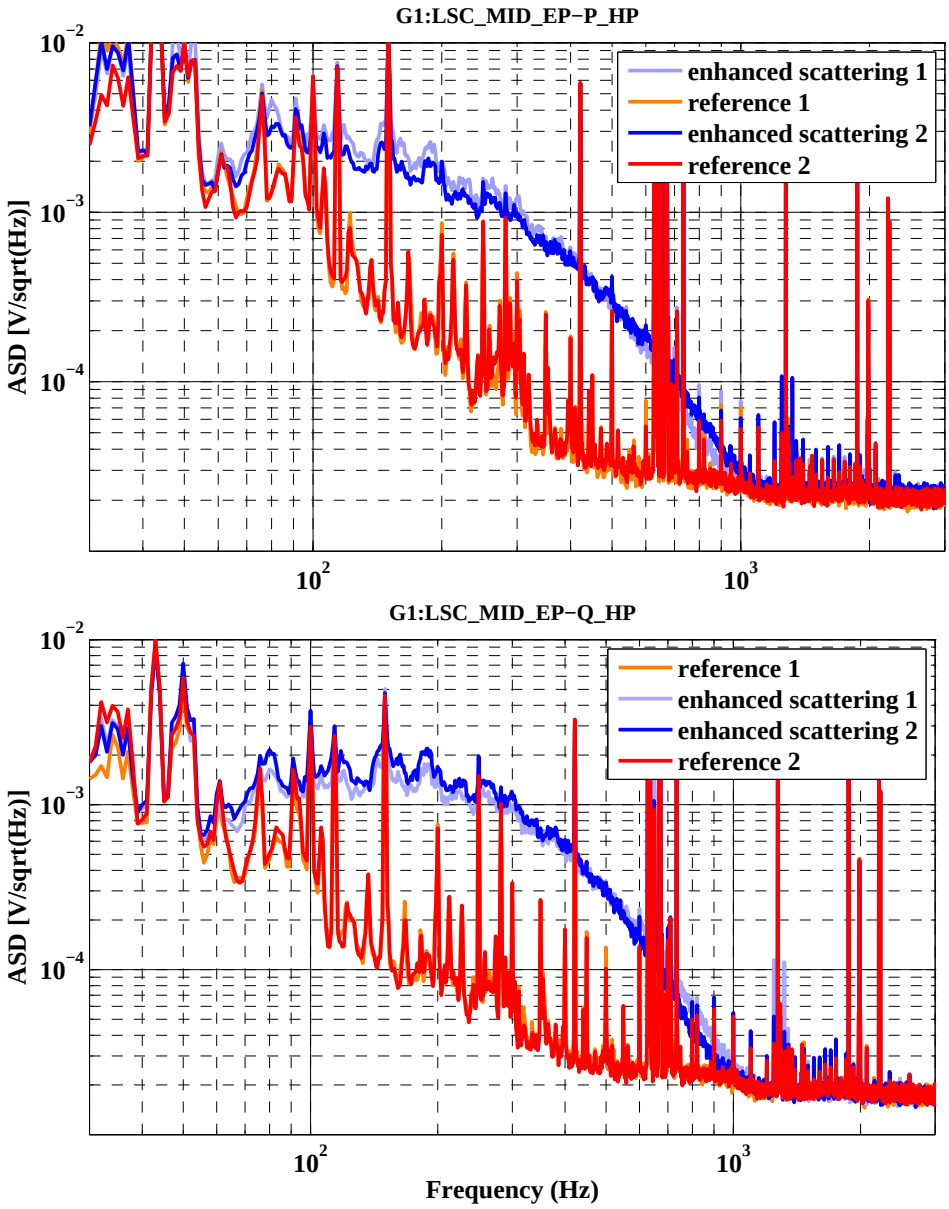

Figure 3.6.: Spectra of the uncalibrated error signal of the differential arm length servo. Shown are both output quadratures, P and Q, for each two times of "clean" data (minimal noise contribution from scattering) in red and orange and two times of enhanced scattering limiting the sensitivity from 60 to 1000 Hz (blue and light blue). The stray light causes excess noise in the typical shoulder shape. Below 100 Hz the stray light is suppressed by the loop gain of the servo controlling the differential arm length of the Michelson interferometer.

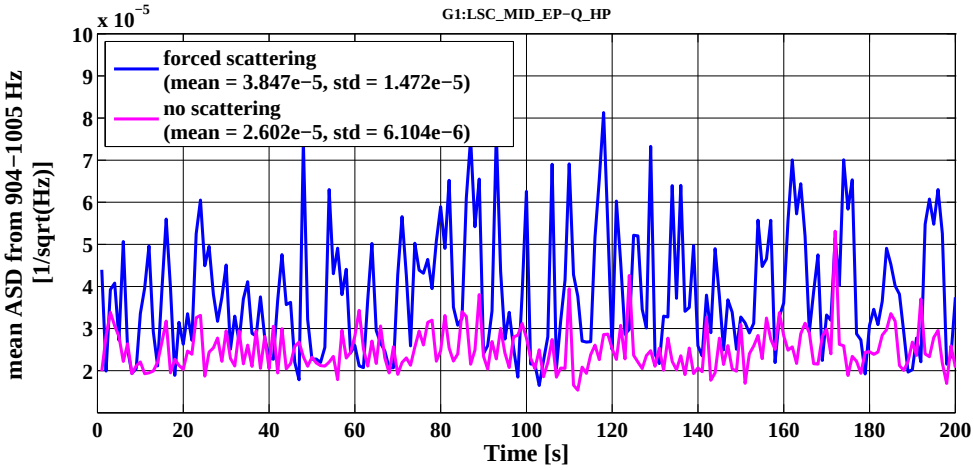

Figure 3.7.: Time series of the mean ASD of the uncalibrated detector sensitivity in the band from 904 to 1005 Hz. The pink trace represents a time when the frequency band was not limited by stray light, while the blue trace indicates a time of enhanced scattering. If stray light is present not only the mean of the time series is larger but also the standard deviation, σ, is strongly increased.

the scattered light noise changes but also the maximal effected frequency. Another way to look at the stationarity of the noise is plotted in Figure 3.7. Depicted are the time series of the mean ASD of the uncalibrated detector sensitivity in the band from 904 to 1005 Hz for two different times. The pink trace represents a time when the frequency band was not limited by stray light, while the blue trace indicates a time of enhanced scattering. If stray light is present not only the mean of the time series is larger but also the standard deviation, σ, is strongly increased.

- **The specific sound of stray light:** An excellent tool to judge the stationarity of a signal on short time scales is the human ear. Listening to a whitened signal representing the sensitivity was found to be the most powerful tool for identifying scattered light noise. At least in GEO stray light had a very specific sound. Two audio examples, of the sound of the sensitivity of GEO 600 for a time of clean data and a time when excess noise from stray light was present, can be found on the CD-ROM (Multimedia Appendix) at the end of this thesis.[4]

[4]The unique sound of stray light is hard to describe in words. Probably everybody of the GEO commissioning team would describe it in a different way. Some call it ”wooshing”, others compare it

- **The typical scattering shoulder:** As already mentioned in Section 3.1 noise from stray light is often found to show up as a shoulder of excess noise. As Figure 3.6 indicates the shoulder starts at low frequency and then extends to a certain frequencies called the *cutoff frequency*. In many cases the cutoff frequency scales with the size of the shoulder at low frequencies as one can see in the righthand spectrogram of Figure 3.5.

Even though none of these three points alone can give a reliable indication, all three together give a pretty strong indication for stray light limiting the sensitivity of the GW detector. If all three indicators suggest the presence of stray light, the next step is to find the source and coupling path of the stray light.

3.4. The filter experiment: A reliable method to identify the source of stray light

In the commissioning of the GEO 600 detector the so called *filter experiment* was found to be the best method to identify and locate limiting scattering paths [Hild06a]. Many potential scattering sources such as the auxiliary beam paths used for control and diagnosis of the detector are located outside the vacuum system. Auxiliary beam paths used for longitudinal and angular control of the interferometer usually contain many optical components like for instance lenses, telescopes or photodiodes, each of these a potential source of scattering.

Let us consider a simplified setup as it is depicted in Figure 3.8 to explain how the filter experiment works. A fraction, A_0, of the light circulating in the main interferometer is entering the auxiliary beam path of interest. A potential source of stray light scatters the light amplitude $A_0 \cdot k_1$ back towards the main interferometer, where k_1 is the scattering coefficient. Usually only a small fraction of $A_0 \cdot k_1 \cdot k_2$ then re-enters the main interferometer mode and is detected. If now an optical attenuator with the amplitude transmission of T_f is positioned between the main interferometer and the scattering source, first of all, the light incident on the scattering source is decreased and afterwards the scattered light going back into the interferometer is also attenuated. Overall the light amplitude re-entering the detection path is reduced from $A_0 \cdot k_1 \cdot k_2$ to $A_0 \cdot T_f^2 \cdot k_1 \cdot k_2$ by inserting the optical attenuator.

to an avalanche or a storm. I think the best way is to listen yourself.

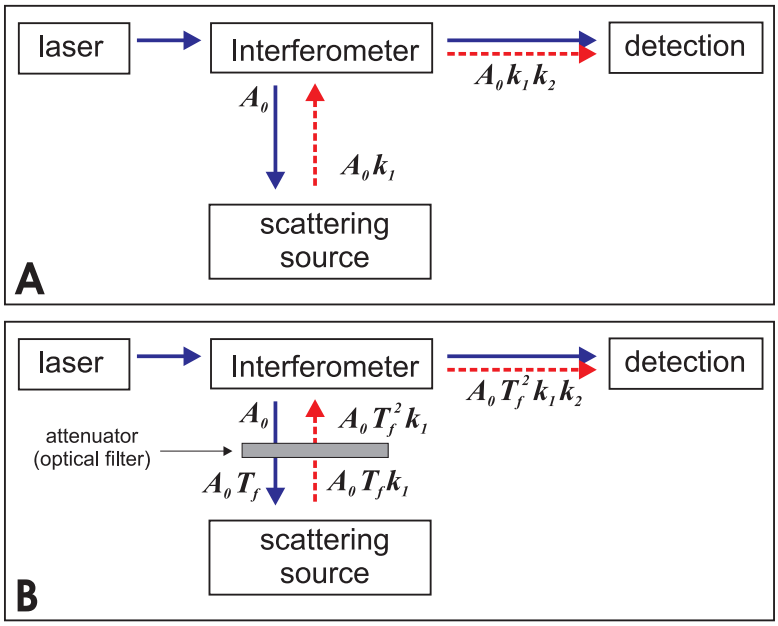

Figure 3.8.: Sketch of the filter experiment which provides an easy and reliable method to identify stray light limiting the sensitivity of the interferometer. **Figure A:** A fraction, A_0, of the light circulating in the interferometer leaves the main interferometer and enters an auxiliary beam path (for example used for alignment control). A scattering source in this auxiliary path would scatter $A_0 \cdot k_1$ back towards the interferometer, where k_1 is the scattering coefficient. Assuming the coefficient for the coupling back into the main interferometer to be k_2 a total light amplitude of the scattered light of $A_0 \cdot k_1 \cdot k_2$ is detected. **Figure B:** If an optical attenuator with the amplitude transmission of T_f is inserted between the main interferometer and the source of stray light the detected stray light amplitude is decreased by T_f^2.

If, for example, a neutral density filter is used as an attenuator, which has a power transmission of about 60 % at $\lambda = 1064\,\mathrm{nm}$ we expect the sensitivity limiting stray light contribution to go down by 60 % as well. Now by putting in the filter at different positions in the auxiliary path we can identify component by component their contribution to the detected scattering. However, as the inserted filter is an additional potential source for scattering it is necessary to take great care of the quality and cleanliness of the filter in order to not spoil the measurements. To decrease the chance of added scattering the filter must not be installed under normal incidence. In addition, as it is shown in Section 3.6 it is essential to avoid placing the filter near a beam waist.

Of course in the case the light in the auxiliary beam is used for automatic control of the interferometer it is necessary to adjust the gain of the servo in order to compensate for less light power hitting the photo detector.

3.4.1. Limitations of the filter experiment

Obviously it is not easily possible to insert an attenuator to any beam path inside the vacuum system. Therefore the filter experiment is limited to the parts of the auxiliary beams that are located outside the vacuum system. Another restriction can be given for scattering sources in the main detection path: For many conditions the potential benefit from reducing stray light in this case is compensated by less signal on the main photo detector. If we take for example a sensitivity which is at the frequencies of interest limited to equal shares by stray light and shot noise the stray light contribution[5] will decrease by T_f as well as the shot noise level will increase by T_f.

Finally the strongest limitation of the method is that only stray light contributions that actually limit the total detector noise can be identified. As long as the stray light does not contribute significantly to the detector noise we have no measure whether the stray light was reduced or not. This method does not allow for projecting the stray light noise.

[5] In opposite to the scenario described in Figure 3.8, when the attenuator is placed in the detection path the scattered light is only attenuated once.

3.5. Experience of stray light problems in GEO

In fall 2004 the sensitivity of GEO 600 was found to be limited by stray light induced noise over a wide range of the detection band. A typical scattering shoulder with a cutoff frequency of about 1.2 kHz was traced back to backscattering on the signal recycling bench. The steps involved in reducing the stray light on this optical table are a good example how to eliminate stray light problems in the optical setup of an auxiliary path.

On the signal recycling bench a pick-off beam, originating from the beam splitter AR coating in the east arm, is detected and used for longitudinal control and auto alignment of the signal recycling mirror (see Figure D.1). Figure 3.9A shows the original layout of the bench as it was present in late summer 2004. The beam leaves the vacuum system through an AR coated window and passes an AR coated focusing lens L1. Afterwards a set of two beam steering mirrors (bd1, bd2) is used to align the beam onto the second AR coated lens L2 of the beam telescope and a 2-axis galvo-scanner. Finally the beam is detected by a quadrant diode. With the aid of the filter experiment we identified L2 and the galvo scanner as sources of limiting stray light noise. A reduction of the stray light was achieved by replacing L2 and the galvo scanner by a high quality beam director[6]. In a next step we found bd3 still causing a measurable amount of stray light coupling to the GW channel. This was mainly caused by the fact that bd3 was located close to a beam waist, which is in terms of stray light in a very critical position for any kind of optical elements, regardless of their quality (see Section 3.6). Therefore the quadrant diode was moved in a next step closer towards L1 in order to avoid the presence of any beam waist on the SR bench. The corresponding layout which was used during the S4 science run is depicted in Figure 3.9C. Figure 3.10 shows the sensitivity improvements from autumn 2004 achieved by minimizing stray light from the signal recycling bench.

The curious reader might ask, why the optical layout of the bench was reorganized, instead of simply attenuating the stray light by installing several optical attenuators (permanent filter experiment). In general such an approach should have worked out, even though it always feels better to eliminate the source of a problem instead of suppressing the consequences. However, in the special case of the GEO SR bench any attenuation of the light level would have caused an increased feedback noise of the signal recycling

[6] In GEO galvo scanners are commonly used in front of all quadrant diodes in order to make sure the beams are well centered on the diodes all the time. However, after taking out the scanner from the signal recycling bench no excess noise was found in any of the related control loops.

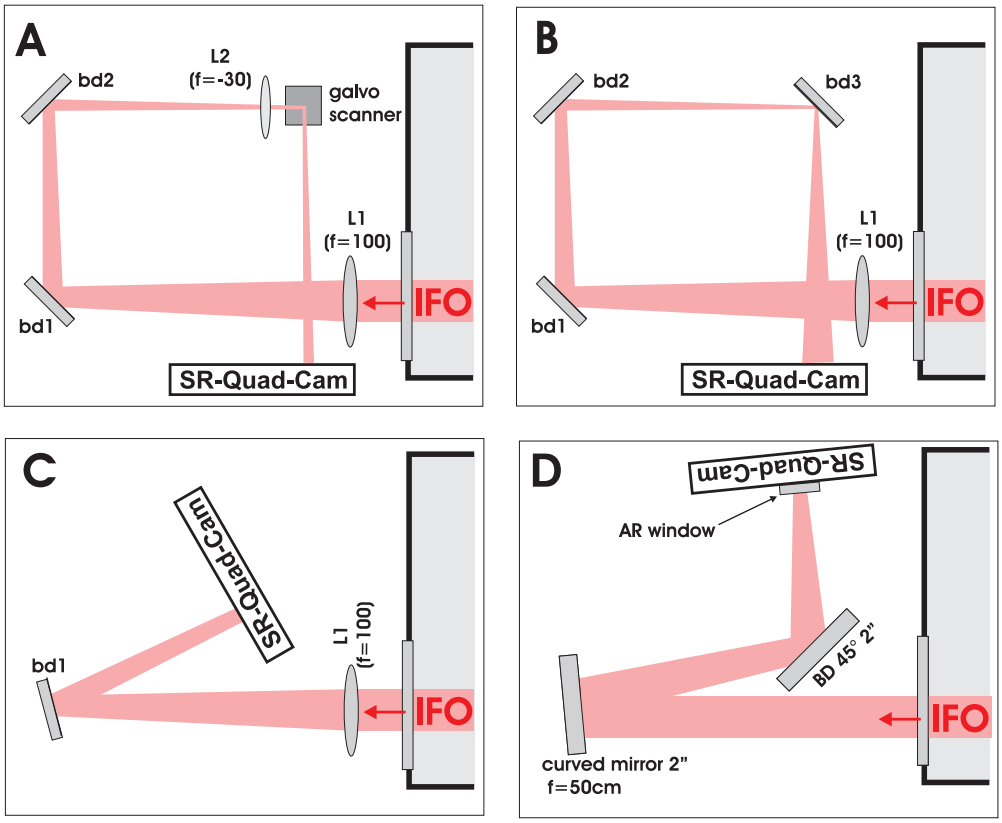

Figure 3.9.: Progression of the optical layout of the signal recycling bench in order to reduce stray light. **A:** Original layout of the bench from summer 2004. The beam leaves the vacuum system through a window, passes a focusing lens L1 and two stearing mirrors (bd1, bd2) which are used to align the beam to the second lens L2 of the beam telescope and 2 axis galvo-scanner. Finally the beam is detected by a quadrant diode. **B:** With the aid of the filter experiment we identified L2 and the galvo scanner as sources of limiting stray light noise. Both components were taken out and replaced by a single high quality mirror (bd3). **C:** S4 configuration. In a next step we found bd3 still causing a measurable amount of stray light. This was mainly caused by the fact that bd3 was located close to a beam waist, which is in terms of stray light in a very critical position for any kind of optical elements, regardless of their quality (see Sec.3.6). Therefore the quadrant diode was moved in a next step closer towards L1 in order to avoid the presence of a beam waist on the SR bench. **D:** S5 configuration. At the start of 2006 we found again stray light limiting the improved sensitivity of GEO 600. The un-coated window of the quadrat photodiode was replaced by an AR coated fused silica window. In a second step L1 was replaced by a curved 2" diameter mirror.

longitudinal loop which is limited by shot noise for frequencies of our interest. As the feedback noise of this loop is already close to limiting the overall sensitivity of GEO 600 in the few hundred Hz region, any reduction of the stray light noise by attenuating the beam path would have been compensated by larger feedback noise in the attenuated setup.

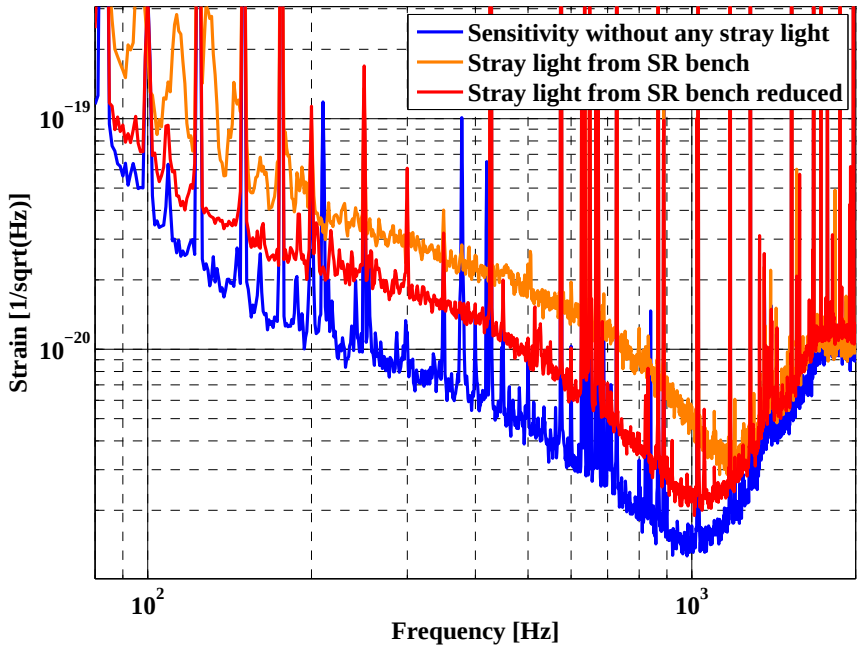

Figure 3.10.: Sensitivity progress of GEO 600 from autumn 2004. By eliminating stray light from the signal recycling bench the sensitivity of the GEO 600 detector was improved by about a factor of 3 for frequencies between 100 and 1000 Hz.

After S4 GEO's sensitivity was improved by about a factor of 10 in the few hundred Hz region at the beginning of 2006 again scattered light originating from the SR bench was found to limit the sensitivity. The dominating source of stray light was the low quality window of the quadrant photo detector. The original window was cut off and the diode was clamped in between two copper plates of which one was holding a 1" AR coated fused silica window. The AUTOCAD drawing of this diode holder can be found in Appendix C. The major difficulty of realizing this setup is to cleanly cut off the window of the quadrant diode. In contrast to small single element diodes where the window can easily be taken off, removing the window of a large quadrant diode poses difficulties. Due to the much larger ratio of diameter to thickness of the housing it turns

out to be nearly impossible to cut off the window without partly cracking it and spilling many small splinters over the active area of the diode. The only reliable way to get rid of the splinters was found to be repeated rinsing the whole diode with a few milliliters of ethanol and immediately afterwards drying it with compressed nitrogen.

In a second step of improvement the lens (L1) was replaced by a high quality 2" curved mirror. There was no strong indication that L1 was causing any additional stray light noise. However, in contrast to a curved mirror lenses always have the disadvantage that a fraction of their surface is always perpendicular with respect to the incidence beam. Finally it has to be mentioned that all secondary beams, such as the reflected beam from the photodiode itself, have to be properly dumped.

3.6. The cat's eye effect

As already stated in the previous section one important experimental finding of our stray light investigations was that stray light sources positioned close to a beam waist caused the largest stray light contributions to the GEO 600 sensitivity. Analogous to the cat's eye effect the light scattered directly at a beam waist has exactly the right geometrical mode to reenter the main interferometer.

Figure 3.11 shows an illustrative example of an optical configuration which is similar to the signal recycling bench described in the previous section. The subplot 1 shows the setup with no stray light present. Inside the central cluster the main interferometer beam has an radius of $\omega_{cc} \approx 1\,\mathrm{cm}$. A fraction of the beam leaves the interferometer at the beam splitter AR coating and is then focused down on the SR bench. With the drawn lens of 50 cm focal length an beam waist of $\omega_0 \approx 17\,\mu\mathrm{m}$ is generated. For the following analysis we assume the light amplitude incident to the lens is A_0 and all beams have an gaussian profile at all positions. For all scenarios described below we will use the same source of scattering which is a square area of $5 \times 5\,\mu\mathrm{m}$ which is assumed to scatter proportional to $cos(\varphi)$ into the solid angle, where $\varphi = 0$ corresponds to normal incidence.

Figure 3.11.2 shows the situation for the scattering square directly located in the waist. Since the beam is so small at the waist, A_2 which is the fraction of A_0 incident to the

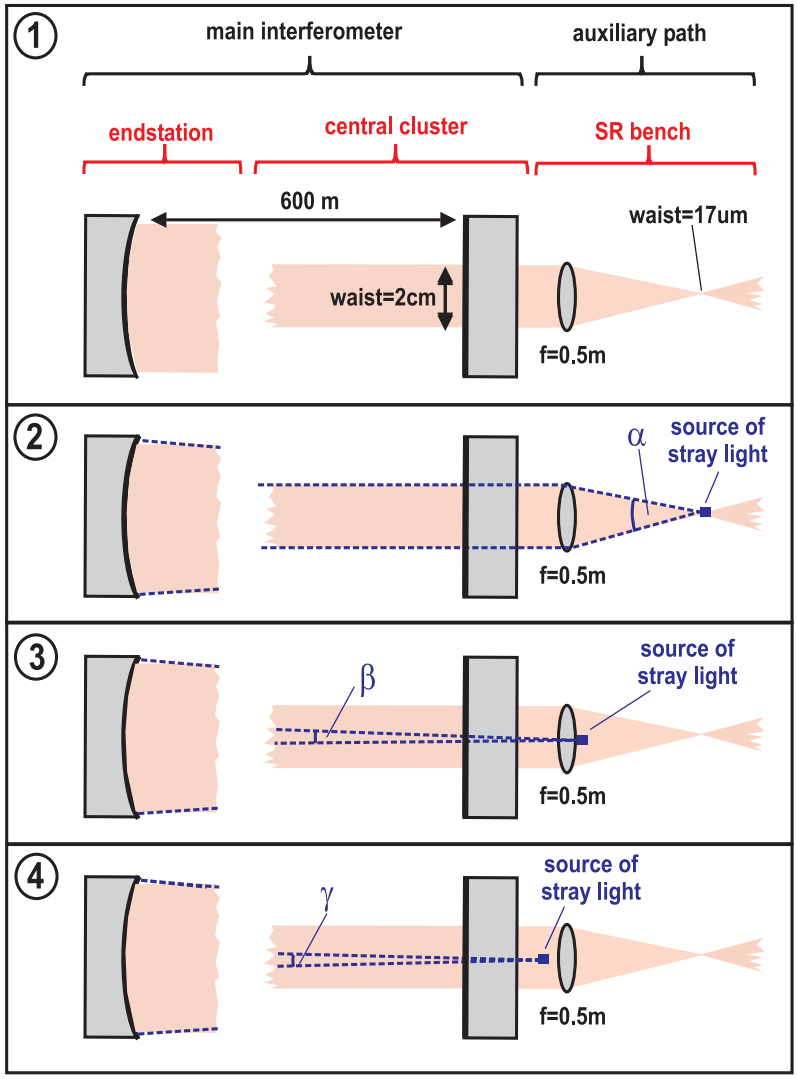

Figure 3.11.: Illustrating schematic of the cat's eye effect: The scattering efficiency of a scattering source strongly depends on its position in the auxiliary path. An extremely large back scattering efficiency is found for a stray light source sitting directly in the beam waist, because in that case first of all a large light power is reflected and secondly all light scattered back towards the lens reenters the main interferometer in the correct mode. A scattering source located right in the beam waist (panel 2) is found to have a $1.6 \cdot 10^9$ larger backscattering efficiency than the same scattering source sitting in the non diverging beam in front of the lens (panel 4). A detailed description of the depicted scenarios can be found in the text.

scattering square, is quite large:

$$A_2 = 0.2 \cdot A_0. \tag{3.2}$$

All of A_2 scattered back into α, which is 2.3°, reenters the main interferometer and is transferred to the output.

The situation when the same scattering source is placed right behind the lens is shown in Figure 3.11.3. In this scenario A_3 which is the fraction of A_0 incident to the scattering square is much smaller than before due to the larger beam radius.

$$A_3 = 1.6 \cdot 10^{-7} \cdot A_0 \tag{3.3}$$

Furthermore, the light scattered back is to a large fraction not in the correct interferometer mode. An upper limit for the amount of light that can in principle[7] reenter the interferometer and being transferred to the output is given by $\beta = 0.017$ which originates from the requirement that the stray light has at least to hit the far mirror (diameter = 18 cm) at a distance of 600 m. This means that the scattering efficiency will be very small in this case due to the small accepted angle β.

Finally in Figure 3.11.4 a scenario is depicted where the scattering square is placed on the left hand side of the lens in the parallel beam. The light amplitude A_4 incident onto the square is, due to equal beam sizes, identical to A_3.

$$A_4 = 1.6 \cdot 10^{-7} \cdot A_0 \tag{3.4}$$

Also the angle of acceptance γ is equal to β.

The overall amount of light backscattered into γ, $A_{4\text{back}}$, can be described by the following expression:

$$A_{4\text{back}} \propto A_4 \int_0^{\gamma/2} \cos(\varphi) d\varphi. \tag{3.5}$$

Analogously $A_{3\text{back}}$ and $A_{2\text{back}}$ can be calculated. If we normalize the results by $A_{4\text{back}}$ we get the following normalized backscattering efficiencies.

Exactly at the beam waist the backscattering efficiency is 1.6 billion times larger than for a scattering surface at the lens. From this result we can derive the rule that we have

[7] Assuming all light is converted by mode healing from the signal recycling back into the ground mode.

Scenario	Efficiency of backscattering
2	$1.6 \cdot 10^9$
3, 4	1

Table 3.1.: Summary of the normalized backscattering efficiencies for the three scenarios depicted in Figure 3.11

to avoid placing optics exactly in the beam waist of any auxiliary beam path directly connected to the main interferometer, or even better to avoid the presence of any waist at all if possible.

3.7. A special class of stray light noise: the "ripples"

In this section a class of stray light noise is described, the so called *"ripples"*. For two reasons these ripples are very interesting: First of all they have a noteworthy shape in the frequency domain and secondly this kind of stray light noise was limiting the sensitivity of the GEO 600 detector in the few hundred Hz range at least part time of S5.

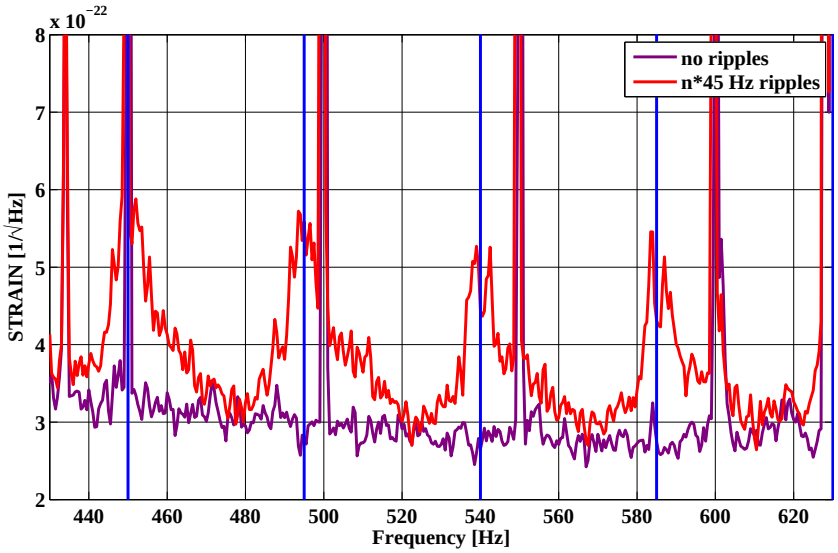

Figure 3.12.: Strain sensitivity of GEO 600 for a time when the n*45 Hz ripple noise is present (red) and reference time (purple). The vertical blue lines indicate harmonic frequencies of 45 Hz.

During S5 excess noise was frequently observed that showed up in the few hundred Hz region of the sensitivity as a series of equidistant bumps. Figure 3.12 shows spectra of a reference time (purple) when no ripples were present and a time with ripple noise (red). As indicated by the blue vertical lines which are drawn at harmonic frequencies of 45 Hz the ripples show up in this case at n*45 Hz. At the center frequency of the bumps the sensitivity is decreased by up to 80 %. The bumps have a FWHM of about 10 Hz and from the presence of their wings even in the middle between two bumps the sensitivity seems to be slightly decreased.

The n*45 Hz ripples showed up during S5 in irregular intervals of several hours and were then present for about 20 minutes. Figure 3.13 depicts how the n*45 Hz ripples shows up in the sensitivity. Plotted are spectrograms of H and the seismometer in the north end station. Both spectrograms are normalized by the overall average in each frequency bin. Reddish pixels indicate values larger than the average. Between hour 3 and 3.5 an excess noise is present at 45 Hz in the seismic. At the same time we see strong ripples at n*45 Hz in the sensitivity of GEO 600. This observation led to the suspicion that stray light is generated at a seismically driven component in the north end building. This suspicion was further confirmed by the observation of a slight drift in the frequency of the ripples, which was also seen in the frequency of the seismic excitation, as shown in Figure 3.14.

The excess noise in the seismic was tracked down to a cooling fan of a turbo-pump. The fan was automatically controlled and switched on only when a certain threshold of the turbo-pump temperature was crossed. For further experiments the cooling fan was set to continuous operation in order to continuously generate ripples. In that condition a filter experiment was carried out on the optical table in the north endstation. Even with the beam leaving the vacuum completely blocked the ripples stayed constant in size. This for the first time in GEO 600 gives strong evidence for a stray light problem originating from inside the vacuum system.

Potential stray light sources inside TFn are the catcher of MFn, the tank walls and the curved and partly un-coated rim of the view port behind MFn. A series of experiments where the beam position on MFn was changed gave the result that the n*45 Hz ripples are smallest when the beam is not centered on the mirror, but centered on the view port. This makes the view port to be the strongest suspect for being the stray light source. As shown in Figure 4.2 a significant fraction of the beam transmitted through

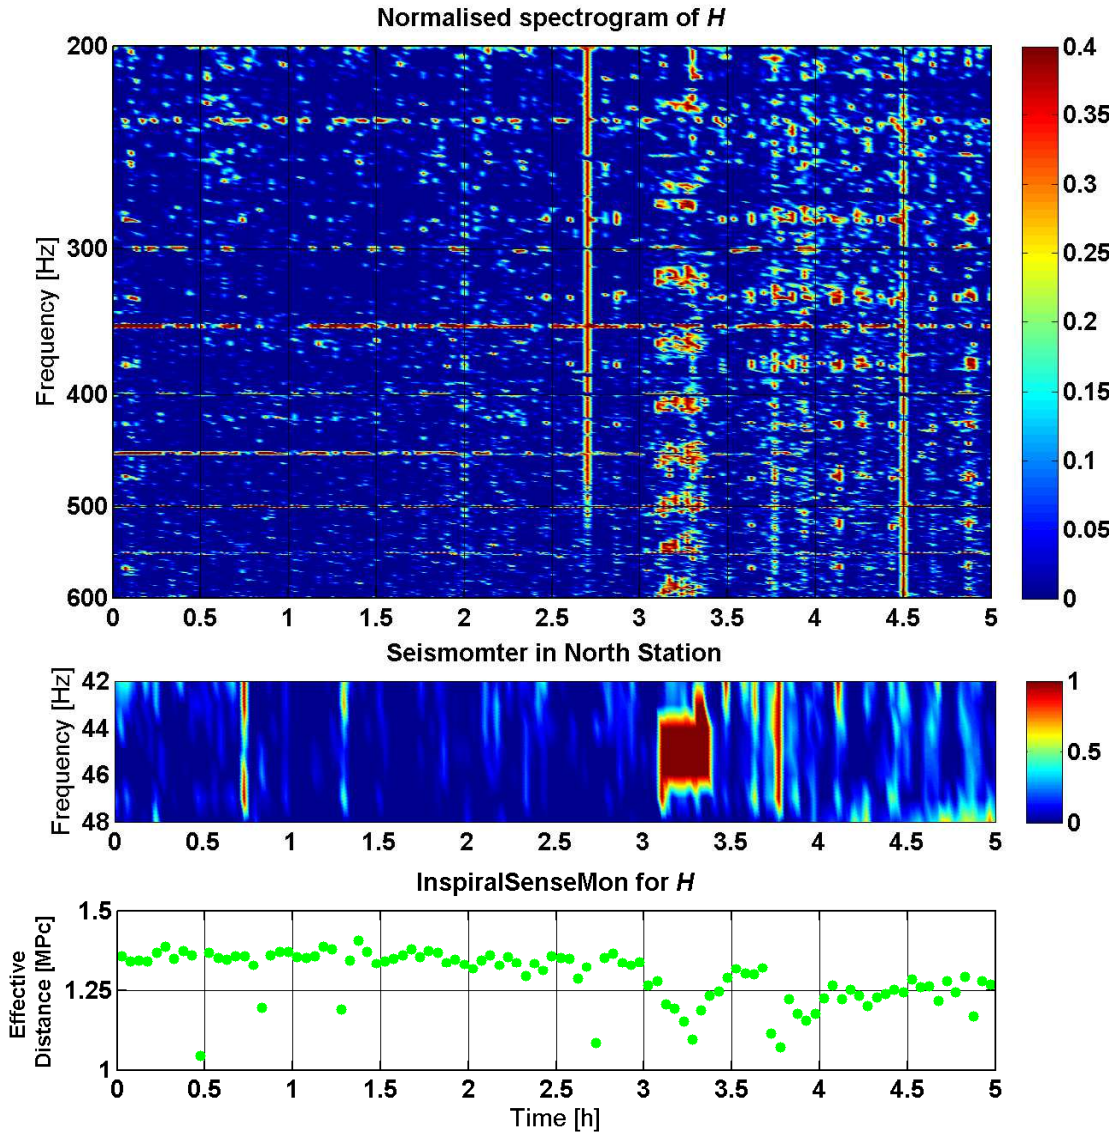

Figure 3.13.: Spectrograms of H and the seismometer in the north end station. Both spectrograms are normalized by the overall average in each frequency bin, thus the varying features are highlighted. Reddish pixels indicate values larger than the average. Between hour 3 and 3.5 an excess noise is present at 45 Hz in the seismic. At the same time we see strong ripples at n*45 Hz in the sensitivity of GEO 600. The decrease in sensitivity can also be seen in the neutron-star-neutron-star (NSNS) inspiral horizon which is decreased by about 10 % in the presence of the ripples. The NSNS inspiral horizon is calculated for neutron stars of 1.4 solar masses and optimal orientation for GEO 600.

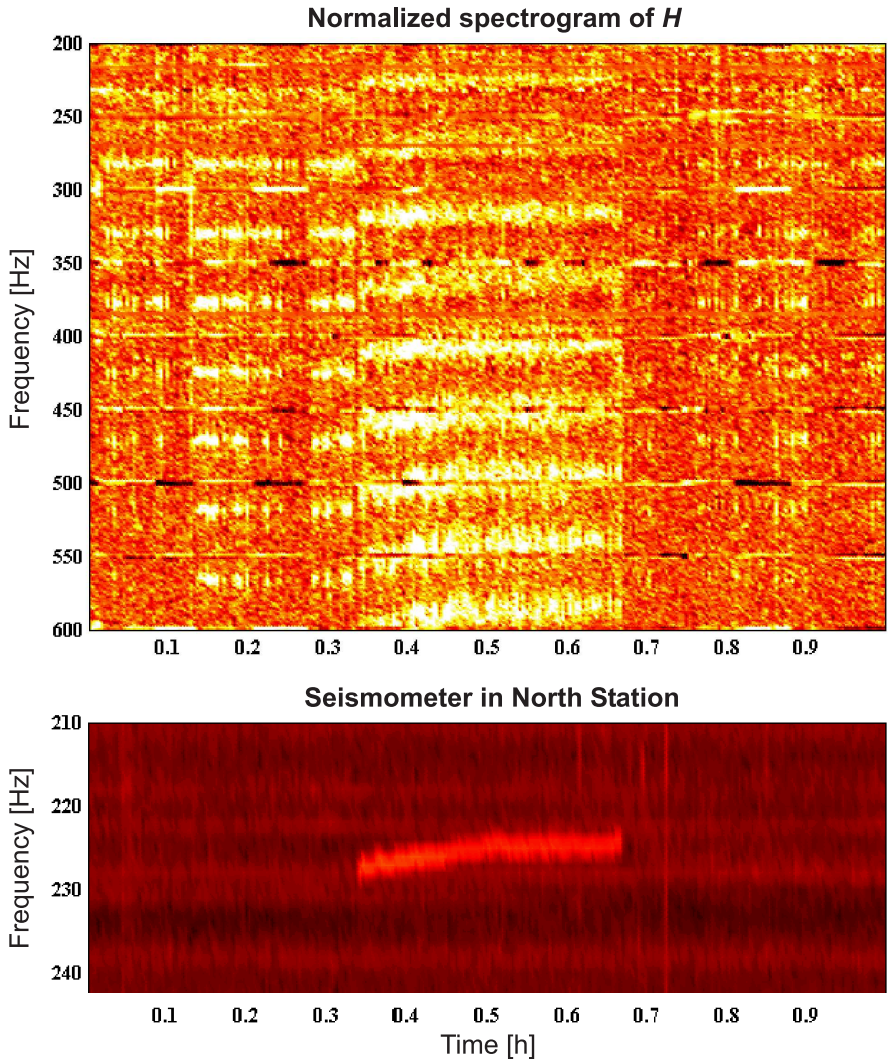

Figure 3.14.: Normalized spectrograms of H and the seismometer in the north end station. Orange pixels indicate the average value, black pixels show values below the average and white pixels indicate values above the average, i.e. excess noise. In H we find two different sets of ripple noise. The first class are weak ripples with frequencies corresponding to n*47 Hz, present for example at hour 0.2, 0.3 and 0.9. The second class of ripple noises are the strong n*45 Hz ripples, present in the period from hour 0.35 to 0.65. The frequency of this class changes slightly between hour 0.35 and hour 0.5. The same drift is observed in the fifth harmonic of 45 Hz in the seismometer signal from the north station. This gives a very strong indication for the n*45 Hz ripples be generated by seismically driven stray light generation in the north end station.

MFn is clipped at the too small view port.

In order to eliminate the n*45 Hz ripples we plan in a first step to reduce the seismic excitation in the north station. If that does not give enough reduction of the ripples we plan in a second step to open the vacuum system and exchange the view port by a larger one.

So far I only described the class of n*45 Hz ripples. As can be seen in Figure 3.14 we also observed a second class of ripples with a fundamental frequency of 47.2 Hz. The origin of these ripples is still under investigation.

3.8. Summary

Stray light is one of the main noise sources in gravitational wave detectors. Tiny amounts of phase shifted stray light can cause sensitivity limiting excess noise. A well known class of stray light noise is the scattering shoulder which was observed in all currently operating gravitational wave detectors (see Figure 3.1). The stray light problem might even become more important in the next generation of gravitational wave detectors operating with up to 1000 times larger light powers.

In order to widen the understanding of stray light generation and propagation through the interferometers, in this work a device was developed able to generate stray light with a controllable phase shift. With the aid of this device stray light injections have been carried out and it was proven that the stray light behavior and transfer can be explained in a purely linear coupling scheme.

Furthermore in Section 3.3 a rough guide is given which indicators point to stray light problems. A powerful tool to identify the origin of the scattered light in auxiliary beam paths, the so called filter experiment, was presented in Section 3.4.

In order to avoid stray light problems some simple rules have to be observed:

- Avoid the presence of a beam waist in auxiliary beam paths in air.
- If you cannot avoid the presence of a beam waist, do not place a optical component close to it.
- Only use low scatter optics, preferably with sub-angstrom surface finish and ion-beam-sputtered dielectric coatings.

- Always properly dump any secondary beams.
- Reduce movement of optical components by using stiffer mounts.
- Less seismic and acoustic excitation helps.

After two years of nearly continuous work on stray light problems in GEO 600 we now have a good understanding of scattering and know which aspects have to be taken into account for the design of next generation detectors.

Chapter 4.

Photon pressure calibration

4.1. Introduction

The production of a precisely calibrated output stream of a gravitational wave detector is one of the most challenging detector characterization tasks. An accurate calibration is essential for any multi-detector analysis. A lot of research effort is currently focussing on the use of null-stream construction [Wen05]. Null-streams combine the outputs of multiple detectors in order to produce a data stream containing no GW information, which can be used for veto analysis. However, it is clear that if the strain signals from the individual detectors are subject to systematic calibration errors then the resulting null-stream will not be truly null and could contain residual traces from any detected GW signal. Another class of multi-detector analysis, requiring high calibration accuracy are coherent analysis (for example, when searching for pulsar signals [Dupuis05]) where phase inaccuracies could potentially destroy a signal.

For the official calibration of the GEO 600 detector, we use an on-line time-domain technique to produce two calibrated signals, each potentially containing gravitational wave information, one for each output quadrature, P and Q [Hewitson04]. These two calibrated data streams are then optimally combined, using a maximum likelyhood method, in order to give a single signal with the best snr at all frequencies, H [Hewitson05].

The calibration of a gravitational wave detector can in general be split into two parts. The *absolute* calibration is given by a single overall factor, while the *relative* calibration represents a frequency dependent contribution. The absolute calibration of GEO 600 is a rather complicated procedure. In order to obtain a calibration for the ESD, the main actuator for the differential arm length of the interferometer, the ESD is first calibrated

back to the common mode error point of the frequency stabilization loop, which is then calibrated back through the mode cleaners to the frequency of the master laser, which is finally calibrated by using the well known free spectral range of the first mode-cleaner. Besides accumulating errors due to the many steps involved, this procedure implicates some drawbacks: some of the measurements can only be performed with low SNR and others are limited to be carried out in a certain frequency range. Furthermore, the procedure, which takes about on day on the whole, needs to be done partly with an unlocked interferometer, which means that the detector is not taking science data for the duration of the measurements.

Given the facts stated above, it is highly desirable to find new methods for providing an independent calibration of the gravitational wave detector. One approach is to use intentionally induced gravity gradients to apply a well known force to one of the test masses [Mantone06], [Hild04]. One proposal for such a "gravity calibrator" employing 3 masses rotating in a commercial spin dryer can be found in Appendix F. Another method is to use the photon pressure of a power modulated laser beam in order to apply a force to the test mass [Weiland04], [Mossavi06]. The mayor advantage of this method is that the displacement of the test mass, $x(\omega)$, is given in the ideal case by the simple relation:

$$x(\omega) = \frac{2 \cdot P}{M \cdot c \cdot \omega^2} \tag{4.1}$$

where P is the modulated light power, M is the mass of the test mass, c represents the speed of light and ω is the modulation frequency of the calibration signal. All values going into Equation 4.1 are, in principle easily measurable to a high precision. Figure 4.1 shows the corresponding (idealized) pendulum response of the lowest stage of a GEO main suspension. For frequencies much larger than the resonance frequency the magnitude of the response is analogous to Equation 4.1 proportional to $1/f^2$, and the pendulum follows the excitation with a phase shift of ϕ = -180 deg.

4.2. Experimental setup of the photon pressure calibrator

An optical layout of the north end station of GEO 600 where the photon pressure calibrator is currently installed is shown in Figure 4.2. The beams from the main interferometer are drawn in red color. A small fraction of the light hitting MFn from the south is transmitted through the test mass. It then leaves the vacuum system via a view port,

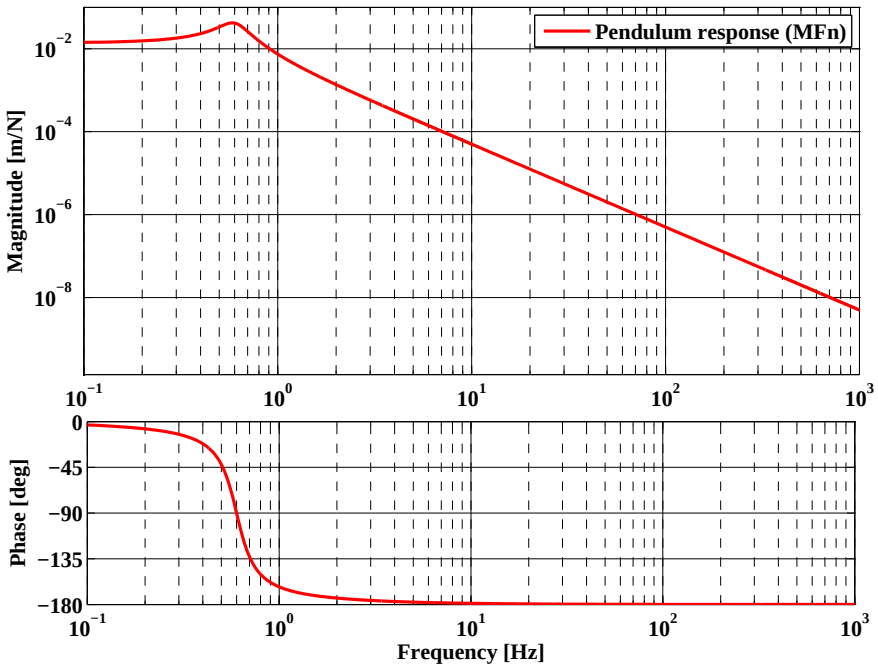

Figure 4.1.: Response function of the lowest stage of a GEO 600 main pendulum. For frequencies much larger than the resonance frequency the pendulum follows with a phase shift of ϕ = -180 deg.

is focused down by a lens (LNB) and is finally detected on the north bench by a spot position detector (PSDNB) and a CCD (CCDNB), both used for alignment control. As this auxiliary beam is essential for the alignment control of the main interferometer we cannot allow for any disturbance in its beam path, which sets some restrictions for the setup of the photon pressure calibrator.

The GEO photon pressure calibrator uses a fiber-coupled laser-diode with a wavelength of 1035 nm as a light source. After the light leaves the fiber it is collimated by a lens (collimator) of 60 mm focal length. The converging beam enters the vacuum via the view port and has a waist of about 5 mm diameter at the front surface of MFn. The PCAL beam (green in Figure 4.2) first passes the AR coating at the back surface of MFn and travels through the test mass substrate, made of fused silica, before it gets reflected at the HR coating. Then the PCAL beam passes the substrate and the AR coating a second time, leaves the vacuum system again via the view port and is finally dumped at the north bench. Some problems are connected to the setup described above. The beam profile provided by the laser diode is not a TEM_{00} and quickly diverges after being reflected at the test mass. Therefore, clipping of the outgoing beam at the small view port (radius = 4 cm) cannot be ruled out, thus a reliable measurement of the reflected light power is not accessible. Furthermore, the PCAL beam does not pass the view port and the mirror under normal incidence. Even though the angle is only about 2 degrees, effects depending on the polarization of the light may occur.

4.2.1. Measurement of the modulated light power

As described in the previous section the main disadvantage of the actual photon pressure calibrator setup is the fact that the light power reflected from the test mass is not accessible via any easy measurement. Therefore the light power is measured by an internal monitor photodiode connected to the laser diode. This signal is recorded in the DAQS and will be referred to as PCALmon in the following. PCALmon was calibrated at DC using a calibrated power meter. The measurement of the light power is then propagated through the collimator lens ($T_{\mathrm{lens}} = 0.9988$) and the view port ($T_{\mathrm{vp}} = 0.9986$)[1]. The reflection of the AR coating and the transmission of the HR coating can be neglected since both are, according to their specifications, clearly below a tenth of a

[1] As the transmission of the currently used view port cannot be measured in situ, the given value was measured at a spare view port with identically specified properties.

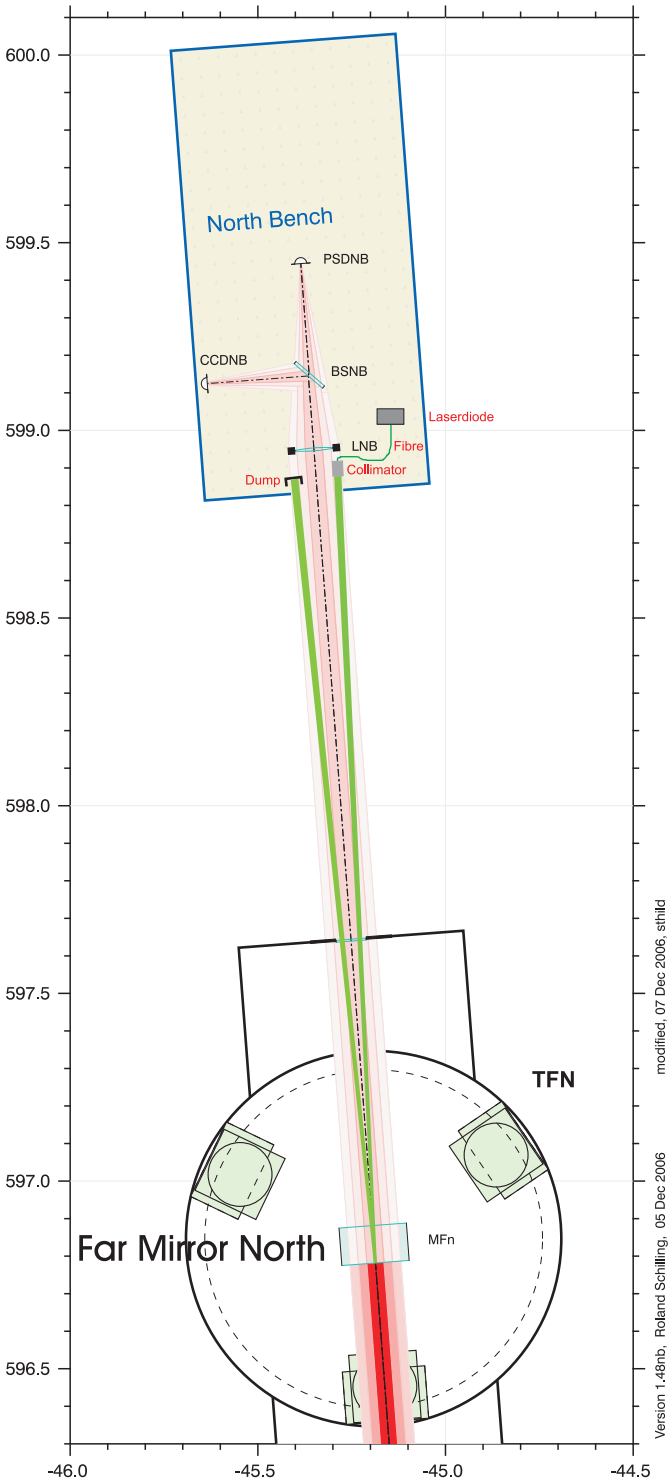

Figure 4.2.: OPTOCAD layout of the optics in the north end station of the GEO 600 detector, including the setup of the photon pressure calibrator.

percent. Again a direct in situ measurement of these two coatings is not possible.

However, a reliable measurement of the reflected DC light using a large lens (LNB on Figure 4.2) to collect all the light leaving the vacuum, showed that only 77 % of the light power entering the vacuum are leaving it afterwards. This strong power loss can only be explain by absorbtion due to dirty optics. Again an in situ measurement of the losses is not possible without opening the vacuum system. Venting the vacuum system was not possible due to the high risks involved, such as breaking a fused silica fibre of the quasi-monolith mirror suspension.

The unexplained loss of 23 % is the largest limitation of absolute accuracy of this setup. Depending on the position of the losses, any calibration derived from this photon pressure calibrator may be wrong by 23 % !! For all investigations in this chapter we will assume symmetrically distributed losses, meaning that 11.5 % of the light power are lost in front of the HR coating and 11.5 % are lost after the HR coating.

Altogether, the effective light power is estimated in the followin way

$$P[\mathrm{W}] = \mathrm{PCALmon}[\mathrm{V}] \cdot T_{\mathrm{lens}} \cdot T_{\mathrm{vp}} \cdot K_{\mathrm{pm}} \cdot (0.885 \pm 0.115) \tag{4.2}$$

where K_{pm} includes the calibration of the power meter and the calibration from PCALmon to the power meter.

4.3. Injections with different amplitudes

Injections using the photon pressure calibrator have been performed with different amplitudes in order to check that the response of the system is linear with respect to the amplitude of the modulated light power. A sine wave of 134 Hz has been injected with four different amplitudes, between 50 and 500 mW.

Figure 4.3 shows the analysis of this measurement. In the upper figure the magnitude of the transfer coefficient from PCALmon to H is plotted over the amplitude of the modulated light. The mean is indicated by red dashed line. The lower figure shows the deviation of each measurement point from the mean. We observe that the response function of the photon pressure calibrator is linear within ±4 % for different amplitudes of the modulated light power.

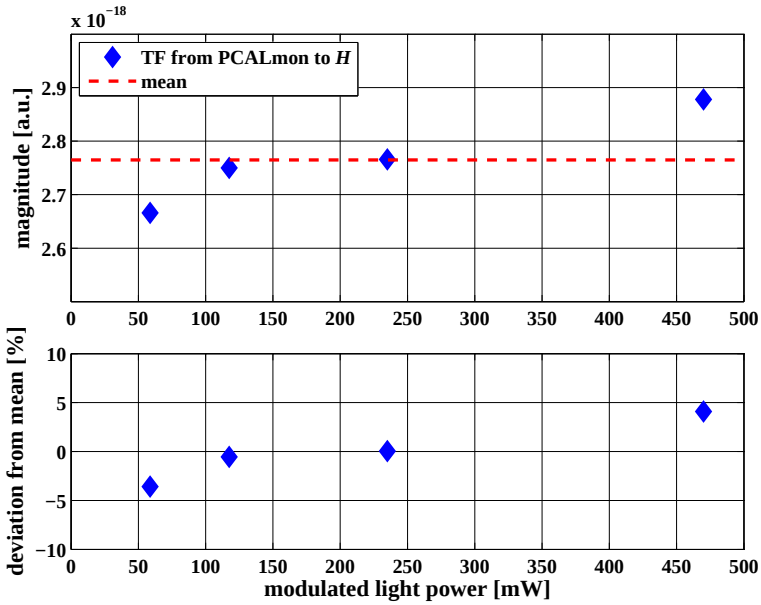

Figure 4.3.: Measurement of the transfer coefficient from PCALmon to H for various amplitudes of the modulated light. The upper plot shows the magnitude of the transfer coefficient (blue diamonds) and the mean (red dashed line). In the lower plot the deviation of each measurement from the mean is plotted. All measurements agree within $\pm 4\,\%$ with the mean.

4.4. Injections with different frequencies

One of the main goals of the experiments using the photon pressure calibrator is to check the relative accuracy (frequency dependence) of the official calibration. Therefore injections over the full detection band have been performed. Due to the strongly decreasing response ($1/f^2$) of the system it is not possible to get identical SNR at all frequencies. Especially towards high frequencies only small SNR could be achieved and the uncertainties of the measured value originating due the noise floor needs to be taken into account. Analogous to measuring the amplitude of an ESD line, described in [Koetter03], the amplitude of a photon pressure calibrator injection, A_{pcal}, can be approximated by

$$A_{\mathrm{pcal}} = \sqrt{V_{\mathrm{pcal}}^2 - \eta^2}, \tag{4.3}$$

where V_{pcal}^2 is the power measured in the frequency bin containing the injection and η^2 represents the averaged power of noise floor in the frequency bins around the injection.

Figure 4.4 shows the result of photon pressure calibrator injections at various frequencies. Each point is derived from a measurement that uses 2 minutes of data for computing a single FFT.[2] The blue diamonds are the amplitudes of the injections, A_{pcal}, as seen from the GW channel, which represent the official calibration. The red circles show the amplitude of the PCAL injection predicted from PCALmon, $A_{\mathrm{pcal}}^{\mathrm{theo}}$, using Equation 4.1 and represent the photon pressure calibration. Above 3 kHz the measurements are not accurate due to too low SNR as indicated by the measurement of the noise floor (green stars). At all frequencies the injections show up smaller in the official calibration than expected from the photon pressure calibration. Furthermore the discrepancy between the two calibration methods is observed to vary with frequency. Especially towards higher frequencies the deviation seems to increase strongly. The ratio of the calibration derived from the photon pressure calibrator and the official calibration is plotted over frequency in the upper subplot of Figure 4.5. The red circles are calculated assuming the observed power loss of 23 % (see Section 4.2.1) is caused half on the way in and half on the way out of the vacuum system. The two blue dashed lines indicate the extremes, i.e. all 23 % lost on the way in and all 23 % lost on the way out. The observed

[2] In order to get best SNR in this measurement we have to choose a high frequency resolution. The frequency bin to be analysed is determined automatically by the used MATLAB script by finding the frequency bin of maximum power in the amplitude spectrum of PCALmon. The full MATLAB code used for these investigations can be found in Appendix E.

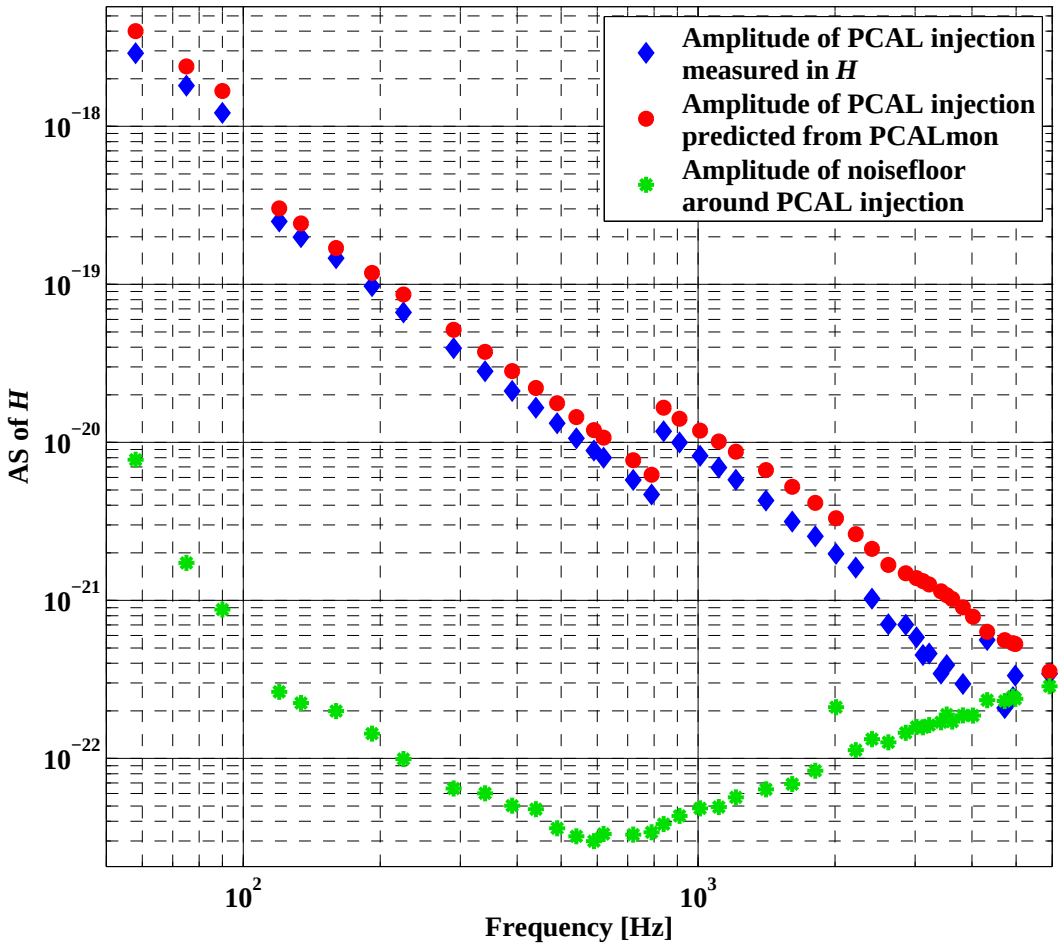

Figure 4.4.: Photon pressure calibrator injections for various frequencies. The blue diamonds represent the amplitude of the injections, A_{pcal}, already corrected for the noise floor using Equation 4.3. The red circles show the amplitude of the PCAL injection predicted from PCALmon, $A_{\mathrm{pcal}}^{\mathrm{theo}}$, using Equation 4.1. A discrepancy between the official calibration (blue diamonds) and the calibration derived from PCAL (red circles) is observed. Above 1 kHz the discrepancy seems to quickly increase. For frequencies higher than 3 kHz the measurements are not accurate due to too low SNR as indicated by the measurement of the noise floor (green stars). The injections in the frequency band from 100 to 800 Hz were performed using a smaller amplitude.

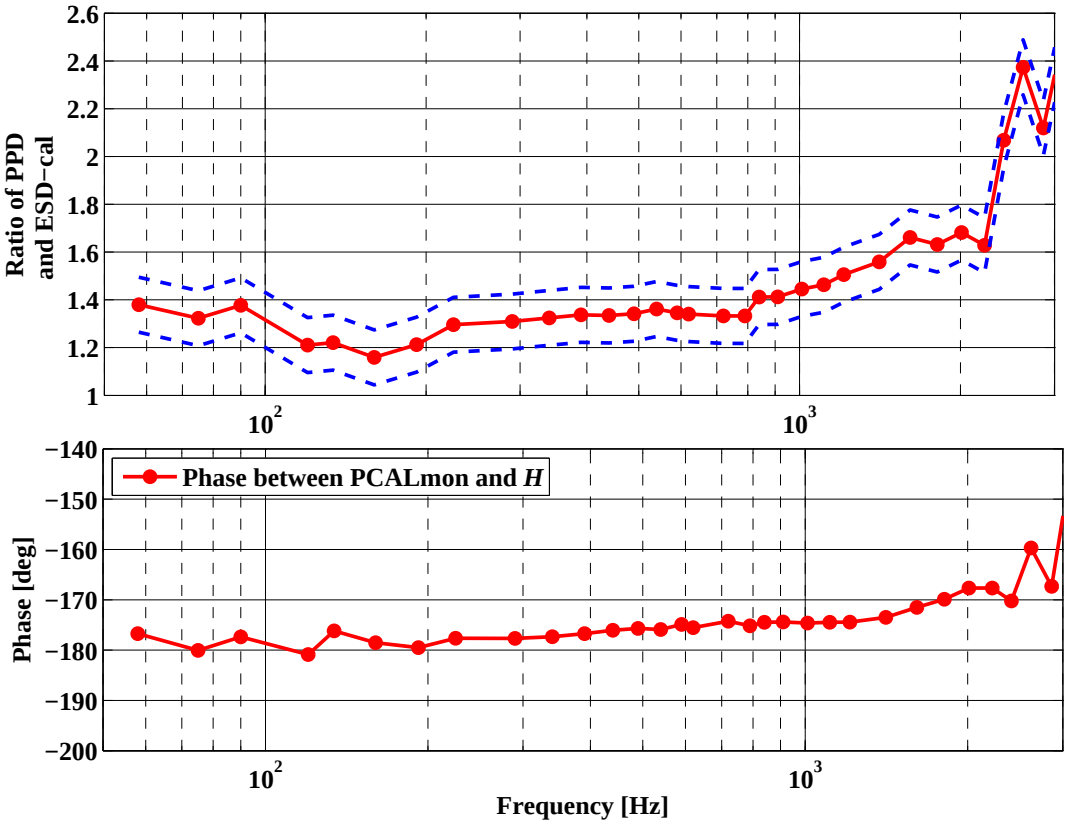

Figure 4.5.: *Upper plot*: Ratio of the photon pressure calibration and the official calibration versus frequency. The blue dashed lines indicate an uncertainty of ±11.5 %, caused by the observed power loss of 23 % (see Section 4.2.1). The observed discrepancy between the two calibration methods is on average about 20 to 40 % for frequencies below 1 kHz. Above 1 kHz the discrepancy quickly increases to about 120 % at 3 kHz. *Lower plot*: Phase relation between injected light power (PCALmon) and H. For all frequencies below 1 kHz the phase is -180 degrees within 5 degrees. Above 1 kHz the phase starts slowly to go off and reaches about -160 degrees at 3 kHz.

discrepancy between the two calibration methods is on average about 20 to 40 % for frequencies below 1 kHz. Above 1 kHz the discrepancy quickly increases to about 120 % at 3 kHz. The lower subplot of Figure 4.5 shows the phase relation between injected light monitored by PCALmon and H at the frequency of the injection. As we would expect from the pendulum response the phase is about -180 degrees. For all frequencies below 1 kHz the phase is -180 degrees within 5 degrees. Above 1 kHz the phase starts slowly to go off and reaches about -160 degrees at 3 kHz.

The discrepancy between the two calibration methods is surprisingly large, especially considering that the official calibration is, as we will see in Section 4.5, strongly believed to be correct. The observed deviation can roughly be separated into two phenomena: First of all there seems to be an absolute discrepancy of 20 to 40 % showing up equally at all frequencies. Secondly, at high frequencies the relative deviation increases strongly; the response of the photon pressure calibrator does not follow the $1/f^2$ expected from the pendulum response.

One effect that could explain the absolute mismatch is photon pressure calibrator induced test mass misalignment, which will be described in detail in Section 4.8. To find a mechanism that can explain the frequency dependent discrepancy seems to be harder. Any kind of potential beam clipping should occur frequency independent. Also the above mentioned photon pressure calibrator induced test mass misalignment or polarization related problems can only explain a frequency independent error. As will be shown in Section 4.7 the behavior of the photon pressure calibrator at high frequencies might be explainable by photon-pressure-induced non-rigidity of the test mass.

4.5. Validation of the official calibration

So far we compared the official calibration with the calibration derived from the photon pressure calibrator. The observed discrepancy can of course originate from either the official calibration being wrong, the photon pressure calibrator being wrong or both being wrong. There is no easy way to distinguish these three possibilities. However, the official calibration of GEO 600 was repeated and evaluated several times by several people over the last few years. Therefore the official calibration is strongly believed to be correct within 10 % in magnitude and 20 degrees in phase for frequencies between 50 and 2000 Hz. This statement includes the absolute calibration accuracy as well as the

relative calibration accuracy. Two validation measurements important for the context of this work are presented in the following.

4.5.1. Transfer function from ESD to H

The frequency dependent discrepancy between the official calibration observed in Section 4.4 could also be explained by a potential relative error of the official calibration. In order to rule out any relative inaccuracy in the official calibration we performed noise injections into the electro static drives (ESD) and measured the transfer function from the input of the ESD to H.

The electro static drives are believed to have a flat frequency response for all frequencies of interest. We would therefore expect to find the transfer function from the ESD to H to follow a $1/f^2$-law, originating from the pure pendulum response. The correctness of the ESD model was checked by white-noise injections in the power-recycled Michelson mode, where the optical response is known to be flat.

Figure 4.6 shows the measurement of the corresponding transfer function for frequencies between 50 and 2000 Hz. The signal was injected at the last OP of the electronics controlling the Michelson differential arm length. Then the transfer function from the feedback monitor of high voltage amplifiers (HVA) to H was computed and corrected for the responses of the dewhitening filters installed behind the high voltage amplifiers. As the upper subplot of Figure 4.6 indicates the transfer function is very close to an $1/f^2$-behavior. In center plot Figure 4.6 the deviation from an $1/f^2$-fit is shown. In the lower plot of Figure 4.6 the phase of the transfer function is plotted versus frequency.

Overall we can state that this measurement confirms a relative calibration accuracy of $\pm 10\,\%$ in magnitude and ± 5 degree in phase is achieved for frequencies between 50 and 2000 Hz.

4.5.2. ESD injections up to high frequencies

As already stated at the beginning of this chapter the main purpose of a calibration based on the photon pressure calibrator is to get an absolute and relative comparison to the official calibration. To get a measure to compare the photon pressure calibration to we have to make sure that we compare it to a meaningful measure. Therefore we have

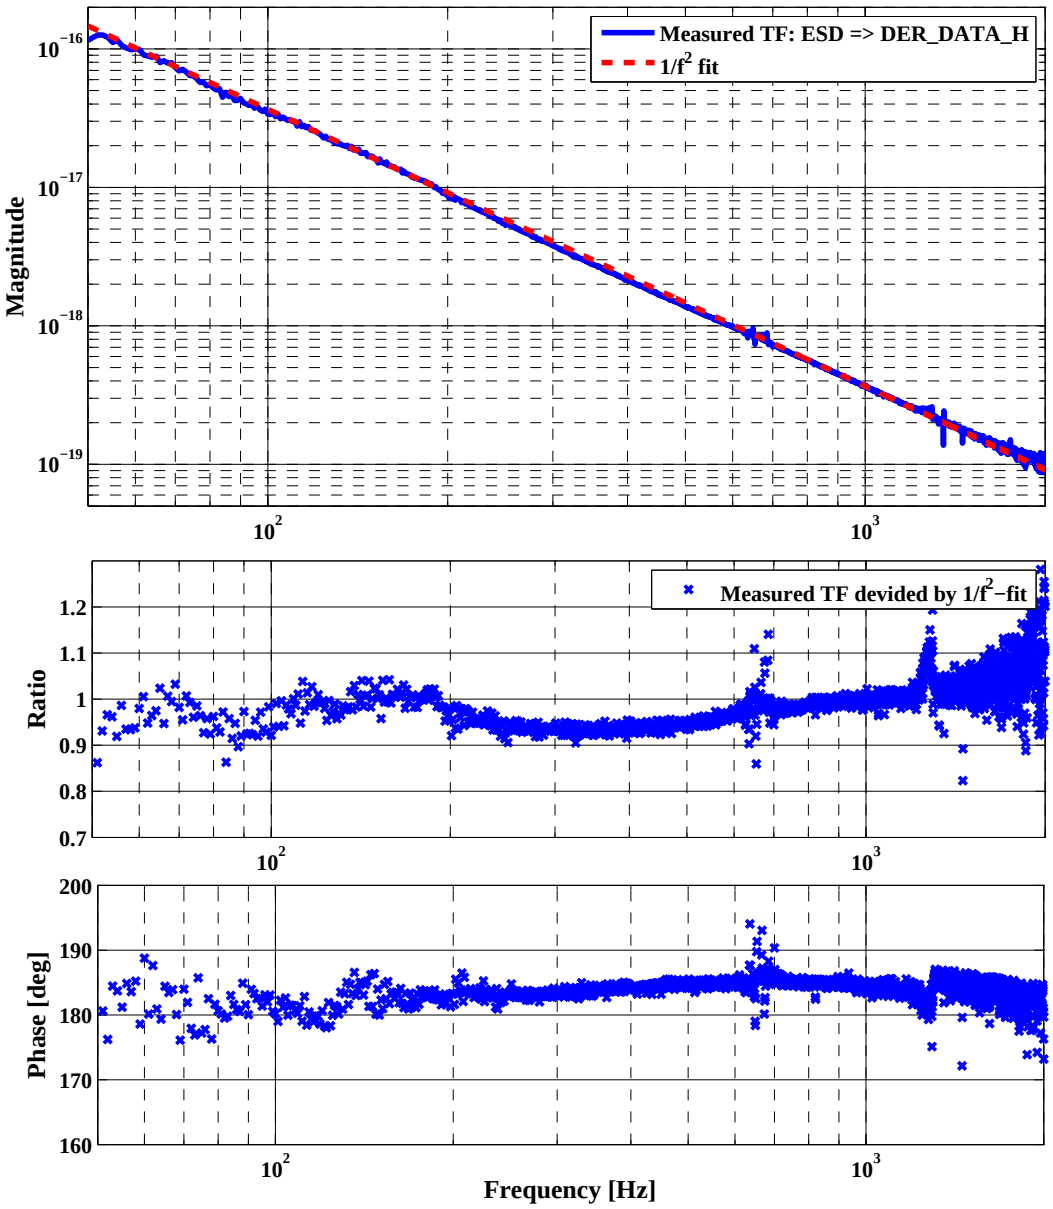

Figure 4.6.: Measurement of the transfer function from the input of the ESD to the calibrated output of GEO 600, H. *Upper plot*: Measurement of the transfer function (solid, blue line) and a corresponding $1/f^2$-fit (dashed, red line). Above 1.5 kHz the accuracy of the measurement goes slightly down due to low SNR of the measurement. *Center plot*: Ratio of the measured transfer function and the $1/f^2$-fit. *Lower plot*: Phase between the injected signal and H. Overall a relative calibration accuracy of $\pm 10\,\%$ in magnitude and ± 5 degree in phase is achieved for frequencies between 50 and 2000 Hz.

to validate the official calibration to the best of our knowledge before we can use it as an 'absolute standard'.

Most of the astrophysical analysis using data from GEO 600 consider only frequencies up to 2 kHz. That is why so far the calibration was examined only up to this frequency. However, some of the measurements presented in this chapter are performed at frequencies as high as 6 kHz. Therefore we have to make sure that a reasonable relative calibration accuracy is given also at higher frequency. The method we can use for this investigation is similar to the one described in Section 4.5.1, but at high frequencies we have to inject single discrete lines instead of broadband noise in order to get a sufficient SNR in the measurement.

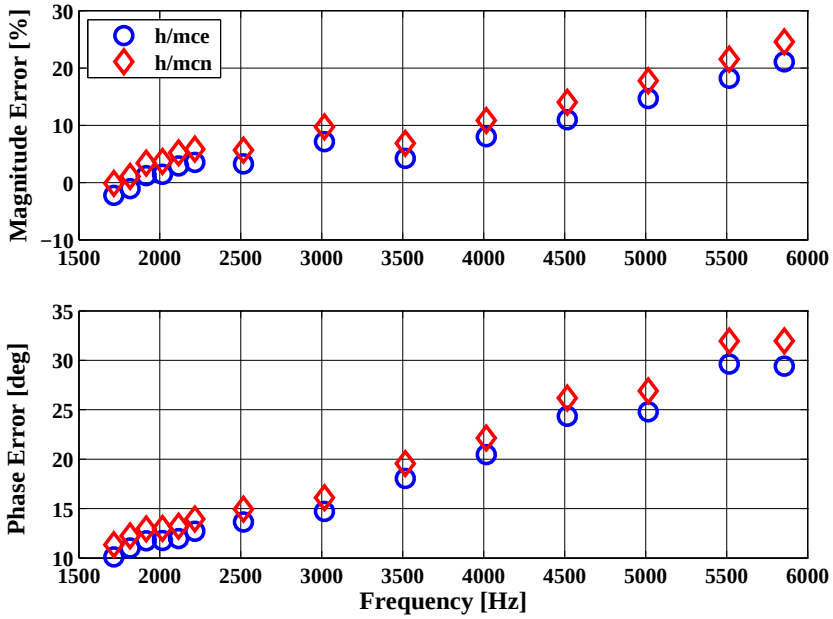

Figure 4.7.: Measurement of the relative calibration accuracy of the official calibration for high frequencies. Plotted are the differences between the official calibration (H) and the propagation of the injections through the loop model for two individual ESD at MCe and MCn. The analysis of this injections was provided by J.R.Smith.

Figure 4.7 shows the analysis of the high frequency ESD injections. The magnitude and phase of the injections measured in the officially calibrated data are compared to the expected values from propagating the injections through the loop model for each for the

two ESD, MCe and MCn. Compared to the measurements at 2 kHz for frequencies up to 6 kHz the relative error in the official calibration increases by 20 % in magnitude and 20 degrees in phase.

The relative errors of the official calibration are in summary:

- For frequencies below 2 kHz: 10 % in magnitude and 5 degree in phase.
- For frequencies between 2 and 6 kHz: 20 % in magnitude and 30 degree in phase.

4.6. The phase picture

The observed discrepancy of the official calibration and the photon pressure calibration can only be explained in the presence of an additional unknown effect, I will call "mystery effect" in this section, that adds to the pendulum response. As I will show in this section

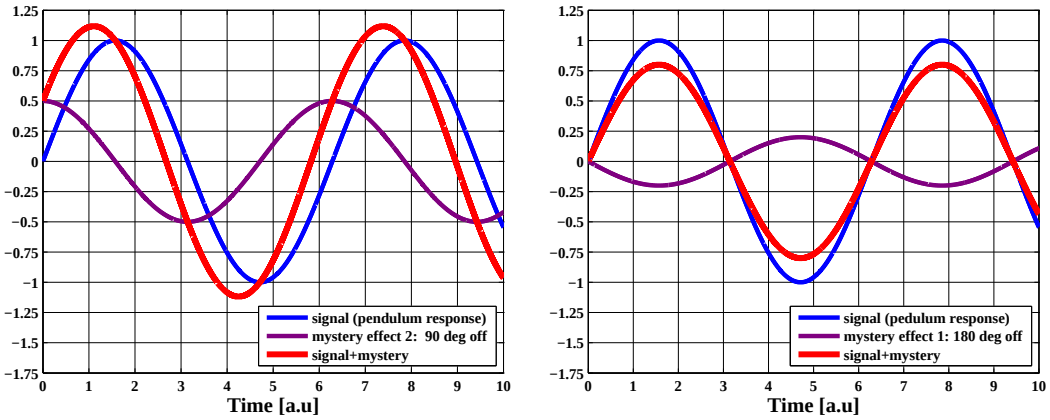

Figure 4.8.: The observed discrepancy of the official calibration and the photon pressure calibration might be explainable by an additional "mystery" effects adding to the pendulum response. *Left plot*: If the mystery effect is 90 deg off phase with the pendulum response the overall response would be increased (and the phase shifted). Therefore such n "mystery" effect cannot explain the observations of smaller overall response (and a constant phase of -180 degree). *Right plot*: Only a mystery effect 180 degrees off phase from the pendulum response can explain the observation of a reduced overall response (and a constant phase of -180 degrees).

the measurements shown in Figure 4.5 already contain very strong boundaries for the

behavior of the unknown "mystery" effect. In order to explain the absolute and the relative discrepancy of the two calibration methods, the "mystery" effect has to add to the pendulum response in a way that, first of all the overall response gets smaller in amplitude, and secondly the phase of the overall response still stays at -180 degrees. As indicated by Figure 4.8 these two conditions can be satisfied by an effect that is 180 degrees out of phase from the pendulum response, or in other words, an effect that is in phase with the modulated light of the photon pressure calibrator.

4.7. Non-rigidity of the test mass

The widely held assumption with in the GW-community so far has been that a test mass acts like a rigid body for frequencies below the first internal resonance. However, no quotable reference could be found that documents or proves this hypothesis.

In fact, in this section I will present some investigations disproving the theory of test masses being rigid bodies at low frequencies.

The idea of this traditional model is that a mirror for all frequencies below its first internal mode, which is for the GEO test masses around 11 kHz [Smith04], behaves equivalent to any other oscillator:

- It just follows the excitation without any phase lag (phase difference = 0 degree)
- The response is flat in frequency and equals the response at a frequency of 0 Hz (DC).

However, obviously at DC we can (to a tiny amount) compress any piece of glass by pushing from both sides, or stretch it by pulling on both ends. In a linear setup the amount of the compression (or elongation) ΔL only depends on the Young's module E_{young} of the material and the geometry of the test body

$$\Delta L = \frac{1}{E_{\text{young}}} \frac{L \cdot F}{A}, \tag{4.4}$$

where L is the length and A the cross section of the test body and F is the applied force.

The beam of the photon pressure calibrator hits the high reflective coating of the test mass and pushes at the surface of the mirror. Due to the inertia of the test mass the

force applied to the surface causes a deformation of the test mass. In order to find out whether this effect can be responsible for the strong discrepancy between the official and photon pressure calibration observed at frequencies around a few kHz, the main question we have to answer first is if the effect from force-induced mirror-deformation is roughly of the same size as the center of mass movement of the test mass induced by the photon pressure calibrator. In Section 4.7.1 a rough estimation is given using a very simple model, while in Section 4.7.2 a finite element analysis of the problem is presented.

4.7.1. Rough estimation of photon pressure calibrator induced test mass deformation

As we first just want to get an estimation of the order of magnitude of any effect related to photon pressure calibrator-induced mirror-deformation, we can use a simplified model using the following assumptions:

- The beam of the photon pressure calibrator has a flattop profile and illuminates the full mirror.
- The backplane of the test mass is fixed in position.

In this case we can simply apply Equation 4.7. With the parameters of the GEO test masses $L = 0.1\,\mathrm{m}$ and $A = \pi \cdot 90^2\,\mathrm{mm}^2$, Young's module for Suprasil of $E_{\mathrm{young}} = 7 \cdot 10^4 \mathrm{N/mm}^2$ [Heraeus] and a photon pressure induced force $F = 2.25 \cdot 10^{-9}\,\mathrm{N}$ (750 mW light power) we obtain a homogenous elongation of the test mass of:

$$\Delta L = 1.26 \cdot 10^{-19}\mathrm{m} \tag{4.5}$$

This corresponds to an apparent strain H_{def} of

$$H_{\mathrm{def}} = 2.1 \cdot 10^{-22}. \tag{4.6}$$

If we now compare this result with the measurement shown in Figure 4.4 we find that for high frequencies (a few kHz) this effect might have some non negligible influence. In conclusion that means that we have to evaluate this effect with a more realistic model, which is presented in the next section.

4.7.2. Finite element analysis of photon pressure calibrator induced test mass deformation

The finite element method (FEM) is a numerical technique to simulate complex mechanical and thermal setups. This type of analysis is widely used in engineering and has proven its reliability. One of the most powerful tools for finite element analysis (FEA) is the software ANSYS [Ansys], which was used for the analysis described below. The FEM simulation presented here was done by our colleagues from Glasgow: I.Martin, S.Reid and J.Hough.

The test mass (diameter = 18 cm, thickness = 10 cm, bulk material = suprasil) is represented by 87000 discrete nodes. A total force of 2.77 N (diameter = 5 mm, gaussian profile) is applied to the center of the front surface of the test mass.[3]

Figure 4.9 shows the setup and the result of the analysis. In the simulation the force is applied from the outside to the front surface of the test mass while in the photon pressure calibrator setup the test mass surface is pushed from inside. Since the deformation depends on the intermolecular forces, which can, for small deformations, be assumed to be linear, the simulated setup is equivalent to the photon pressure calibrator setup. The lower subplot of Figure 4.9 shows the resulting displacement in z-direction (along the axis of the main interferometer beam). The simulation and the corresponding result are rotationally symmetrical. The area of the front surfaces, illuminated by the photon pressure calibrator beam, is locally squeezed. The maximum displacement of $5 \cdot 10^{-9}$ m occurs in the center of the front surface.

4.7.3. Effective test mass displacement

The displacement measured by the interferometer is determined by the overlap of the photon pressure calibrator beam and the main interferometer beam, which can be described by a gaussian beam. The radial intensity, $I(r)$ is given by

$$I(r) = exp\left(\frac{-2r^2}{\omega^2}\right) \tag{4.7}$$

where ω is the radius of the beam. At the north end mirror the radius of the main interferometer beam is about 2.4 cm. Each point of the mirror surfaces contribution

[3] The test mass is held in place using a inertial relief function.

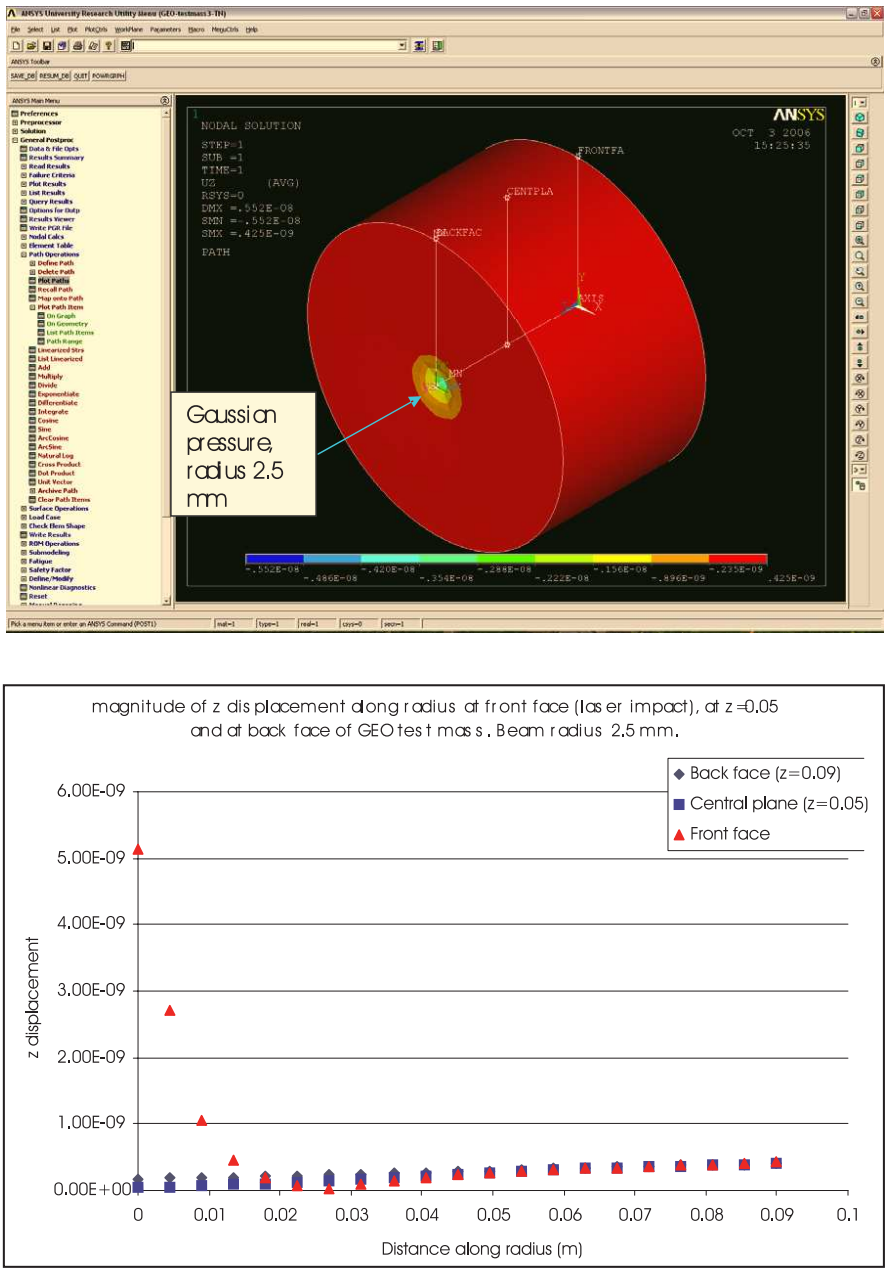

Figure 4.9.: *Upper plot*: Finite element model (FEM) of the deformation of a GEO test mass caused by the beam of the photon pressure calibrator. A total force of 2.77 N (diameter = 5 mm, gaussian profile) is applied to the center of the front surface of the test mass. The test mass is held in place using a inertial relief function. The analysis was done using the ANSYS software [Ansys]. The mirror was modelled by 87000 nodes. *Lower plot*: Result of this analysis. Plotted is the displacement over the radius of the test mass. The whole FEM analysis was provided by our colleagues from Glasgow: I.Martin, S.Reid and J.Hugh.

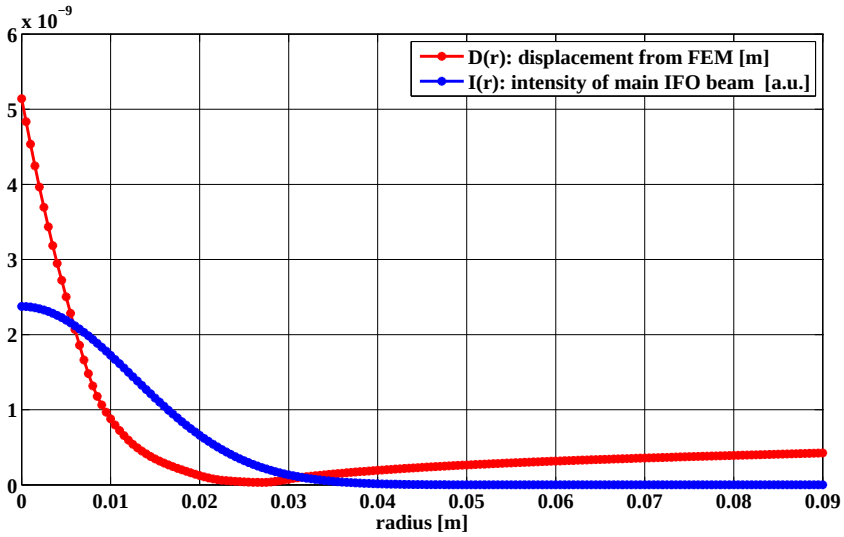

Figure 4.10.: Radial profile of the photon pressure calibrator induced test mass deformation, $D(r)$, and the intensity of the main interferometer beam, $I(r)$. The effective displacement of the test mass measured by the interferometer depends on the overlap of these two functions and is proportional to the $I(r) \cdot D(r)$.

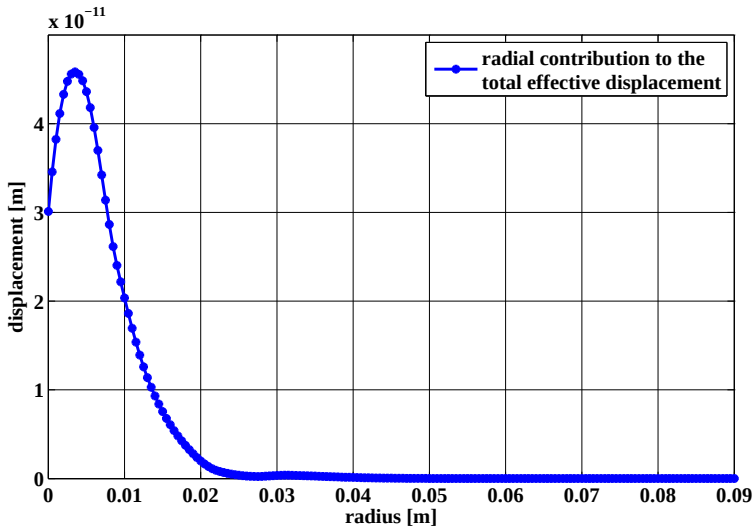

Figure 4.11.: Radial contribution to the effective displacement for photon pressure calibrator induced test mass deformation computed using Equation 4.8. The total effective displacement amounts to $7.57 \cdot 10^{-10}$ m.

to the total effective displacement, D_{total}, weighted by the product of the power of the main interferometer beam, $I(r)$, and the corresponding displacement $D(r)$. For a radially symmetric setup, as described above, the total effective displacement can be expressed by a single integral:

$$D_{\text{total}} = \int_0^{0.09\text{m}} \int_0^{2\pi} D_{\text{eff}} \cdot dr \cdot d\varphi = \int_0^{0.09\text{m}} 2\pi \cdot r \cdot k_I \cdot I(r) \cdot D(r) \cdot dr. \tag{4.8}$$

The factor k_I is a normalization factor for $I(r)$ in order to give

$$\int_0^{0.09\text{m}} 2\pi \cdot r \cdot k_I \cdot I(r) \cdot dr = 1. \tag{4.9}$$

Using Equation 4.8 the total effective displacement amounts to $7.57 \cdot 10^{-10}\,\text{m}$. Figure 4.11 shows the radial contribution to the effective displacement for photon pressure calibrator induced test mass deformation.

4.7.4. Comparison of pendulum response and mirror deformation

The last section showed that the test masses are not completely rigid and that the photon pressure calibrator beam really causes a non-negligible deformation. Next we have to evaluate how strong the displacement originating from the non-rigidity of the test mass is, compared to the displacement of the center of mass (originating from the pendulum response). Since both responses are linear for the applied light power of the photon pressure calibrator we can simply compare their responses.

The pendulum response, α_{pen}, follows a $1/f^2$-law for frequencies above 100 Hz, has a magnitude of $5 \cdot 10^{-7}\,\text{m/N}$ at 100 Hz and is 180 degrees out of phase with the power modulation (see Figure 4.1). The response of the mirror deformation, α_{def}, is assumed to be flat in frequency and in phase with the modulated light power for frequencies below the first internal resonances of the test mass. In Section 4.7.3 an effective displacement of $7.57 \cdot 10^{-10}\,\text{m}$ was found for an applied force of 2.77 N, which leads to a response of $2.73 \cdot 10^{-10}\,\text{m/N}$. The magnitude and phase of α_{pen} and α_{def} are shown in Figure 4.12, in blue (dashed) and red (dashed-dotted), respectively. The total response, α_{total}, plotted in green (solid) is the sum of the two individual responses:

$$\alpha_{\text{total}} = \alpha_{\text{pen}} + \alpha_{\text{def}}. \tag{4.10}$$

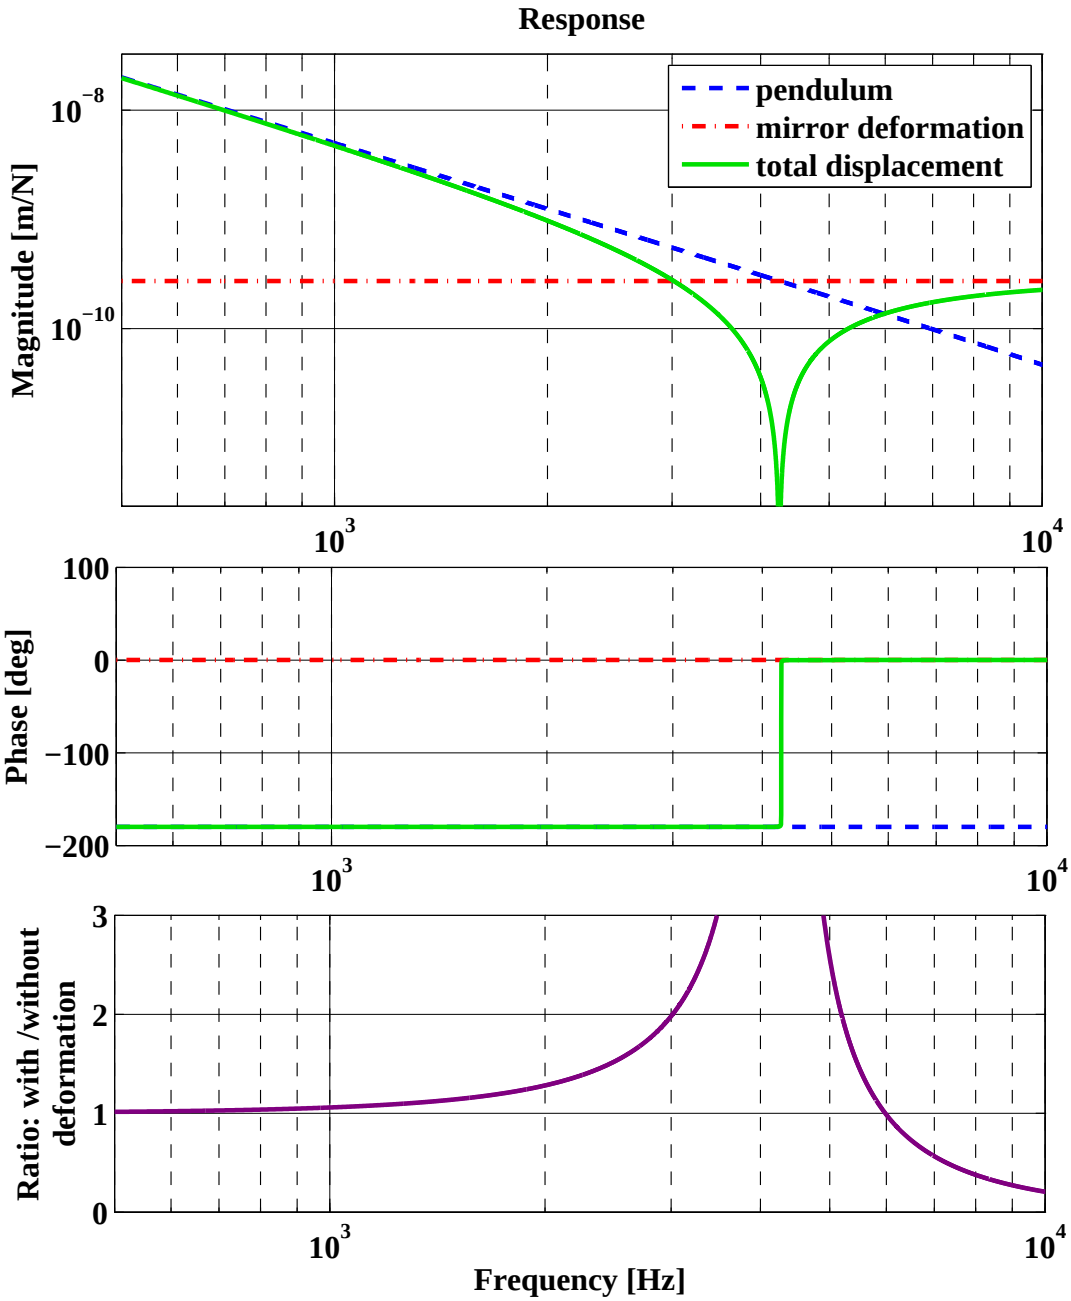

Figure 4.12.: Simple model for the photon pressure calibrator taking into account the responses from the pendulum and from the mirror deformation effect. The pendulum response follows a $1/f^2$-law and is 180 degrees out of phase from PCAL. The mirror deformation has a flat response and is in phase with PCAL. If both responses are added a notch appears at the frequency where both responses have equal size. The purple trace shows the expected discrepancy between the official calibration and photon pressure calibrator.

The total response shows a steep notch at the frequency where both individual responses have the same size and compensate each other completely due to having opposite phase. At the frequency of the notch the phase of α_{total} jumps from -180 to 0 degrees. The resulting discrepancy between the official calibration and the calibration derived from the photon pressure calibrator, including the effect from mirror deformation, is shown in lowest subplot of Figure 4.12.

In order to prove this model we have to do photon pressure calibrator injections up to higher frequencies. It will be difficult to find the notch in the magnitude of the response because at these frequencies the snr of any injected line is going the be very small, even for measurements of very long duration. However, the distinct change in phase should be measurable with reasonable effort.

4.7.5. High frequency injections using the photon pressure calibrator

Long duration injections using the photon pressure calibrator have been performed for frequencies in the range from 3 to 6 kHz. The snr of a periodic signal increases with the length of data used for a single FFT. This is due to the fact that by decreasing the width of the frequency bins, the noise contained in the signal-bin is decreased, while the signal stays constant. For the measurement presented in this section FFT containing between 2 and 10 hours of data were used. Such amounts of data[4] are difficult to handle with standard computers. This problem can be avoided by using a heterodyning technique. The time series of the data containing the signal of interest, $E_{\text{sig}} \cdot sin(\omega_{\text{sig}} t)$, is multiplied by a sine wave with a slightly lower frequency, ω_{het}:

$$E_{\text{sig}} \cdot sin(\omega_{\text{sig}} t) \cdot sin(\omega_{\text{het}} t) = \frac{1}{2} E_{\text{sig}} [cos(\omega_{\text{sig}} - \omega_{\text{het}})t - cos(\omega_{\text{sig}} + \omega_{\text{het}})t] \qquad (4.11)$$

The second term of the right hand side of Equation 4.11 still contains the signal, but shifted towards even higher frequencies. The signal component we are interested in is shifted to a very low frequency, $(\omega_{\text{sig}} - \omega_{\text{het}})$, which for our investigations was chosen to be 9 Hz. After heterodyning, the data stream is strongly low passed and down sampled to give a data stream that can be handled by desktop computers.

In order to compute the transfer function from PCALmon to H, both data streams are processed with the same heterodyning algorithm. Afterwards, the transfer function is calculated using the *tfe* function of MATLAB.

[4] 10 hours of data sampled with 16384 Hz consist of about 600 000 000 data points.

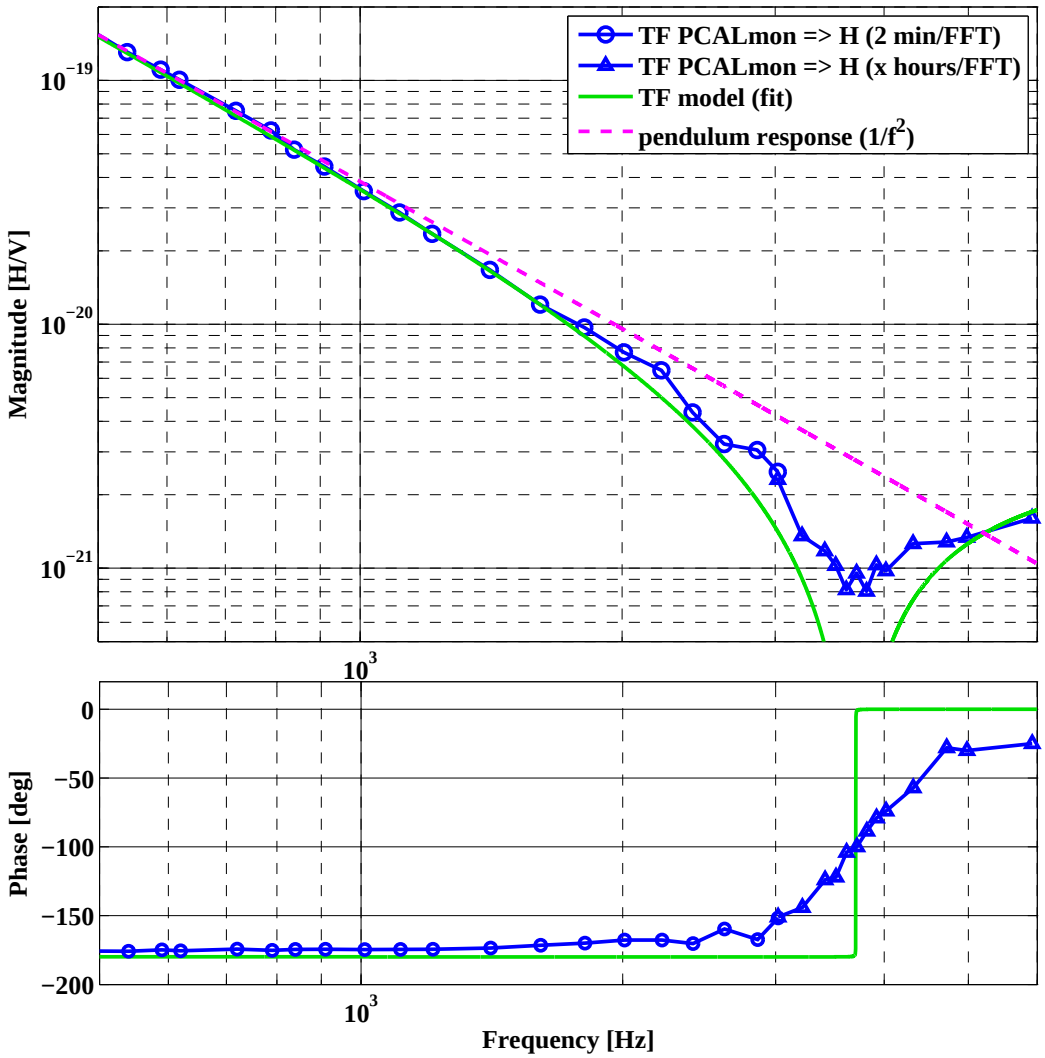

Figure 4.13.: Measurement of the photon pressure calibrator response at high frequencies. The measurements at frequencies below 3 kHz (blue circles) are the same as presented in Section 4.4. The measurement points above 3 kHz (blue triangles) are derived from long data stretches and contain up 10 hours of data in a single FFT. The green line represents the model described in Section 4.7.4. The model was fitted in order to shift the notch frequency from 4.25 to 3.8 kHz. The $1/f^2$ response from the pendulum is indicated by the pink dashed line. The presence of the expected notch structure is clearly confirmed by the measurement. However, the notch seems to be smeared out which might be explainable by beam jitter of the main interferometer beam (see Section 4.7.6).

Figure 4.13 shows the result of the photon pressure calibrator injections at high frequencies. The presence of the expected notch structure is clearly confirmed by the measurement. However, the notch seems to be smeared out. The magnitude of the response is about a factor of 3 below the pendulum response for frequencies between 3 to 4 kHz. At 5 kHz the measurement matches the pendulum response and finally at 6 kHz the measured response clearly exceeds the $1/f^2$ behavior of the pendulum response. The green line in Figure 4.13 represents the model including the photon pressure calibrator induced mirror deformation, described in Section 4.7.4. The model was fitted in order to shift the notch frequency from 4.25 to 3.8 kHz; this required an increase in the response, α_{def}, by about 25 %, from the originally estimated value of $2.73 \cdot 10^{-10}$ m/N to $3.41 \cdot 10^{-10}$ m/N. Around the notch frequency, the phase of the photon pressure calibrator response also changes significantly from about -165 degree at 2.8 kHz to about -30 degree at 4.8 kHz. A phase of nearly 0 degree at high frequencies clearly indicates that the response is no longer dominated by the pendulum response.

All together this result clearly confirms the hypothesis that the observed relative discrepancy between official and photon pressure calibration at high frequencies is caused by the influence of an additional effect with flat response and 0 degree phase lag compared to the modulated light power. The mirror deformation described above is obviously a strong suspect for this additional effect. However, we have to find a mechanism that can cause the smearing out of the notch structure. A candidate for such an effect is given in the next section.

4.7.6. Influence of beam jitter to the photon pressure calibration

So far we assumed a perfect spatial overlap of the beams from the photon pressure calibrator and the main interferometer. The beam of the photon pressure calibrator is expected to show no significant beam jitter because the whole setup is rigidly mounted on an optical table and the leaver of the beam is only a few meters (see Figure 4.2). However, the main interferometer is known to have some beam jitter. On long time scales its position on MFn is controlled by a low bandwidth servo. For frequencies above the unity gain frequency of this servo, which is around 0.01 Hz, the beam jitter is not suppressed.

If the two beams from the photon pressure calibrator and the interferometer move relative to each other, the effective displacement seen by the interferometer changes. A

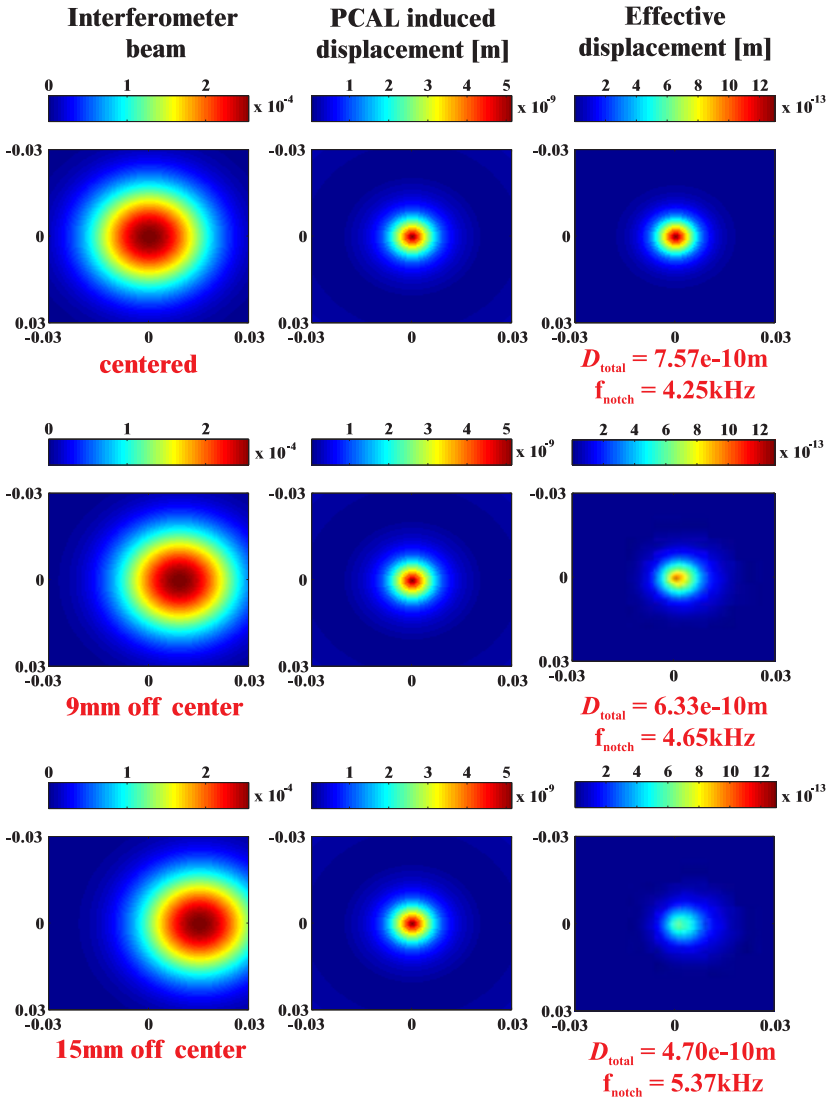

Figure 4.14.: The total effective displacement D_{total} caused by the photon pressure calibrator induced mirror deformation depends on the spatial overlap of the beams from the main interferometer and the photon pressure calibrator. The three plots in the left column show the main interferometer beam ($\text{TEM}_{00}, \omega = 2.4\,\text{cm}$). The plots in the center column display the test mass deformation derived from the FEM simulation (see Section 4.7.2). The right hand column shows the contribution to the effective displacement. All plots show an area of $6 \times 6\,\text{cm}$. A relative drift of the two beams of 15 mm would decrease the D_{total} by about 40 % from $7.57 \cdot 10^{-10}\,\text{m}$ to $4.7 \cdot 10^{-10}\,\text{m}$, corresponding to a change of more than 1 kHz of the notch frequency.

change in the relative size of the two displacement components would lead to a different cross over frequency of the responses from the pendulum and the mirror deformation and thus a shift in the notch frequency. The measurements, shown in Figure 4.13, are averaging over hours and thereby also averaging over different notch frequencies. This would lead to a smearing out of the notch as observed in the measurement.

The question we have to answer now is how much the main interferometer beam moves in reality and whether this movement gives a large enough shift of the notch frequency. Over a period of 10 hours a maximum variation of the position of 9 mm was observed in vertical direction. Analogous to Equation 4.8 we can now calculate the overall measured displacement, D_{total}. As this problem is not any longer rotationally symmetric we have to modify Equation 4.8 slightly by introducing a double integration.

$$D_{\text{total}} = k_I \int_0^{0.09\text{m}} \int_0^{360\,\text{deg}} \cdot I(r,\varphi) \cdot D(r,\varphi) \cdot dr \cdot d\varphi. \tag{4.12}$$

In Figure 4.14 the total effective displacement, D_{total}, caused by the photon pressure calibrator induced mirror deformation is shown for different spatial overlaps of the beams from the main interferometer and the photon pressure calibrator. The three plots in the left column show the amplitude of the main interferometer beam ($\text{TEM}_{00}, \omega = 2.4\,\text{cm}$). The plots in the center column display the test mass deformation derived from the FEM simulation (see Section 4.7.2). The right hand column shows the contribution to the effective displacement derived using Equation 4.12. A relative drift of the two beams of 15 mm would decrease D_{total} by about 40 % from $7.57 \cdot 10^{-10}$ m to $4.7 \cdot 10^{-10}$ m, corresponding to a change of 600 Hz of the notch frequency.

Overall the influence of beam jittering of the main interferometer beam seems to be sufficient to explain that the measured notch in Figure 4.13 is smeared out.

4.7.7. Conclusion and consequences

In the previous section a new idea was presented that can, at least to a large extent, explain the strong discrepancy between the official and the photon pressure calibration observed at high frequencies. In contrary to general belief, a test mass made of fused silica seems to show non rigidity also at frequencies below its first internal resonance.

The achievable accuracy of a calibration derived from a photon pressure actuator is at least to some extent limited by the non-rigidity of the test mass for frequencies in

the kHz range. However, careful design and the implementation of new ideas, like for instance minimizing the overlap of the PCAL beam and the interferometer beam by the use of two off center PCAL beams [Savage06], may help to improve the calibration accuracy. However, it needs to be taken into account that even off center PCAL beams can excite eigenmodes of the test mass.

Finally it has also to be stated that the above described deformation of a test mass can not only be induced by strong modulated light beams, but also by any other kind of inhomogeneous actuation, such as for example coil magnet actuators.

4.8. Effects from test mass rotation

The photon pressure calibrator might cause a non-negligible rotation or tilt of the test mass. One potential mechanism for that would be if the photon pressure calibrator is hitting the test mass off center. The frequencies of our interest are far above the resonance frequencies of the suspension, thus we consider the test mass as being a free mass for rotation or tilt. The rotation corresponding to an angle θ can be described by using the moment of inertia I

$$\theta(\omega) = \frac{2 \cdot P \cdot d_{PPD}}{c \cdot I \cdot \omega^2} \tag{4.13}$$

where P is the modulated light power, ω is modulation frequency and d_{PPD} the distance of the PPD beam center from the center of the testmass.

Figure 4.15 depicts the longitudinal effects from mirror rotation. If the beam from the main interferometer is centered on the testmass the longitudinal displacement is given by

$$x_d \approx \frac{d}{4}\theta^2 \qquad \text{for} \quad \theta \ll 1. \tag{4.14}$$

In the case that the beam of the main interferometer is off center, then the effective displacement, x_d also contains a factor linearly depending on θ [Weiland04]:

$$x_r \approx d_c\theta + \frac{d}{4}\theta^2 \qquad \text{for} \quad \theta \ll 1. \tag{4.15}$$

For very small angles, θ, as the ones we are interested in we can neglect the second part of Equation 4.15 and take only the first term. Together with Equation 4.13 this gives

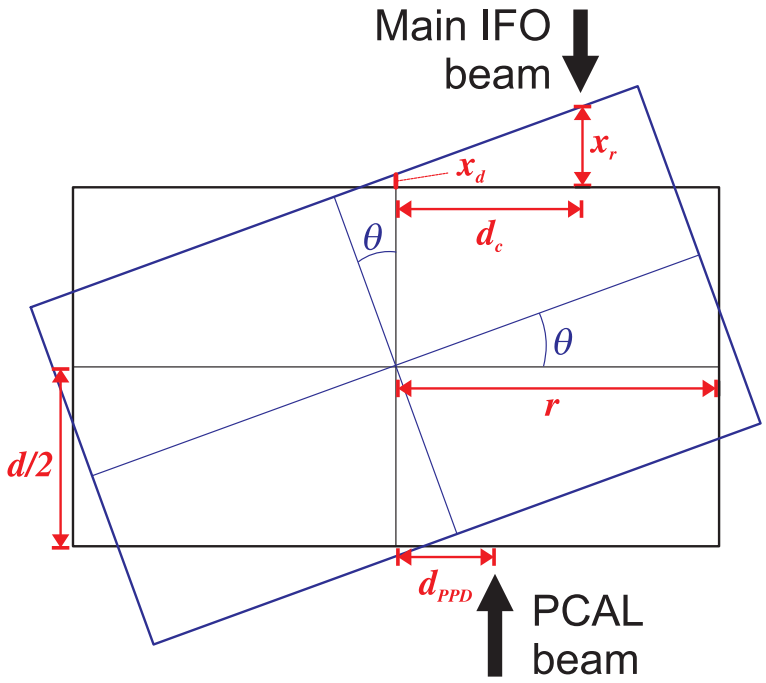

Figure 4.15.: Rotation of the mirror induced by the photon pressure drive will yield a longitudinal displacement of x_d in the case that the main interferometer beam is centered on the test mass. If the main interferometer beam is off center the longitudinal displacement is given by x_r.

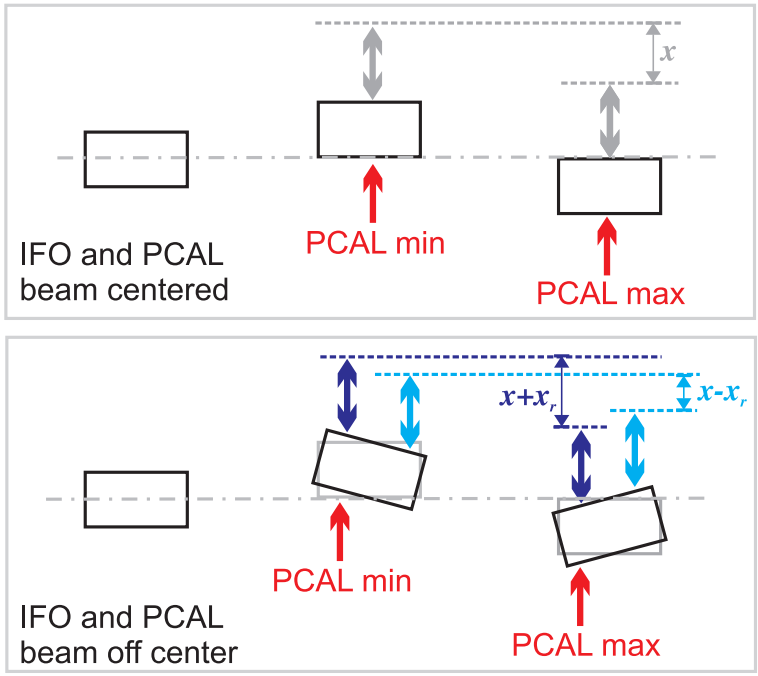

Figure 4.16.: *Upper plot*: When the PCAL beam (red) and the main interferometer beam (grey) are centered the amplitude of the photon pressure calibrator injection is x. *Lower plot*: When both beams are off center to the same side the measured amplitude of the injection will be increased to $x + x_r$ (blue). If both beams are offset to opposite sides the measured signal amplitude is decreased to $x - x_r$ (cyan).

an angle-independent displacement

$$x_r(\omega) \approx \frac{2P \cdot d_c \cdot d_{PPD}}{I \cdot c \cdot \omega^2} \tag{4.16}$$

which only depends on the modulation frequency and the distances of the laser beams from the center of the testmass.

If we want to check the influence of the rotational induced displacement we have to compare this with the longitudinal displacement from the pure pendulum transfer function

$$x(\omega) = \frac{2 \cdot P}{M \cdot c \cdot \omega^2}. \tag{4.17}$$

The ratio is

$$\frac{x_r(\omega)}{x(\omega)} = \frac{M d_c d_{PPD}}{I} \tag{4.18}$$

and does not depend on ω. Hence the rotation of the photon pressure calibrator induced test mass rotation results in a frequency independent error, i.e. an absolute error. Using $M = 5.3$ kg and $I = 0.01601\,\mathrm{kgm}^2$ we can calculate how far the beams have to be off center to explain the observed error of 30 % in Figure 4.5:

$$d_r d_{PPD} = 0.3\frac{I}{M} = 9.075 \cdot 10^{-4}\mathrm{m}^2 \tag{4.19}$$

Assuming both beams to be misaligned by the same distance we would have to take the square root which would give $d_r = d_{PPD} = 3.0\,\mathrm{cm}$.

If we were aiming for an 1 % accuracy we would have to make sure that both beams, the one from the photon pressure calibrator and the one from the interferometer are well centered on the test mass to within 0.5 cm.

Unfortunately with the currently installed setup of the photon pressure calibrator it is not possible to get an estimate better than a few centimeters of the position where the PCAL beam hits the mirror. This is mainly due the fact that the position of MFn in respect to the view port used for the PCAL beam is not accurately known. Furthermore the positions of the view ports available at MFn do not allow for a more accurate optical estimation of the spot positions. However, in the following section a method will be presented to accurately determine the spot position of the photon pressure calibrator beam by scanning the test mass with the position of the main interferometer beam.

4.8.1. Method to determine the off centering of the photon pressure calibrator

As given by Equation 4.15 the effective displacement x_r depends on one hand on the photon pressure calibrator induced misalignment of the test mass and on the other hand on the spot position of the main interferometer beam. If the beam from PCAL is exactly centered on MFn, no test mass misalignment is induced, and changing the spot position of the main interferometer beam should not change x_r. However, in the case the beam from PCAL is off center, x_r is a function of the spot position of the main interferometer beam, d_c. This relation can be used to accurately determine the position of the PCAL beam hitting MFn, d_{PPD}. Figure 4.17 shows the corresponding

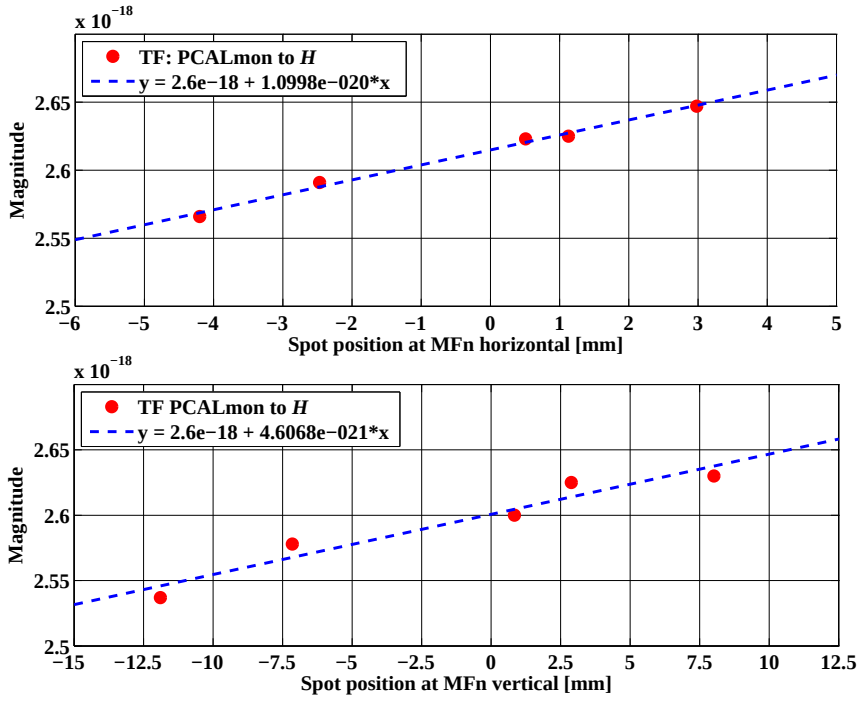

Figure 4.17.: Magnitude of the transfer function from PCALmon to H versus the position of the main interferometer beam at MFn. *Upper plot*: Changing the position of the main interferometer beam on MFn in horizontal direction changes the photon pressure calibration by 4.23 % / cm. *Lower plot*: Changing the position of the main interferometer beam on MFn in vertical direction changes the photon pressure calibration by 1.71 % / cm.

measurements. The position of the main interferometer beam was shifted on MFn and

the transfer function from PCALmon to H was measured. Changing the position of the main interferometer beam on MFn in horizontal direction changes the photon pressure calibration by 4.23 %/cm, while in vertical direction a change of 1.71 %/cm is found. Using Equation 4.18 these values can be used to calculate the horizontal and vertical off centering of the PCAL beam, d_{PPD}^{rot} and d_{PPD}^{tilt} respectively.

$$d_{PPD}^{\mathrm{rot}} = 12.8\,\mathrm{mm} \quad \wedge \quad d_{PPD}^{\mathrm{tilt}} = 5.2\,\mathrm{mm} \tag{4.20}$$

Assuming that the main interferometer beam and the beam from the photon pressure calibrator are off center in the same direction, the interferometer beam would have to be 44 mm off center to explain the smallest observed discrepancy of 20 % (see Figure 4.5) between the official and the photon pressure calibration. Such a large off centering cannot be completely excluded but seems fairly unlikely. Using the method described here d_{PPD} can iteratively be minimized. However, in order to keep the duty cycle of GEO 600 in S5 as high as possible, this work was postponed so far.

4.9. Determining the sign of H

For all kinds of network analysis that use data from two or more gravitational wave detectors (see, for example, [Ajith06a, Wen05, Candonati04, Rakhmanov05, Heng03]) it is indispensable to get well calibrated detector outputs. First of all a correct strain amplitude output is needed and secondly the sign of H must be determined.

In principle this information is easily accessible from the polarity of the fast actuators used for longitudinal control of the Michelson differential arm length which are in case of GEO 600 the ESDs. However, in reality the injected signals pass a complex system of electronics containing many stages with potential swaps of sign, like for instance inverted OPs and differential senders and receivers. Thus, one needs to very carefully measure the polarity of many pieces of electronics to find the correct sign of H.

A much less vulnerable procedure to determine the sign of H is provided by the photon pressure calibrator which only involves a very simple and clearly laid out system. The monitor photodiode built in the photon pressure calibrator laser diode and recorded in the DAQS (PCALmon) provides a measurement of the light hitting the suspended mirror. As shown in Figure 4.18 the amplifier of the photodiode gives a positive voltage

proportional to the detected light. The force F_{PCAL} acting on MFn is proportional to the voltage recorded in PCALmon.

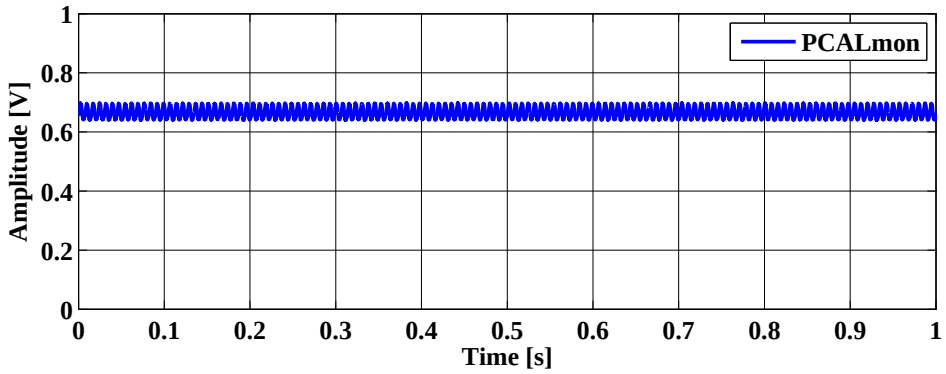

Figure 4.18.: Time series of the signal PCALmon, derived from the internal monitor photo diode of the photon pressure calibrator. The time series consists of a DC voltage of 0.67 V and an AC peak-peak voltage of ±25 mV corresponding to the injected calibration signal.

Next it is necessary to measure the phase relation between PCALmon and H by means of computing the transfer function at the frequency of the photon pressure calibration line f_{PCAL}= 134 Hz. Figure 4.19 shows this transfer function for a time during S5. The two signals have opposite phase, $\phi_{F_{\mathrm{PCAL}}\rightarrow H}$ = -180 deg out of phase. Finally we need to take the pendulum response of the MFn suspension into account. As indicated by Figure 4.1 the phase of the pendulum response is $\phi_{F_{\mathrm{PCAL}}\rightarrow x_{\mathrm{MFn}}}$ = -180 deg for a frequency $f \gg f_0$ where f_0 the resonance frequency of the pendulum and x_{MFn} the movement of MFn is.

Putting both relations together we get:

$$\phi_{x_{\mathrm{MFn}}\rightarrow H} = \phi_{F_{\mathrm{PCAL}}\rightarrow H} + \phi_{F_{\mathrm{PCAL}}\rightarrow x_{\mathrm{MFn}}} = -360\,\mathrm{deg} \tag{4.21}$$

Due to the fact that the photon pressure calibrator shines onto the back of MFn $x_{\mathrm{MFn}} > 0$ corresponds to a shortening of the north arm. Hence, all together we determine the sign of H as follows:

$$H > 0 \quad \text{for} \quad \delta l_{\mathrm{north}} < \delta l_{\mathrm{east}} \tag{4.22}$$

$$H < 0 \quad \text{for} \quad \delta l_{\mathrm{north}} > \delta l_{\mathrm{east}} \tag{4.23}$$

where l_{north} and l_{east} are the lengths of the north and the east arms, respectively.

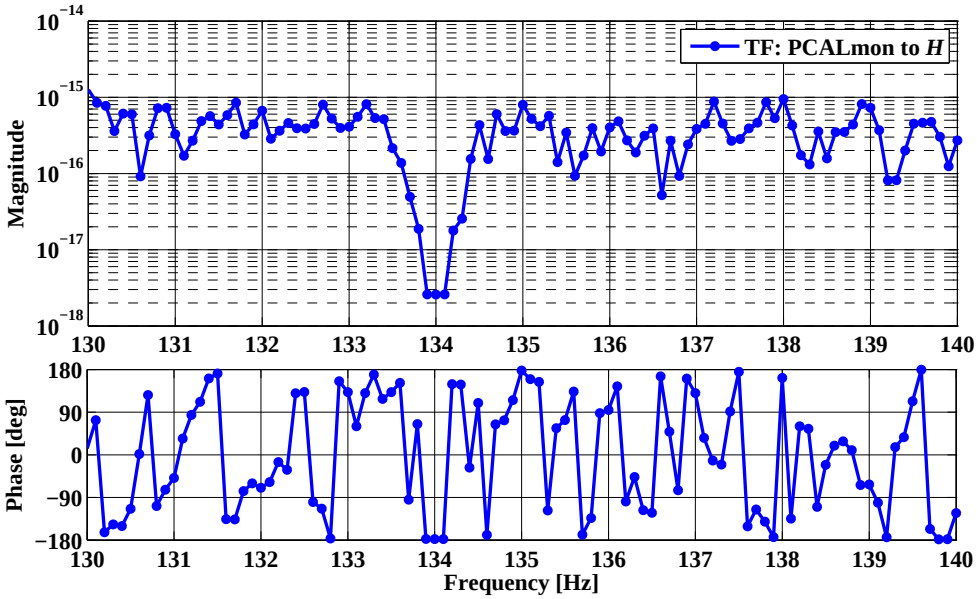

Figure 4.19.: Transfer function from the photon pressure calibrator monitor diode (PCALmon) to H . The photon pressure calibrator is used to apply a calibration line at $f_{\mathrm{PCAL}} = 134\,\mathrm{Hz}$. Only at this frequency is the transfer function is physically meaningful. The phase difference between both signals was measured to be $\phi_{F_{\mathrm{PCAL}} \to H} = $ -180 deg.

4.10. Summary

In this section experiments and investigations related to establishing a photon pressure calibration for GEO 600 are presented. The experimental setup and potential imperfections are described in detail in Section 4.2. A direct comparison of the relative and absolute values of the official GEO calibration and the calibration derived from the photon pressure calibrator is given in Section 4.4. The discrepancy between the two calibration methods was found to be unexpectedly large. The two resulting absolute calibrations seem to be different by about 20 to 40 %, which might be explained by effects from photon pressure induced test mass rotation as described in Section 4.8. The Section 4.7 focuses on the strong discrepancy of the relative calibration found at high frequencies, which can be explained by photon-pressure-induced deformation of the test mass. A finite element analysis is presented which predicts the presence of a notch structure in the response of the photon pressure calibrator. In long-duration measurements of the photon pressure calibrator at very high frequencies this notch structure was found. The The effect of non-rigidity of the test mass limits the accuracy of the photon pressure calibrator for frequencies above 1 kHz. Finally in Section 4.9 it is shown that a photon pressure calibrator can be used to reliably determine the polarity of H which is important for any kind of astrophysical analysis using data from more than one GW detector.

Chapter 5.

A statistical veto method employing an amplitude consistency check

5.1. Introduction

One of the most promising class of gravitational wave (GW) signatures that may be detected by the current array of ground-based laser interferometric GW detectors [Hild06c, Waldman06, Acernese06, Ando05] is un-modelled transient (burst) signals arising from short-duration, violent astronomical events. The search for such signals typically focusses on time-scales of the order of a few (or few tens of) milliseconds.

Due to their extremely complicated nature, GW detectors are themselves usually potent sources of transient signals. A subset of such signals arising from many different sub-systems within the detectors can (and do) couple to the main detector output, and hence appear as false GW triggers in any search effort. While a great amount of effort is afforded in the reduction of these instrumental and environmental glitches and/or their coupling to the main detector output (also termed the H channel), there is still a residual number that remain.

Once the glitch population of a particular sub-system (and its coupling to the GW channel), is (physically) reduced to a minimum, the residual must be identified and characterised so as to exclude those glitches from the search for GWs. The rate of false glitches in the GW channel ultimately sets a limit on the confidence with which a particular trigger can be identified as a GW. It is therefore important to try to reduce the number of glitches in the GW channel that are to be considered in a search for GWs. This is traditionally done by *vetoing* those events detected in H using events and

knowledge of events detected in auxiliary channels. Once an auxiliary channel has been identified as being a source of transient events which couple to H, it is termed a veto channel and is then studied and used to reduce the event list of H.

The application of a veto is done by identifying those events in the auxiliary channel which are, in some way, coincident with events detected in H. Detected glitches are typically characterised by a few parameters (time of occurrence, amplitude, central frequency, *etc*), such that saying that two events are coincident can be as simple as saying that they occur at the same time (within some error window) or as complicated as saying that many of the characteristics of the glitches are (within some defined windows) the same. When a parameterisation of glitch events is used to compare events between data-streams, we refer to the resulting veto as a *statistical* veto since its performance is based on the statistical properties of the distributions of glitches in the two data-streams and does not rely on any knowledge of the physical coupling mechanisms involved. Examples of the application of statistical veto methods to GW detector data can be found in [DiCredico05, Akutsu, Beauville05]. Another class of veto methods which relies on detailed knowledge of the coupling mechanism involved in transferring glitches from an auxiliary channel to the H channel, is not discussed here, but an example is given in [Ajith06]. There are also interferometer channels which, by definition, contain negligible GW information but can nevertheless remain highly correlated to the main GW channel. These 'null-stream' channels can also be used as effective veto channels (see [Hanna06, Koetter03, Hewitson05a] for examples). In addition to these single-detector veto methods, there is active research in the use of multiple detector outputs as a means of vetoing the events in a detector network (see, for example, [Ajith06a, Wen05, Candonati04, Rakhmanov05, Heng03]).

The approach of using a pure statistical correlation (such as time of occurence) can, of course, lead to *false vetoes*, that is, events in the auxiliary channel which are only accidentally coincident with events in the H channel. Requiring that more glitch characteristics be 'similar' when performing the coincident test can reduce the false-veto rate (usually at the cost of a reduced veto efficiency). The usefulness of a particular veto channel can be characterised according to the number of H events it can veto (its efficiency) for a given number of false-vetoes (false/accidental-veto rate).

This chapter investigates many aspects of the identification, characterisation and use of veto channels for data recorded from GEO 600, in particular for the case when

the simple coupling described above is further complicated by the presence of GW signal traces in the auxiliary channel. To motivate the application of statistical veto methods to data from GEO 600, in the Sections 5.2 and 5.3 two examples are given where events from the auxiliary channel X and the GW channel H are found to show a significant correlation. Section 5.4 describes the burst detection algorithm used in these studies. Section 5.5 goes on to discuss the *standard* statistical veto and shows an example application (with single and multiple coincidence windows) to data from GEO 600. Section 5.6 shows a possible extension to the classical statistical veto method for the case where the auxiliary channel can contain traces of GW signals, *i.e.*, the channel's sensitivity to GW signals is non-negligible. Section 5.7 shows the application of the extended classical statistical veto method to GEO 600 data. For a month of data the full GEO veto pipeline is applied, also including a statistical veto employing a amplitude consistency check.

5.2. Motivation for a standard statistical veto for GEO 600: Hourly mains glitches

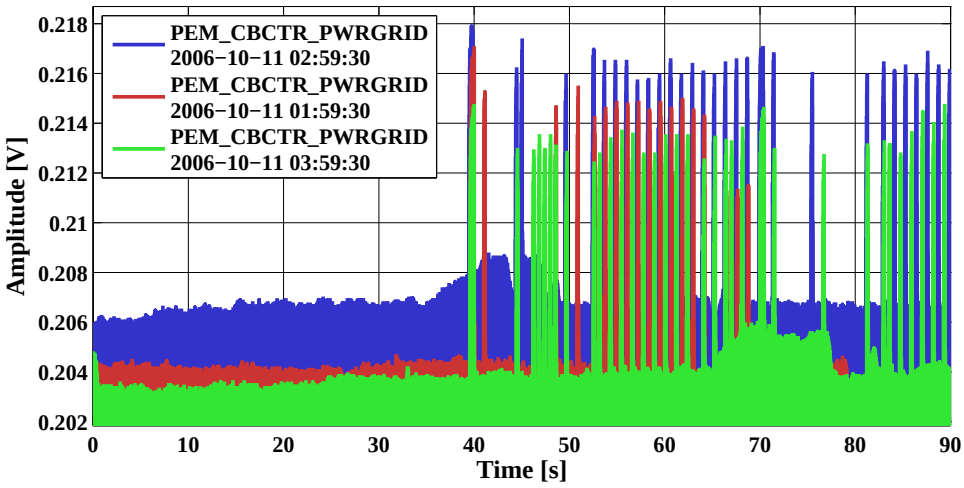

Figure 5.1.: Stacked time series of the mains monitor at the GEO site. Ripple control signals repeatedly show up 10 seconds after the beginning of a UTC-hour.

The power supply companies in Germany use a technique called *ripple control* to trans-

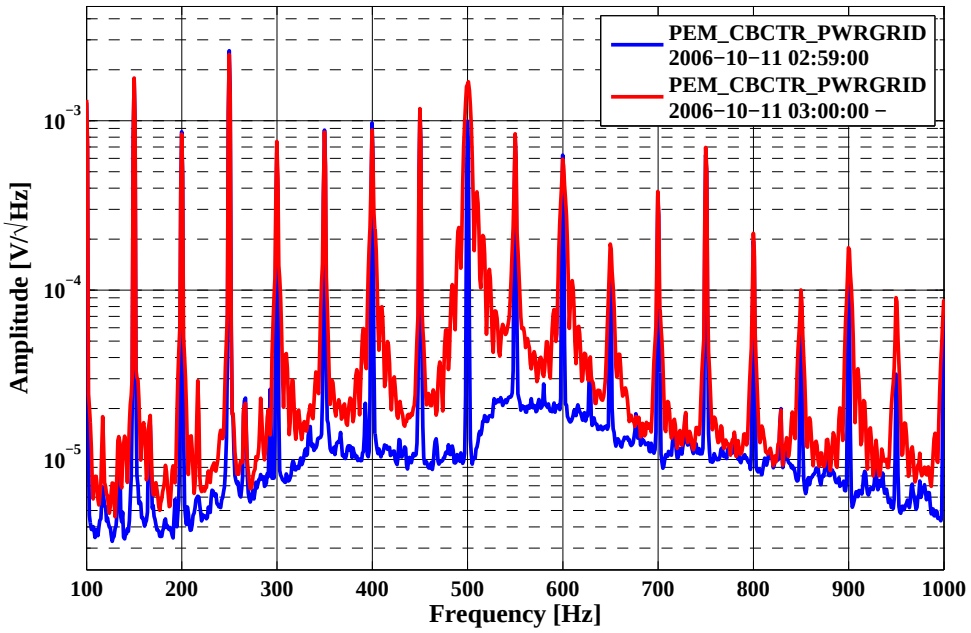

Figure 5.2.: Spectra of the mains monitor for the last (blue) and the first (red) minute of a UTC-hour. The ripple control signal has a nominal frequency of 500 Hz, but it is also strongly visible as sidebands around all harmonics of 50 Hz.

fer information via the mains from the power plant to the consumers. An amplitude modulation with a certain frequency (in our case 500 Hz) is superimposed on the usual 50 Hz power grid in order to remotely control lanterns and night storage heaters.

Figure 5.1 shows overlayed time series from a monitor of the main site power supply (mains). The ripple control signals repeatedly show up 10 seconds after the beginning of an UTC-hour. They consist of an up to 90 seconds long series of on-off-states with a maximum amplitude increase of about 6 %.

Spectra of a time when ripple control signals were present, compared to a time of their absence are shown in Figure 5.2. The ripple control signals have a nominal frequency of 500 Hz, but they are also strongly visible as sidebands around all other harmonics of 50 Hz, especially 400, 600 and 900 Hz.

It was found that, as indicated in Figure 5.3, some of the glitches in the mains monitor are time coincident with glitches in the main gravitational wave channel. A large fraction of the coincident events shows up shortly after the start of an hour. Furthermore nearly all of them are identified to have central frequencies of about 400, 500, 600 and 900 Hz, the same frequencies, where we found most of the excess power in the mains monitor caused by the ripple control (see Figure 5.2).

The coupling mechanism is not completely understood yet. Glitches in the mains can potentially couple in various ways to the GW channel. A glitch in the mains causes a glitch in the magnetic field surrounding the power line which can then interact with magnets glued onto the mirror [Gossler02]. Or the magnetic glitch can directly induce a voltage glitch in a piece of electronics used for control or readout of the detector.

However, as the coupling path for the ripple control signals to the gravitational wave channel is not known and therefore not accessible via measurements, no other veto method than a statistical veto can be applied. In Section 5.5.2 we will show some investigations done in order to find out whether a reasonably performing veto analysis can be based on the mains monitor.

In the long term we plan to filter the ripple control signals out of the local power grid by using some resonant LC-filter stages[1]. The installation of such a filter requires powering down of the full GEO 600 site which needs to be well prepared and is not free of risk.

[1] More detailed information about available filters can be found in http://www.eskap.de/tonfrequenzsperren.pdf .

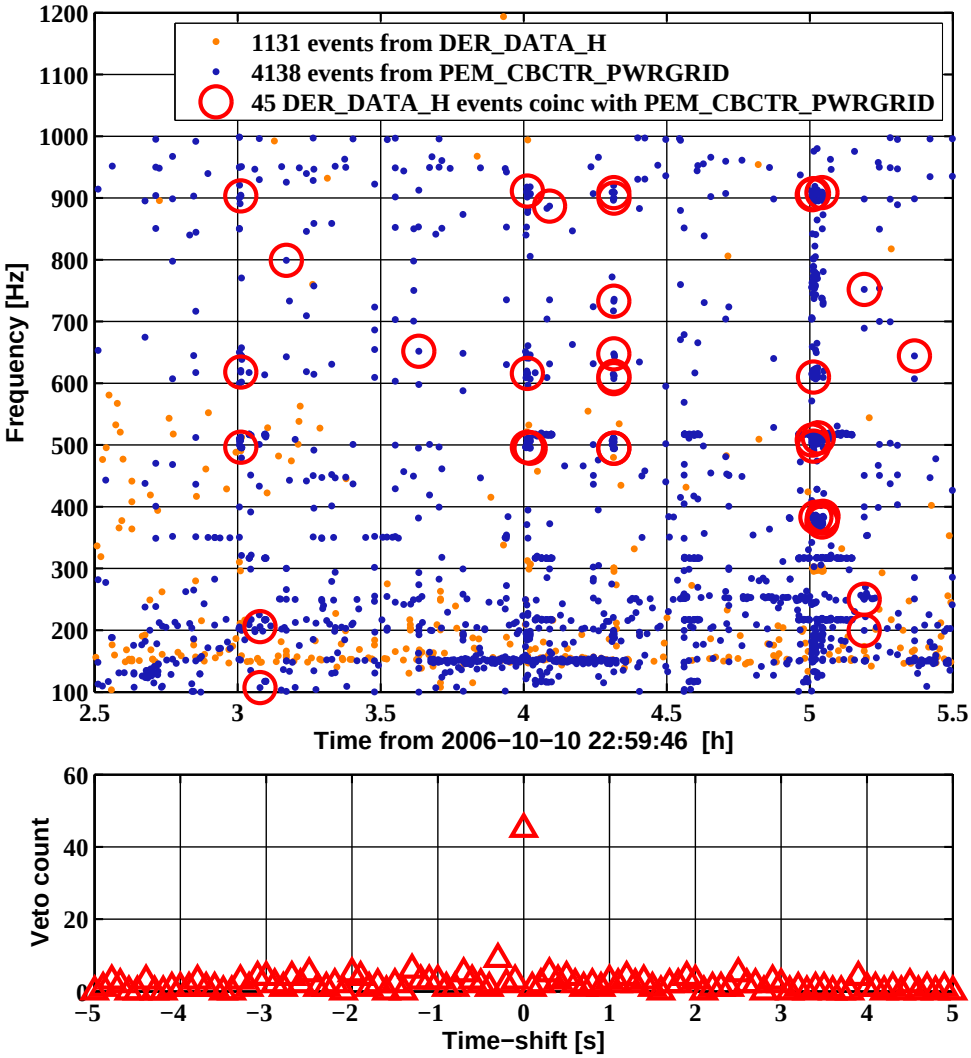

Figure 5.3.: *Upper plot*: Time frequency map of burst triggers in the mains monitor (blue dots) and the main gravitational wave channel (orange dots). The events in the mains monitor that are time coincident with an event in the GW channel are marked with a red circle. A time coincidence window of 10 milliseconds was used. No further coincident condition was imposed. *Lower plot*: Time shift analysis of the coincidence analysis from the plot above. A significant statistical correlation between the events from the mains monitor and the events from the GW channel is confirmed.

5.3. Motivation for a statistical veto with amplitude consistency check: Dust falling through laser beams

In May 2006, a significant increase in the glitch rate of the main GW channel (H) of GEO 600 was observed. A broken air conditioning system blew unfiltered air into the main clean room and increased the dust particle concentration by more than one order of magnitude. It turned out that the increase in the glitch rate of H originated from dust particles falling through the main output beam of the interferometer.

Many glitches in the recorded DC light power hitting the main photodiode (referred to as $\mathcal{P}_{\mathrm{DC}}$), were observed to be coincident with glitches in H. Figure 5.4 shows a time coincidence analysis of the two channels for two different times of the S5 LSC science run. The upper plot shows an 8 hour data stretch from May 2006, when the air conditioning system was broken. 1245 of the 1719 detected events in H (72 %) are time coincident with an event in $\mathcal{P}_{\mathrm{DC}}$. For this analysis a time coincidence window of 10 milliseconds was used. The lower subplot of Figure 5.4 shows the same analysis (with identical parameters) for a data segment from June 2006, when the air conditioning system was fixed again. Compared to the time of high dust concentration, in the low dust condition the total number of events from both signals is significantly reduced. Only about 5 % of the events in H are time coincident with an event from $\mathcal{P}_{\mathrm{DC}}$.

However, tests involving injecting signals (noise, sinusoidal, burst events) into the differential length control actuator for the Michelson Interferometer (to mimic the effect of a GW), showed that $\mathcal{P}_{\mathrm{DC}}$ can contain, to a non-negligible degree, some GW signal. Figure 5.5 shows sinusoidal GW-like hardware injections (calibration lines) using the electro static drives. Spectra of the injected signal (*diff_CAL*) and $\mathcal{P}_{\mathrm{DC}}$ are plotted in the two upper figures. The frequencies of the injected sine waves are indicated by the circled markers. The lower figure shows the coherence of the two signals, which is nearly one for all frequencies of the hardware injections.

Hence, using a standard statistical veto could, undesirably, also veto potential GW events. That is why we developed a method, described in the Sections 5.6–5.7, that extends the standard statistical veto methods by an additional amplitude consistency check.

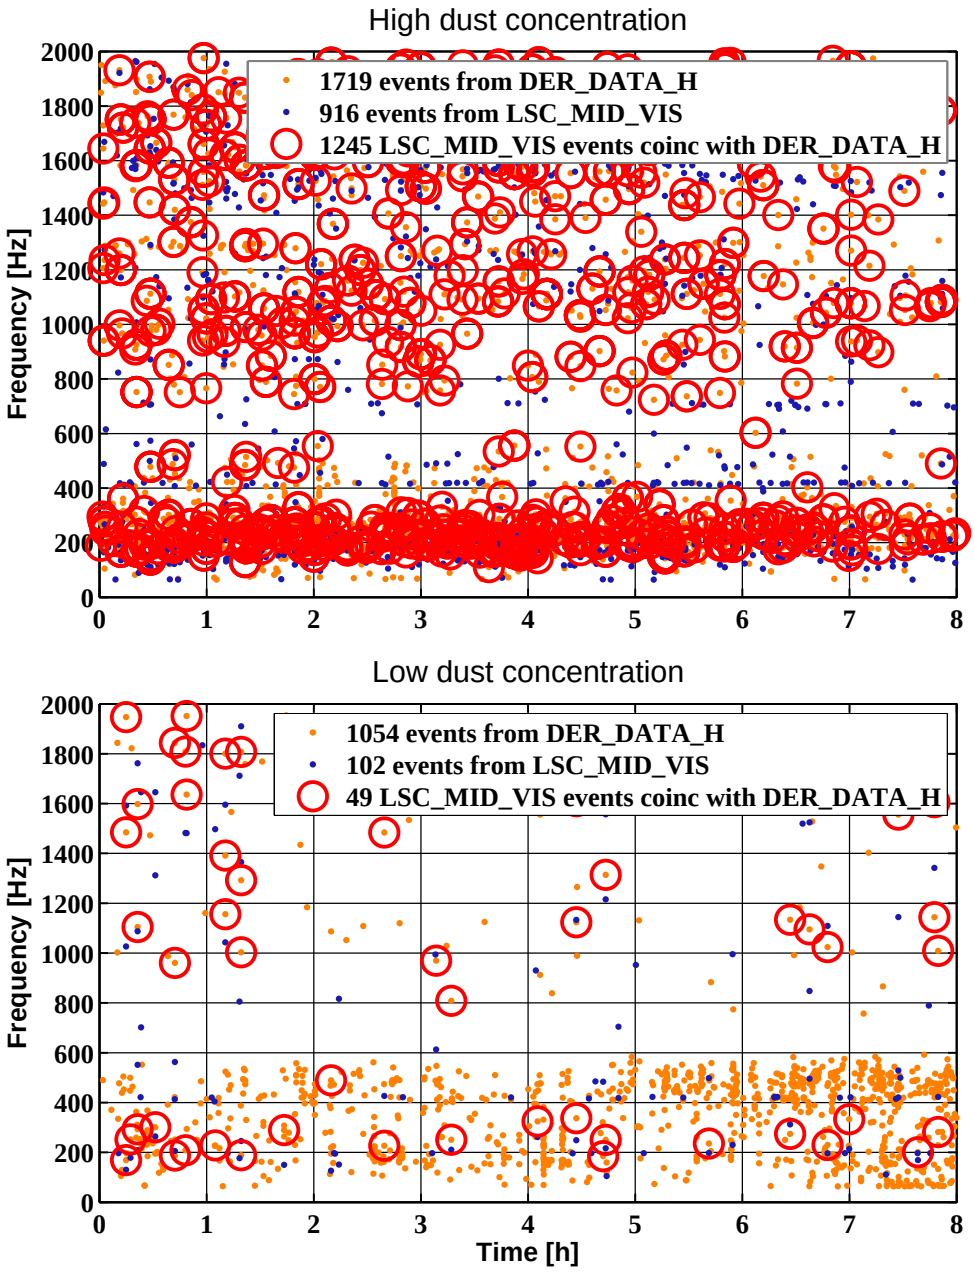

Figure 5.4.: *Upper Subplot*: Time coincidence analysis for the GW channel (H) and $\mathcal{P}_{\mathrm{DC}}$ for a time of high dust concentration at the detection bench, corresponding to a time when the air conditioning system was broken. *Lower Subplot*: The same analysis, but for a time of low dust concentration at the detection bench, corresponding to a time of nominal operation of the air conditioning system. For both analysis a time coincidence window of 10 milliseconds was applied.

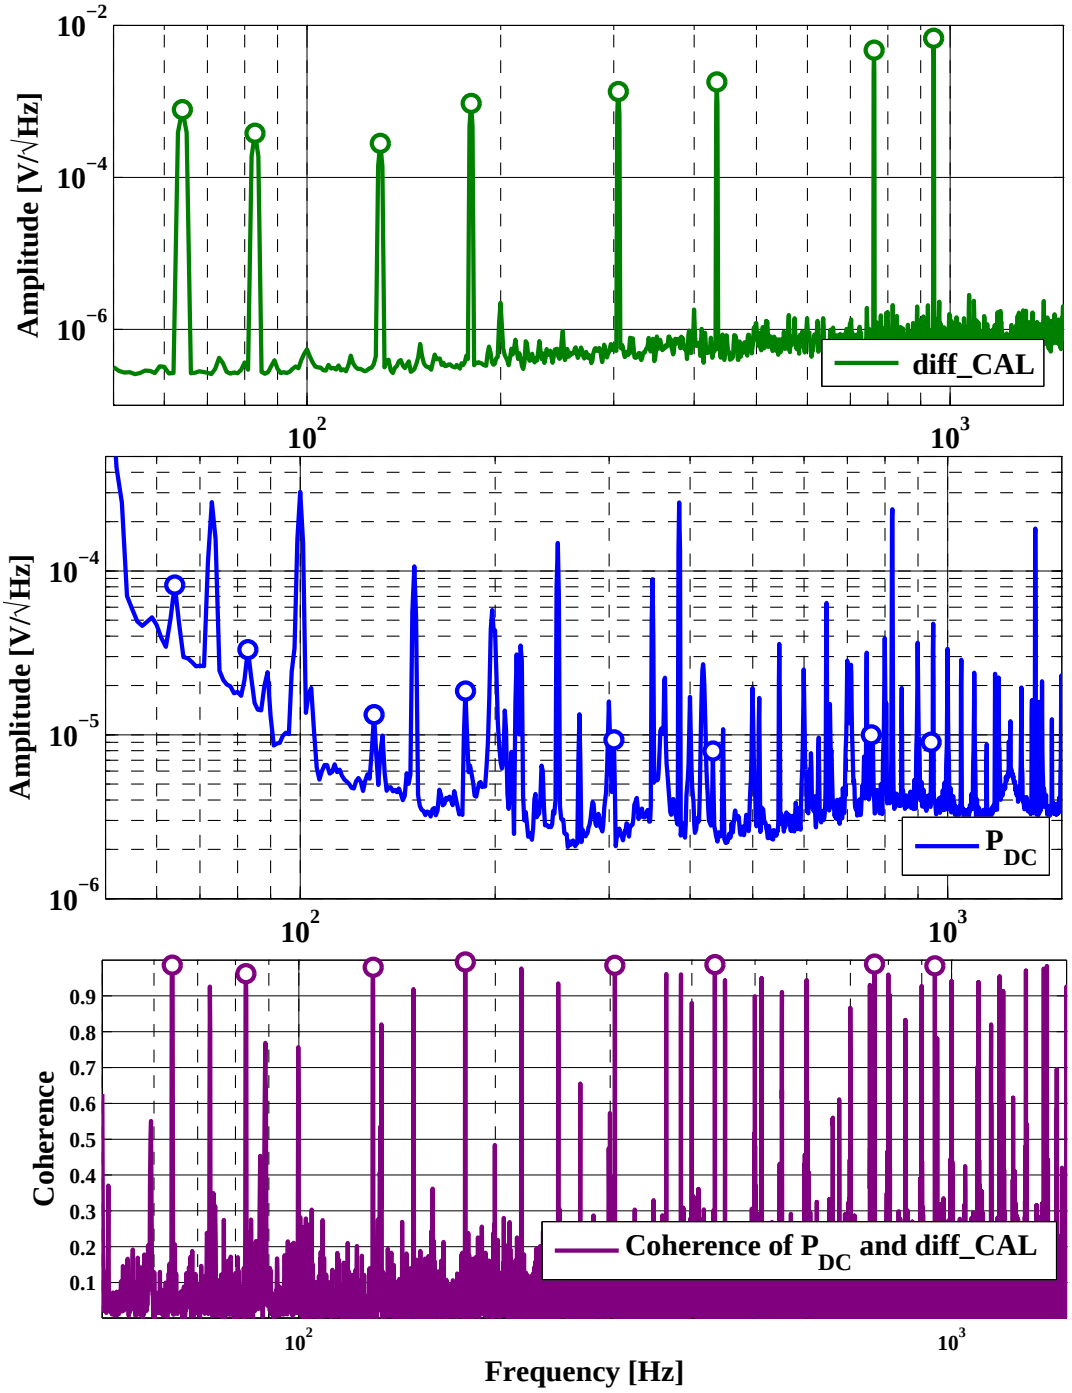

Figure 5.5.: Sinusoidal gravitational wave like hardware injections: The upper plot is a spectrum of the injected signal. The frequencies of the injections are marked with circles. The plot in the middle shows a spectrum of $\mathcal{P}_{\mathrm{DC}}$. The lower plot shows the coherence of the two signals. For all frequencies of the injections the coherence is found to be nearly one. This confirms that a non neglectabel amount of differential arm length signal couples to $\mathcal{P}_{\mathrm{DC}}$.

5.4. Description of the event trigger generator used: mHACR

Any potential *burst* gravitational wave signal is expected to be very weak and of very short duration, barley visible and hard to separate from the intrinsic noise of the instrument. Therefore sensitive detection algorithms have been developed in order to identify and parameterize any excess power in the main gravitational wave output. Examples of these event trigger generators (ETG) used for astrophysical searches are *Kleine Welle* [Chatterji04], *Excess Power* [Anderson01] and *Waveburst* [Klimenko04]. For the commissioning of the GEO 600 detector we use an ETG called *mHACR*, which is described in detail in [Balasubramanian05] [Heng03] and [Hild07a].

For the understanding of the following sections it is important to know how mHACR roughly works. That is why in this section I give a brief and simplified description of mHACR.

32 seconds of data from the channel to be analyzed are divided into short segments of 32 milliseconds length with an overlap of 28 milliseconds. From each of the 32 milliseconds-long subsegments a FFT is computed. Afterwards, all of the FFTs are joined together to give a time-frequency map, also known as spectrogram, with a very high time resolution of 4 milliseconds and a (poor) frequency resolution of 32 Hz. A normalization of the spectrogram is performed, such that the spectrogram has units of power spectral density.

This normalized spectrogram will be called ρ and each pixel ρ_{kl} can be identified by two indexes k and l, representing frequency bin and time, respectively. The main task of the ETG is to identify pixels which are statistically different from the background noise. This is done by computing the significance, s_{kl} of each pixel, given by

$$s_{kl} = \frac{\rho_{kl} - \mu_k}{\sigma_k}., \tag{5.1}$$

where μ_k is the mean and σ_k is the standard deviation of the k^{th} row of ρ. The significance is now used to sort the pixels into three groups of color, according to the following criteria:

$$\text{colour}(\rho_{kl}) = \begin{cases} \text{black}, & \text{if } s_{kl} \geq T_{\text{upp}} \\ \text{grey}, & \text{if } T_{\text{upp}} > s_{kl} \geq T_{\text{low}} \\ \text{white}, & \text{if } s_{kl} < T_{\text{low}}, \end{cases}$$

where T_{low} and T_{upp} are the chosen lower and the upper threshold. For the analysis described in the following the thresholds were chosen to be 5 and 25. In the next step mHACR identifies clusters of neighboring grey and black pixels. If a cluster consists of at least two pixels (black, grey) of which at least one is black, this cluster is identified as a burst event.

5.4.1. Estimation of burst parameter with mHACR

After the burst event is identified by mHACR we need to parameterize this event. Amplitude, time of occurrence, central frequency and duration are, amongst others, the most important parameters for the understanding of the following sections. The signal power of a single pixel, S_{kl}, is given by the power of the pixel minus the mean noise-power of the frequency bin:

$$S_{kl} = \rho_{kl} - \mu_k. \tag{5.2}$$

With this, the amplitude, a, of an event can be computed as

$$a = \sqrt{\frac{\sum_{k,l} S_{kl}}{r}}, \tag{5.3}$$

where r is the redundancy factor accounting for the 28 milliseconds overlap of each FFT. The estimation of the *central frequency*, f_0, and *central time*, t_0, is analogous to the calculation of the centre-of-mass of an extended body. Here, the *signal power*, S_{kl}, in each time-frequency pixel serves as the 'mass' term and the time/frequency associated with each pixel serves as the 'position' term. That is,

$$f_0 = \sum_{k,l} S_{kl}\, f_k \Big/ \sum_{k,l} S_{kl} \tag{5.4}$$

$$t_0 = \sum_{k,l} S_{kl}\, t_l \Big/ \sum_{k,l} S_{kl}. \tag{5.5}$$

Finally, the duration, d, of an event can be estimated by from the extend of the event in the time axis as

$$d = \max(t_l) - \min(t_l). \tag{5.6}$$

Usually there are more parameters available from mHACR, for instance bandwidth, peak power and SNR, but these are not used for any analysis presented in this work. In Figure 5.6 the whole algorithm of mHACR is briefly illustrated.

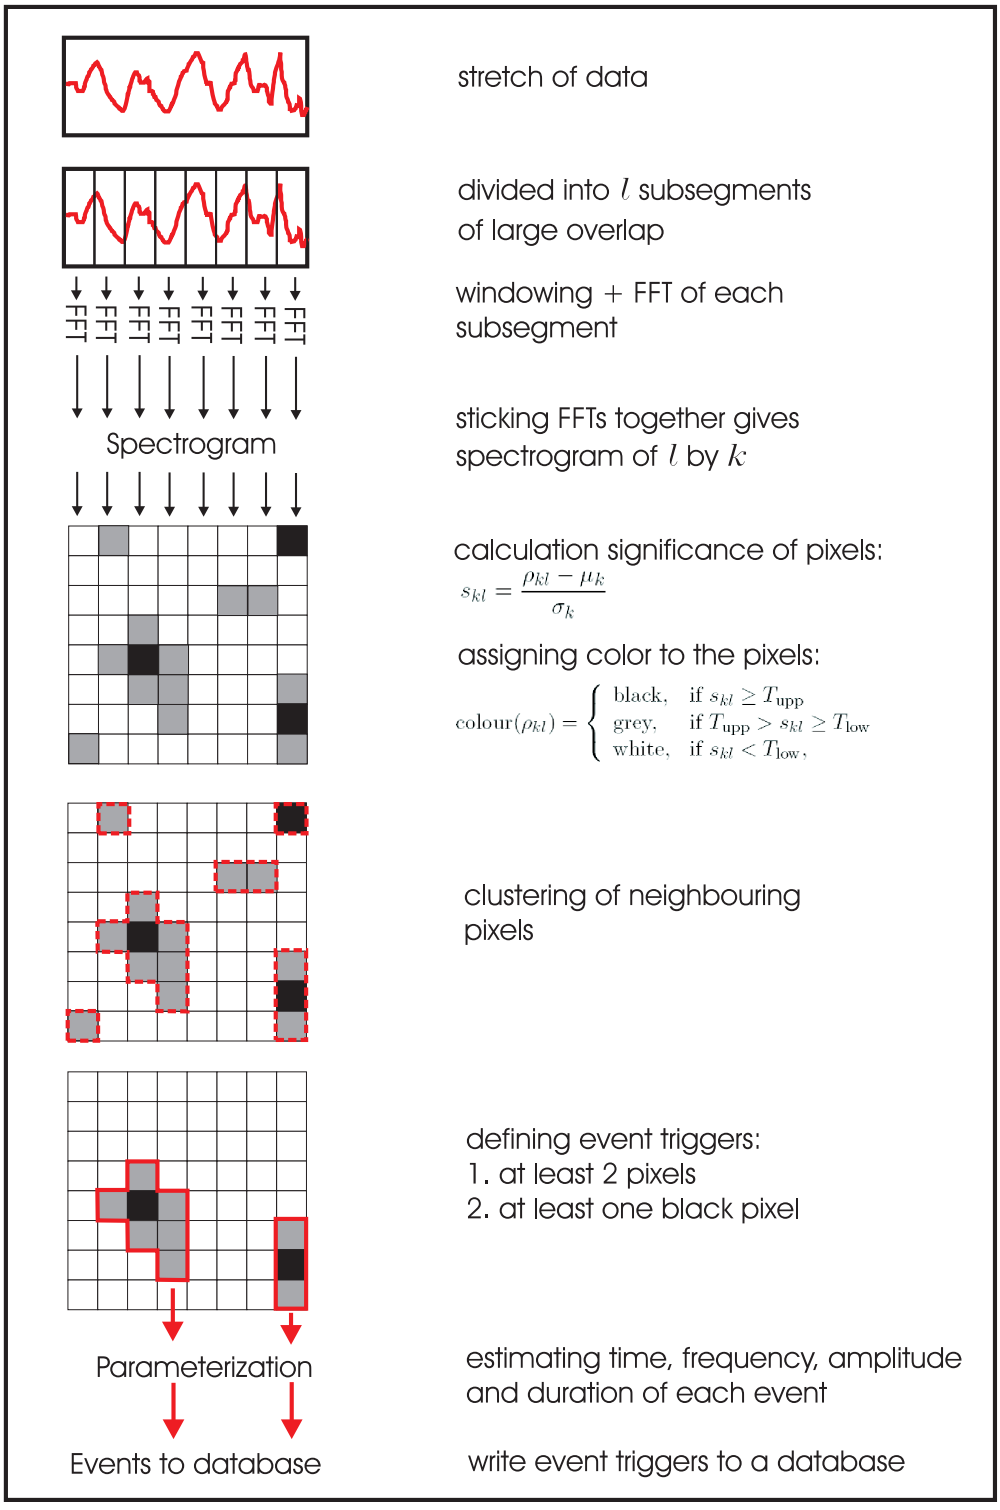

Figure 5.6.: Simplified illustration of the mHACR burst pipeline. A detailed description is given in the text.

5.5. The standard statistical veto

All currently operating GW detectors face the problem that several instrumental and environmental noises can couple to the GW channel. Therefore, it is desirable to identify in the GW stream, those events which can be shown to have a local instrumental or environmental source, and exclude them from any astrophysical analysis.

At each GW detector a multitude of sensors is installed to monitor instrumental noise sources (for instance, laser power noise) and environmental noise sources (such as magnetic fields). In the following, we will refer to both instrumental and environmental noise as technical noise sources.

If detected events in the GW channel are caused by a technical noise source, there will be a significant statistical correlation between the events of the GW channel and those detected in the recording of any device which monitors the noise source. (This assumes that both the main detector output and the auxiliary channel are properly recorded, and that the ETG does a good job of detecting and parameterising any glitch events in the data streams.) Even in the case when the coupling mechanism from the technical noise source to GW channel cannot be measured, we can use the statistical correlation to veto the coincident events.

In order that we end up with a sufficiently low false-veto rate, we must restrict ourselves (for the time-being) to auxiliary channels which cannot contain any GW information.

5.5.1. The method in general

Usually a simple statistical veto is based on the comparison of the time, t_0^H, of the event in the GW channel and the time, t_0^X, of the event in an auxiliary channel. Two events, $H[i]$ and $X[j]$, are defined as being coincident when they are separated in time by less than a chosen time window, $t_{\rm win}$:

$$\mid t_0^H[i] - t_0^X[j] \mid \quad < t_{\rm win}. \tag{5.7}$$

Every event, $H[i]$, that is time-coincident with at least one event from the auxiliary channel is vetoed.

The performance of a veto depends on many parameters (such as the event rates in the individual channels), and needs to be evaluated. The following measures can be useful

to judge the performance of a veto:

- The **Efficiency**, E_X, is the percentage of triggers in the GW channel that are vetoed by the use of the events of the auxiliary channel, X.

- The **Background**, B_X, is the percentage of triggers in the GW channel that are *accidentally* vetoed by the use of the events of the auxiliary channel, X. In general there are two possible groups of coincident events:

  1. The event $H[i]$ is either caused by, or originates from the same source as, the event $X[j]$.

  2. The event $H[i]$ is not caused by any event recorded in the auxiliary channel, but by accident there happens to be an independent event $X[j]$ that is time coincident with the event $H[i]$.

  By time-shifting the events in the GW channel with respect to the events in the auxiliary channel, it is possible to destroy the causal relationship between the events of the two channels and by that, to determine the accidental rate. Sometimes it is useful not to measure the background in percentage, but in units of accidentally-vetoed events per unit time, in order to determine how many potentially real GW events would be missed when applying the veto.

- The **Significance**, S_X, is defined as the ratio of efficiency and background and can be seen as the main figure of merit of a veto analysis. This can be illustrated by some examples. A veto that has a high efficiency of 50 % might also have a high background of, for example, 5 %, which would mean that we would falsely veto a large number of potential GW signals. On the other hand a very low background of 0.01 % does not necessarily guarantee a good veto performance, as it can still have a low efficiency of, say, 0.03 %. That is why we choose here the ratio of efficiency and background as a good way of judging the trade-off between efficiency and background. (When changing the width of a coincidence window, both the efficiency and the background are changed as well, but in general with different slopes.)

- The **Use-percentage**, U_X, is another means of the measuring the veto performance. It is defined as the percentage of the events in the auxiliary channel that can veto an event in the GW channel.

Additional coincident windows

In order to improve the significance of a veto, it might often be useful to demand that, not only are two events coincident in time, but also that other parameters of the events are similar. Assuming the event, $X[j]$, to be the origin of the event $H[i]$, for instance, also the central frequency of the two events, or their duration, might show a correlation. Of course, the strength of the correlation depends strongly on the coupling from channel X to the GW channel, H, and also on the noise level and the stationarity of noise in the two channels. In the worst case, the correlation might be completely destroyed. However, in GEO 600 we found some cases where the application of a second coincidence condition clearly improves the significance of a statistical veto.

In the following sections we will also apply an additional coincidence window, f_{win}, for the central frequency of the events. In that case an event, $H[i]$, in the GW channel is vetoed by the event, $X[j]$, from the auxiliary channel only when the following equation is satisfied,

$$\left|t_0^H[i] - t_0^X[j]\right| < t_{\mathrm{win}} \wedge \left|f_0^H[i] - f_0^X[j]\right| < f_{\mathrm{win}}, \tag{5.8}$$

where $f_0^H[i]$ and $f_0^X[j]$ are the central frequencies of the two events.

5.5.2. Application of a standard statistical veto to GEO S5 data

In this section, we will show some investigations done in order to find out whether it is reasonable to use a monitor of the main site power supply (mains) as a veto channel.

As described already in Section 5.2 glitches on the mains can easily couple to H, while on the other hand it is hard to imagine any way in which a GW could couple back to the mains monitor. This was confirmed by performing GW-like hardware injections. There we inject sine-Gaussian type waveforms into the electrostatic actuators used for the differential length control of the Michelson interferometer and no back coupling to the mains monitor was observed.

Figure 5.7 shows the application of a standard statistical veto to the GW channel using a mains monitor as veto channel. The efficiency and background rate are plotted for time windows between 0 and 20 ms. The shapes of both curves are roughly the same, *i.e.*, the significance stays roughly constant around a value of 20 for different sizes of the time coincidence window.

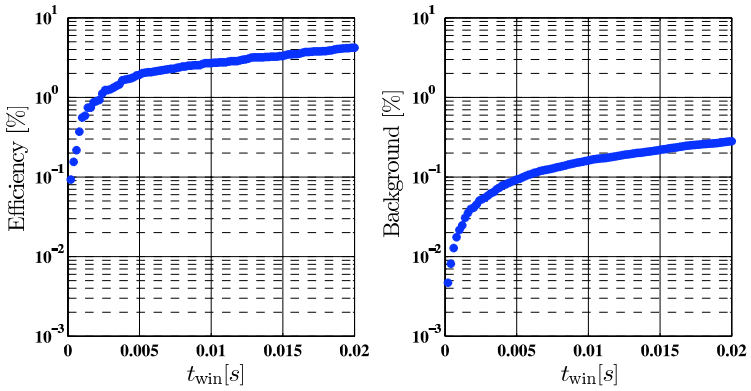

Figure 5.7.: Exemplary application of a statistical veto to a 24 hour stretch of GEO data using a GW-free channel (in this case a mains monitor), as veto channel. Efficiency and background are given as a function of the size of the coincidence time window. The data set used consisted of 3228 and 7725 events in the GW channel and the mains monitor, respectively.

If we choose a time-window of 6 milliseconds in order to get a background of 0.1 %, we achieve an efficiency of about 2 %. Figure 5.8 shows (for the same set of data and a fixed time-window of 6 milliseconds), the effect of including an additional coincidence window for the central frequency of the events.

The right-hand plot of Figure 5.8 shows the improvement in the significance for different sizes of the frequency coincidence window, compared to the case where only a coincidence window for the time of the events is applied. In this case, for all sizes of the frequency coincidence window, the significance is improved. A maximal improvement of about 50 % is achieved for a frequency window of 200 Hz.

If we choose windows, $t_{\mathrm{win}} = 6\,\mathrm{msec}$ and $f_{\mathrm{win}} = 200\,\mathrm{Hz}$, we get an efficiency of 1.5 %, a background of 0.05 %, a use-percentage of 0.6 % and a significance of 30. This example demonstrates the usefulness of additional coincidence windows. However, as the actual performance of this veto is not very impressive in itself, the veto should rather be viewed as an illustrative example.

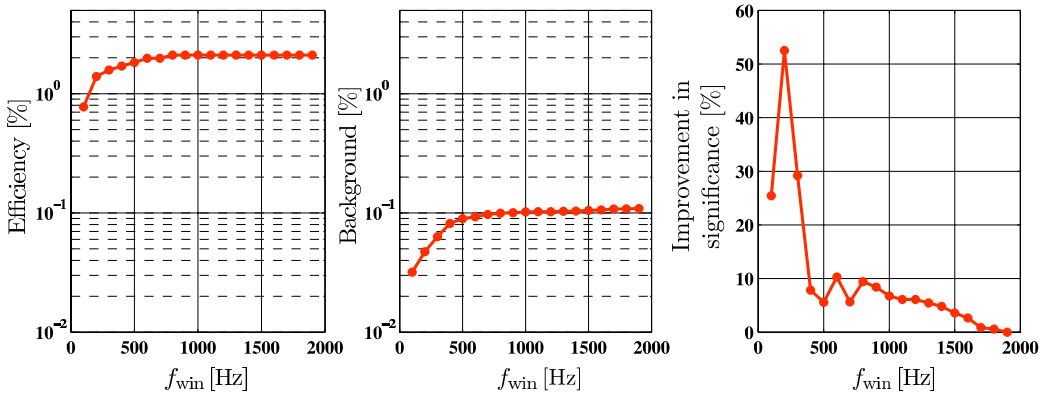

Figure 5.8.: Exemplary application of a statistical veto including an additional coincidence condition for the central frequency of the events. The same data set as for Figure 5.7 is used. A time coincidence window of 6 milliseconds is applied. The background and efficiency are plotted versus the size of the coincidence window for the central frequency. In addition, the right hand plot shows the improvement in significance versus the size of the frequency window. The improvement of significance is the relative improvement compared to the case where no frequency coincidence window is applied.

5.6. A statistical veto for channels containing GW information

In the previous section, we described the statistical veto method using an auxiliary channel containing no gravitational wave information. In this section we will show that, under certain conditions, and when handled with care, a reliable statistical veto can also be based on a veto channel which can contain gravitational wave information.

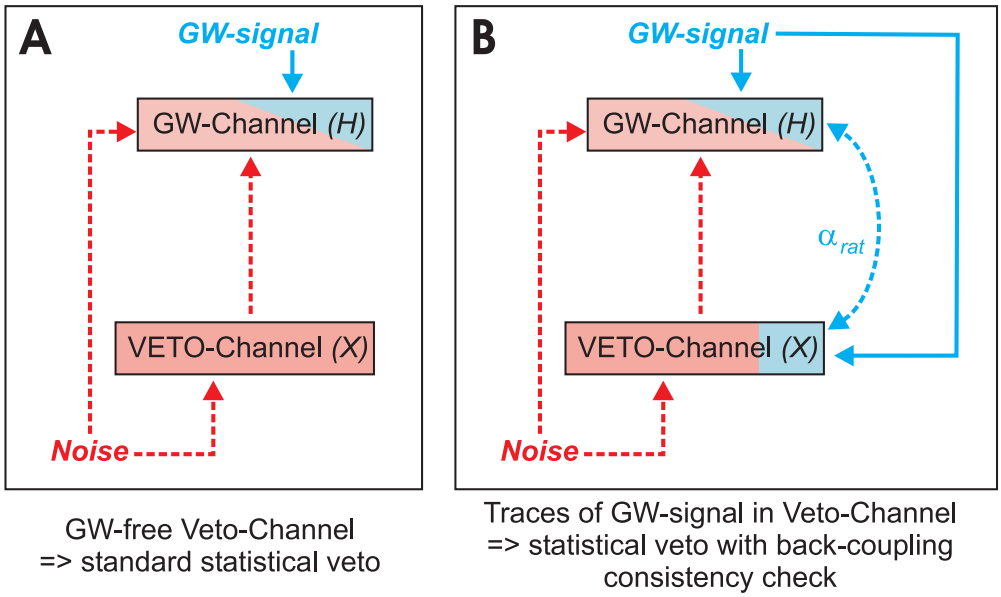

Figure 5.9.: A schematic view of two different scenarios in which coincident transient events can appear in both the main GW channel, H, and an auxilliary channel, X. The first scenario (Panel A) shows coincident events arising from a single noise source, which couples events to H either directly, or via subsystem X, or both. The second scenario (Panel B) shows the case where the events in X can originate, not only from the noise source, but also from the GW signal. The frequency dependent amplitude ratio of a GW-like event measured in both channels, α_{rat}, can be determined by injecting differential arm length noise (to mimic the effect of an GW signal) and measuring the transfer function from H to X.

Figure 5.9 shows two scenarios. Panel A describes the case where there is an (unknown) coupling of a noise source, N, into both the main GW channel, and an auxiliary channel, X; for this case, the standard statistical veto described in Section 5.5 can be applied. Panel B shows the case where the events in X can originate, not only from the

noise source, but also from the GW signal. In order to apply a statistical veto (with a sufficiently low false-veto rate), in such a situation, we have to introduce further coincidence conditions, such as a frequency-dependent amplitude cut. The application of this method requires a rough knowledge of the amplitude ratio, α_{rat}, and its stability.

5.6.1. The method in general

In the presence of gravitational wave signal in the veto channel, we will have two classes of coincidence events to consider when applying a standard statistical veto:

- Noise events that couple via the (red) dashed lines of Figure 5.9. These are the events we would like to veto.
- Gravitational-wave-like events that are showing up in the GW channel as well as in the veto channel.

It is essential to discriminate these two populations and exclude events from the latter class from being vetoed.

A possible way to do this is to compare the amplitudes $a^H[i]$ and $a^X[j]$ of the two coincident triggers $H[i]$ and $X[j]$. In the case that the event $X[j]$ originates from the same GW-like event as the event, $H[i]$, the following (ideal) amplitude ratio can be computed:

$$\frac{a^X[j]}{a^H[i]} = |\alpha_{\mathrm{rat}}[i]|, \tag{5.9}$$

where $|\alpha_{\mathrm{rat}}[i]|$ is amplitude ratio of the GW signal in H and $\mathcal{P}_{\mathrm{DC}}$, α_{rat}, evaluated at the central frequency of the event, $H[i]$, in the gravitational wave channel.

If all quantities in Equation 5.9 are known, the application of the statistical veto is rather simple. First of all, the coincident events need to be determined in the same way as for the standard statistical veto. Secondly, for each pair of events, the ratio of the two amplitudes is compared. If this ratio equals the magnitude of the amplitude ratio, α_{rat}, at the central frequency of the event, the event in the gravitational wave channel is not vetoed. If the amplitude ratio is not consistent with the α_{rat}, the event $H[i]$ is vetoed.

It is also possible that more than one event in the veto channel is coincident with the event $H[i]$. In this case, the H event is excluded from being vetoed if at least one of the

coincident pairs satisfies Equation 5.9.

5.6.2. A 'real-world' scenario

In reality, Equation 5.9 needs to be extended to account for several systematic and statistical errors. Probably the largest contribution to the error originates from the amplitude estimation of the burst events. The errors associated with the amplitude estimation of the events $H[i]$ and $X[j]$ are referred to as $\Delta a^H[i]$ and $\Delta a^X[j]$, respectively. Also, the measurement of the amplitude, $\alpha_{\rm rat}$, can be a source of error. More over, the amplitude ratio can also be non-stationary over time. We represent the cumulative errors due to these two effects by $\Delta\alpha_{\rm rat}$.

Considering these errors, we make a simple generalisation of Equation 5.9 into the 'real-life' situation. In order to veto an event, $H[i]$, in the gravitational wave channel, we first require that it be coincident with the another event, $X[j]$, in the veto channel in the sense of a standard statistical veto (in time and frequency), and secondly that it satisfy either of the following conditions:

$$\frac{a^X[j]}{a^H[i]} < \frac{|\alpha_{\rm rat}[i]|}{(1+\Delta a_{\rm tot})}, \tag{5.10}$$

or

$$\frac{a^X[j]}{a^H[i]} > |\alpha_{\rm rat}[i]|\,(1+\Delta a_{\rm tot}) \tag{5.11}$$

where $\Delta a_{\rm tot}$ is an upper-limit of the cumulative error from the amplitude estimation and the amplitude ratio measurement (also due to the non-stationarity of the amplitude ratio over time).

We will call the veto method based on the condition described above, a *frequency-dependent amplitude cut*, because we cut the events with a certain amplitude ratio out of the list of coincident vetoed events.

5.7. Application of a statistical veto with a amplitude consistency-check to GEO 600 data

In the following three subsections we will present the results of applying a statistical veto with a amplitude consistency check to GEO 600 data using $\mathcal{P}_{\rm DC}$ as the veto channel.

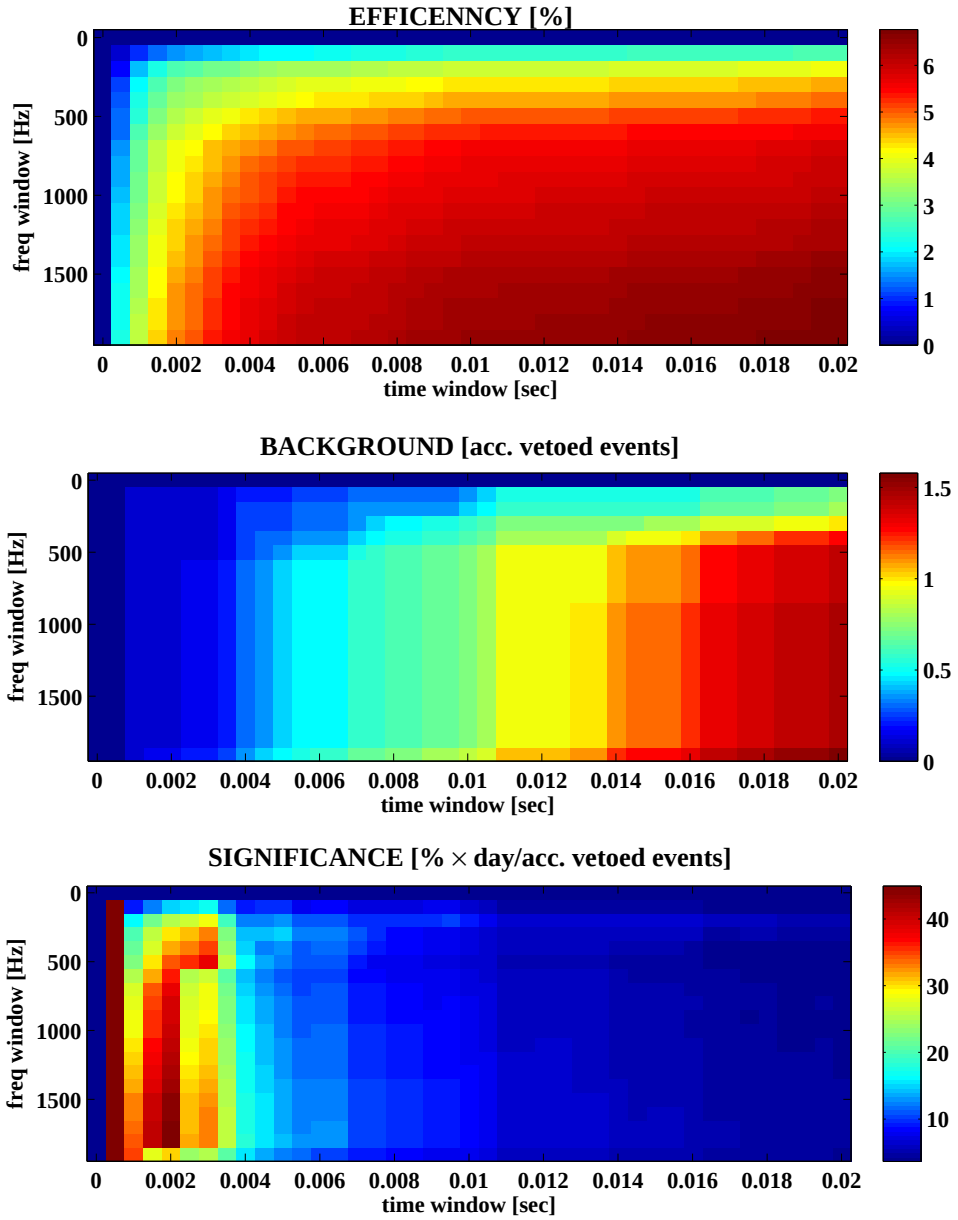

Figure 5.10.: Efficiency, background and Significance of a veto using $\mathcal{P}_{\mathrm{DC}}$ as veto channel for various sizes of the time and frequency coincidence window. To reduce computational resources required for this analysis a data stretch of 24 hours from September 2006 was used instead of the full month. This analysis is done to find good sizes for the coincidence windows. At this stage of the analysis no amplitude consistency-check is applied.

Two different periods of time are analysed. The analysis of a long stretch of data covering the entire month of September 2006 (where the dust concentration in the clean-room was nominal), is presented in subsection 5.7.1. An 8 hour stretch of science data from May 2006 (where a high dust concentration in the clean room was observed), is analysed in subsection 5.7.2. There are only short data stretches available for this period because the broken air conditioning system was fixed within a few days. However, even with the nominal dust concentration restored, still, dust glitches contribute to the glitch rate of H. Finally, the performance of the veto for both periods is compared in subsection 5.7.3.

5.7.1. Data set 1: Full September 2006 with low dust concentration

First we have to determine reasonable sizes for the time and frequency coincidence windows. This was done by computing efficiency, background and significance of the veto for various window sizes for a subset of 24 hours of data from September 2006. The result of this analysis is shown in Figure 5.10. The best significance can be achieved for very small time windows. However for these small time windows the efficiency is very small. That is why we have to trade off significance and efficiency. For a time window of 8 milliseconds and a frequency window of 1000 Hz we achieve a best efficiency for an acceptable background rate of about 0.5 events per day.

For both data sets, and the hardware injections, firstly a coincidence analysis is performed using a time coincidence window of 8 milliseconds and a frequency coincidence window of 1 kHz determined by the analysis described above. The upper plot of Figure 5.12 shows the ratio of the amplitude of the coincident events from $\mathcal{P}_{\mathrm{DC}}$ and H versus the central frequency of the event in H. The (blue) diamonds, corresponding to the GW-like hardware injections, are close to the measured amplitude ratio, α_{rat} (as expected); all the coincident events from the first data set (represented by the purple points), show either a similar amplitude ratio or a higher one. If the ratio is similar to the hardware injections, the points most probably correspond to GW-like events. If the amplitude ratio is higher, this means that $\mathcal{P}_{\mathrm{DC}}$ events show a higher amplitude than is consistent with events originating from a GW-like event. As we do not observe any pairs of events with an amplitude ratio much lower than from the hardware injections,

it is reasonable to simplify Equation 5.11 to the single condition,

$$\frac{a^X[j]}{a^H[i]} > |\alpha_{\mathrm{rat}}[i]|\,(1 + \Delta a_{\mathrm{tot}}). \tag{5.12}$$

Over one month, α_{rat} was measured a few times and $\Delta\alpha_{\mathrm{rat}}$ was found to be less than 0.5.

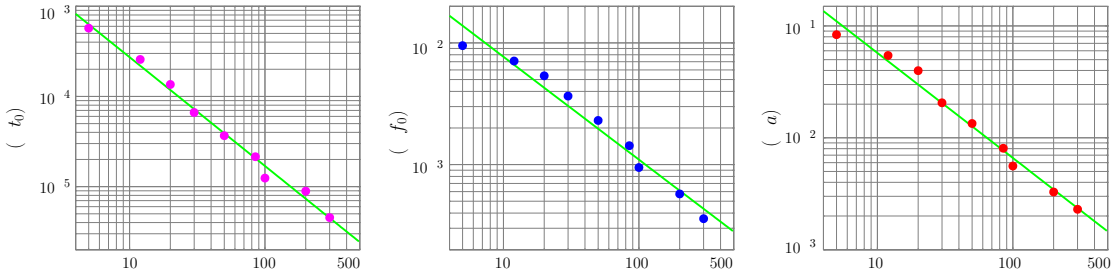

Figure 5.11.: Standard deviation of the distribution of the mHACR errors (in estimating the parameters of injected sine-Gaussian waveforms into gaussian noise) plotted as a function of the snr of the triggers. Also shown are linear-polynomial fits to the data. This plot is taken from [Hild07a] and was produced by P. Ajith.

The main error contribution of the amplitude estimation of the events can be described by three times the standard deviation (3σ) given in the right hand plot of Figure 5.11. The lowest SNR of an event contained in this analysis is about 4, which means that the maximum error in estimating the amplitude of an event is about 60 % (see Figure 5.11). Since the values in Figure 5.11 are estimated from ideal conditions [2], we will allow for a 200 % error in the amplitude estimation to get a safe upper limit of the error. All together, Δa_{tot} amounts to 2.

In the end we get the final set of three veto conditions:

$$\left|t_0^X[j] - t_0^H[i]\right| < 8\,\mathrm{ms}, \tag{5.13}$$

$$\left|f_0^X[j] - f_0^H[i]\right| < 1\mathrm{kHz}, \tag{5.14}$$

[2] The errors in parameter estimation given by a particular detection algorithm depend on many things, for example, the waveform of the transient signal and the characteristics of the underlying data-stream (noise, spectral lines, *etc*).

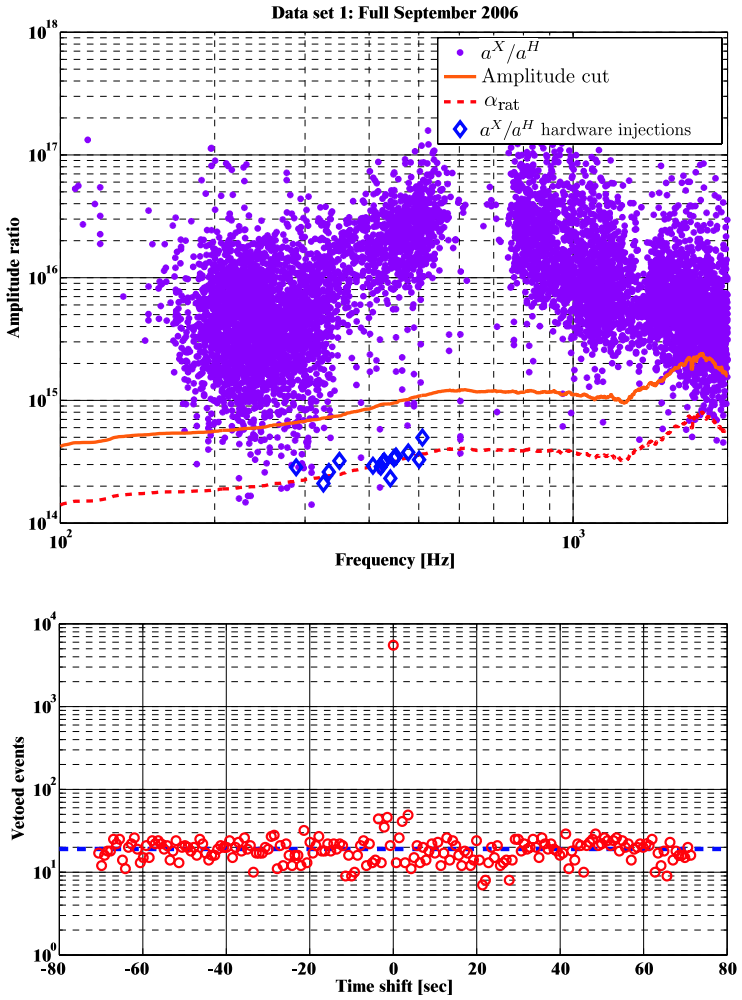

Figure 5.12.: *Upper plot*: Application of a statistical veto with a amplitude consistency check to GEO 600 data for the entire month of September 2006. The (red) dashed line is a measurement of the amplitude ratio, $\alpha_{\rm rat}$. The (blue) diamonds are the amplitude ratios of the coincident events in $\mathcal{P}_{\rm DC}$ and H from GW-like burst hardware injections. The hardware injections are consistent with $\alpha_{\rm rat}$. The solid (orange) line is the chosen amplitude cut, corresponding to $\Delta a_{\rm tot} = 2$. The (purple) points indicate the amplitude ratio of the coincident events from $\mathcal{P}_{\rm DC}$ and H for September. Each H event corresponding to a point above the solid line is vetoed, while each point below the solid line is taken as being consistent with a GW signal and is excluded from being vetoed. *Lower plot*: A time-shift analysis of the statistical veto with a amplitude consistency check for data set 1. 5517 events in H are vetoed, while the background of accidentally-vetoed events amounts to 19.1 events per month.

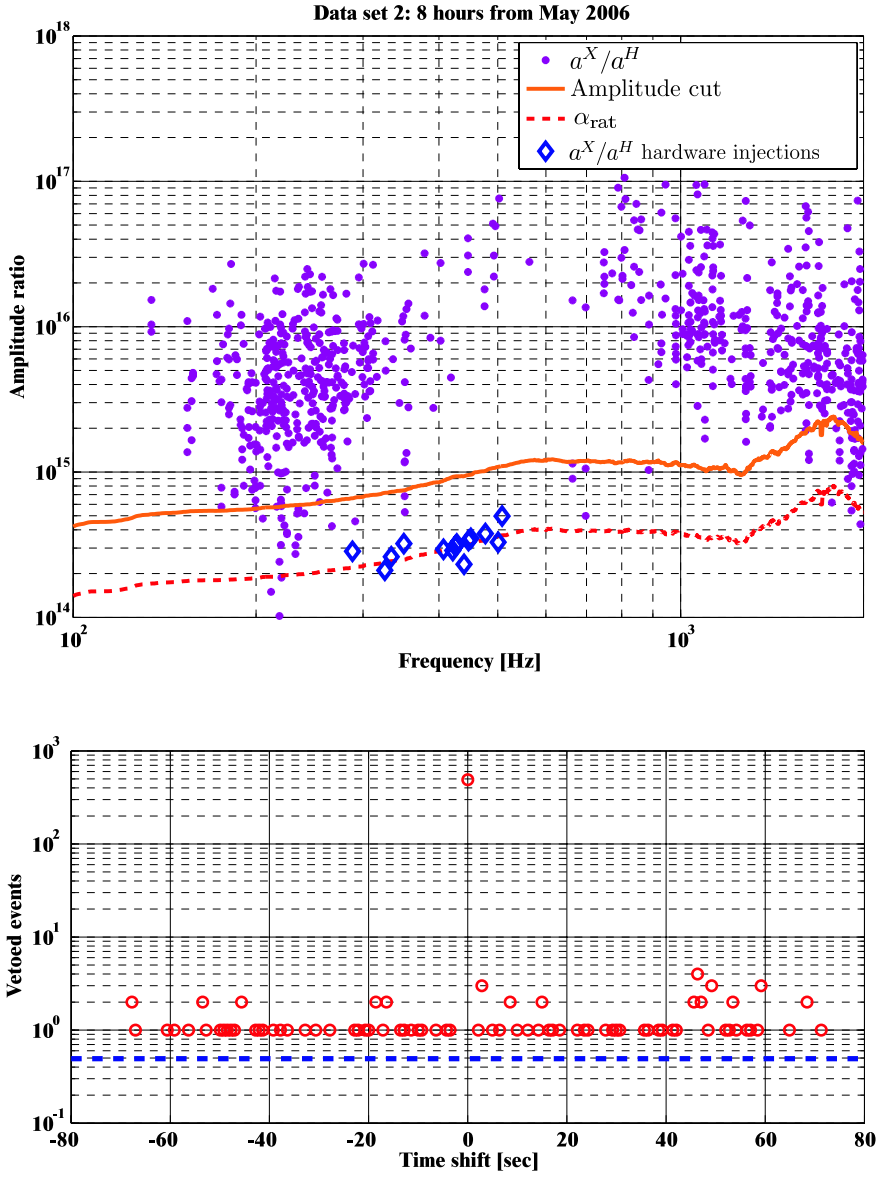

Figure 5.13.: *Upper plot*: The application of a statistical veto with a amplitude consistency check to 8 hours of GEO data from May. For further details, please see Figure 5.12. *Lower plot*: A time-shift analysis of the statistical veto with a amplitude consistency check for data set 2. 291 events in H are vetoed, while the background of accidentally vetoed events amounts to 0.49 events per 8 hours.

and

$$\frac{a^X[j]}{a^H[i]} > 3\,\alpha_{\mathrm{rat}}[i]. \tag{5.15}$$

The last condition can be seen as an amplitude cut. The solid (orange) line in Figure 5.12 indicates the level of this amplitude cut. Each H event corresponding to a (purple) point above the solid line is vetoed, while each point below the solid line is taken as being consistent with a potential GW signal and is excluded from being vetoed. By introducing the amplitude cut the veto efficiency is reduced from 5.94 to 5.72 %. The background rate of this veto is estimated by time-shifting the H events and is indicated by the (blue) dashed line in the lower plot of Figure 5.12.

5.7.2. Data set 2: 8 hours from May 2006 with high dust concentration

Data set 2 is from a time with a high dust concentration in the main clean room. For the analysis, identical veto conditions are applied as for data set 1. The result of the veto application is shown in Figure 5.13.

For this set of data, a high veto efficiency of greater than 20 % is obtained. The background rate of this veto, estimated from a time-shift analysis, is indicated by the (blue) dashed line in the lower subplot of Figure 5.13.

5.7.3. Performance of the veto analysis

The results of applying a statistical veto based on $\mathcal{P}_{\mathrm{DC}}$, together with a amplitude consistency check, are summarised in Table 5.1.

Data Set	1	2
Efficiency [%]	5.72	21.5
Background [%]	0.02	0.02
Significance	286	1075
Use-percentage [%]	20.7	79.8

Table 5.1.: A summary of the results of applying a statistical veto with a amplitude consistency check to two different data sets from GEO 600.

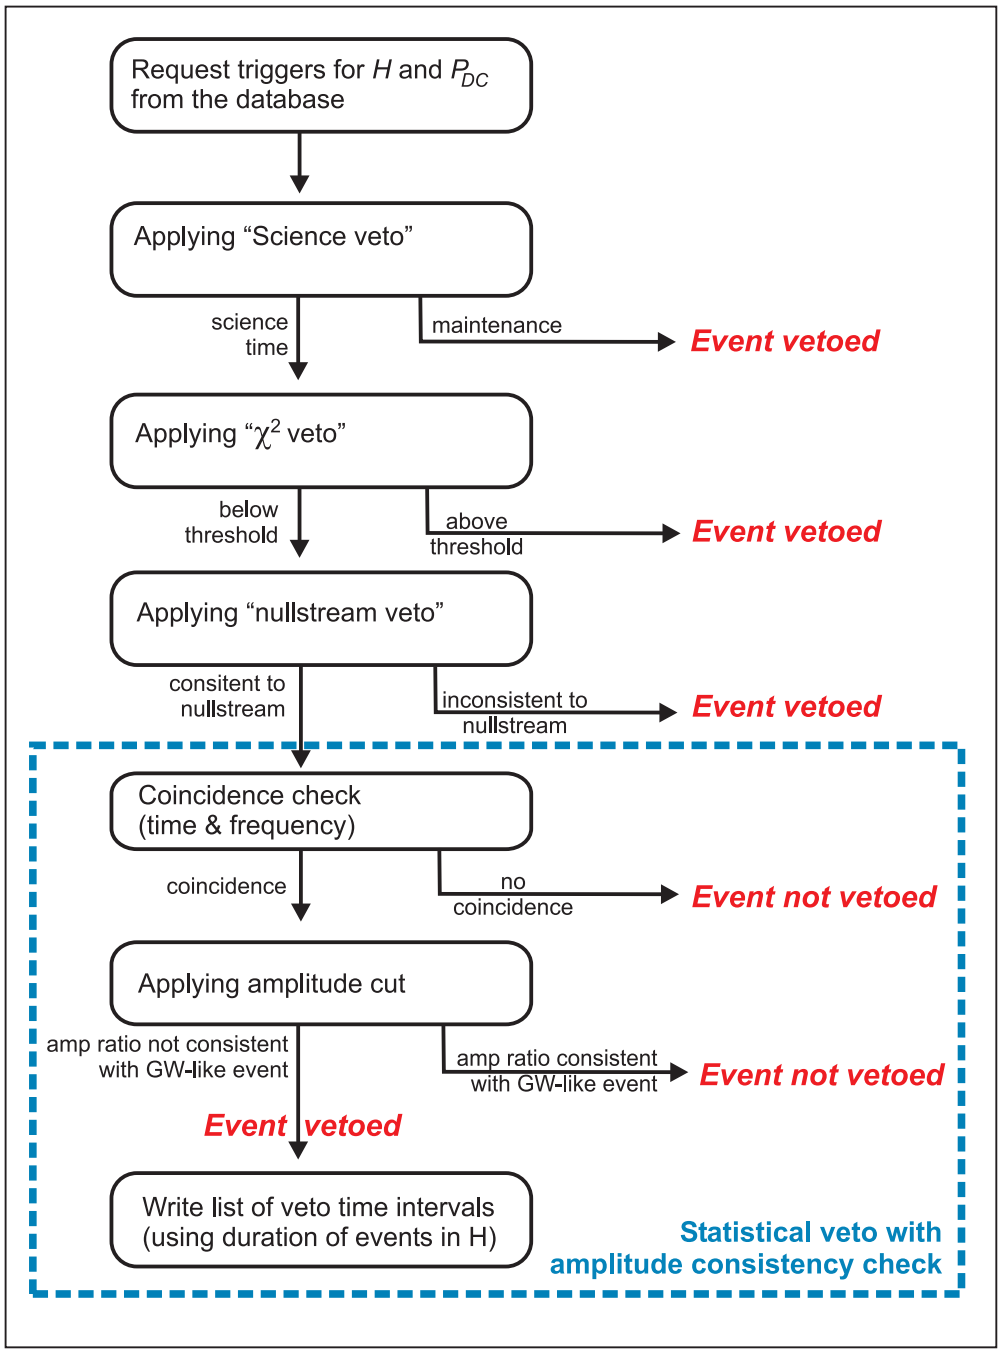

Figure 5.14.: Schematic of the veto pipeline used for the analysis of Data Set 1 (full September 2006). Before the statistical veto three other vetoes (science, χ^2 and null stream) are applied. The output of the whole pipeline is a list of veto intervals.

Figure 5.14 gives a schematic overview of veto analysis performed for the analysis of full September 2006. The corresponding Matlab script can be found in Appendix G.

5.8. Summary

It was shown that the performance of a standard statistical veto can be improved by application of more than one coincidence window. Furthermore, a new veto method was developed which allows the use of veto channels which can contain GW signal. By introducing an amplitude consistency check, safe statistical vetoes can be derived from interferometer channels. GW-like hardware injections have been performed to demonstrate the robustness of this veto method. Application of a statistical veto with amplitude consistency check to data from the GEO 600 detector was shown to perform well, giving a veto efficiency of up to 20 % and a use-percentage of up to 80 %. This new method is generally applicable and can also be used on the data from other GW detectors.

Chapter 6.

Towards DC-readout for GEO 600

6.1. Introduction

All of the currently running large-scale gravitational wave detectors are operated at the dark fringe and use a heterodyne readout. For a Michelson interferometer without signal recycling the choice of this operating point has two predominant advantages: First of all, the couplings of some technical noise, for example laser power noise, are suppressed. Secondly, the power recycling technique can easily be implemented.

However, the experience in the currently running interferometers reveal several problems connected to a heterodyne readout:

- As it will be shown in Section 6.2 a heterodyne readout always implies an increased shot noise level with respect to a homodyne readout.
- Phase noise of the applied modulation would probably limit the sensitivity of advanced detectors.
- Since the Michelson RF sidebands propagate differently through the interferometer than the carrier light the spatial overlap of the GW signal (carrier) and the local oscillator (Michelson sideband) might be imperfect.
- In an interferometer with detuned signal recycling the presence of imbalanced RF sidebands at the output port increases and complicates the technical noise contributions [Hild07b].

A way to get around these problems is to choose an operating point slightly off the dark fringe and to use a DC-readout (homodyne) scheme.

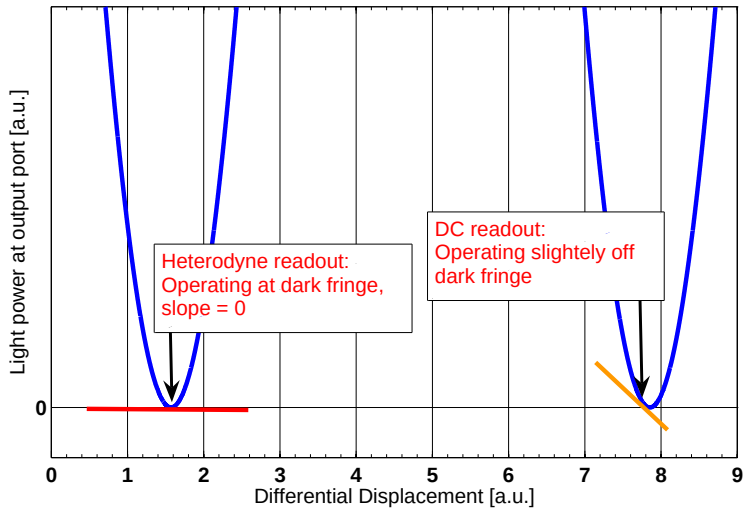

Figure 6.1.: Overview of the operating points of a heterodyne and DC-readout scheme. Currently GEO 600 uses heterodyne readout and is operated at the dark fringe. A DC-readout scheme uses an operating point slightly off the dark fringe. While in the heterodyne case RF sidebands are used as local oscillator, in the DC-readout scheme a fraction of the carrier light can leave the interferometer at the output port and serve as local oscillator.

Figure 6.1 schematically depicts the two different readout schemes. The currently in GEO 600 used heterodyne readout is shown on the left side: The Michelson interferometer is operated at the dark fringe, the slope of the light power is 0, and heterodyne sidebands at RF are used for the readout in order to produce a bipolar control signal. On the right side the situation used for DC-readout is shown. The operating point is slightly off the dark fringe, thus a fraction of the carrier light can leave the interferometer and serve, due to the large power recycling gain, as a highly stabilized local oscillator at the photodiode. Since the slope of the output light level versus differential arm length is not zero any more a bipolar control signal can be obtained from the level of DC light.

Due to the advantages of DC-readout with respect to heterodyne readout, for advanced LIGO [AdvLIGO] a DC-readout scheme will be used. Also for GEO 600 there are good reasons to change over to a DC-readout scheme as will be shown in the following sections.

6.2. Motivation

In the next few years LIGO as well as VIRGO are going to improve their detectors. Both plan for precursor projects, called enhanced LIGO [Adhikari06] and VIRGO+ with moderate sensitivity improvements before going to advanced LIGO [AdvLIGO], [Giaime] and advanced VIRGO [AdvVIRGO]. As shown in Figure 1.1 the current sensitivity of the only 600 m long GEO 600 detector is competitive to the much longer detectors only at frequencies above 500 Hz. Therefore in the near future any sensitivity improvement of GEO 600 at high frequencies is probably going to be more valuable than an improvement at low frequencies.[1]

Figure 6.2 shows the S5 noise projections of the GEO 600 detector [Smith06]. Above 400 Hz the uncorrelated sum of the individual noise contributions is mainly dominated by the modelled shot noise[2]. The first step in order to improve the sensitivity of GEO 600 at

[1] This statement is of course build on many assumptions, which might change in future. However, it bases on our currently best knowledge.

[2] Due to the asymmetric sidebands present at the output of a detuned signal recycled interferometer, the calculation of the shot noise limit of GEO 600 is more complicated than for a detector without signal recycling or tuned signal recycling and is therefore still a field of research. However, assuming completely unbalanced Michelson sidebands we can calculate an upper limit of the shot noise for the heterodyne readout. It was estimated by using the *pdS2*-command of FINESSE. The outcome of the FINESSE simulation was then multiplied by two correction factors: First a factor $1/\sqrt{2}$, accounting

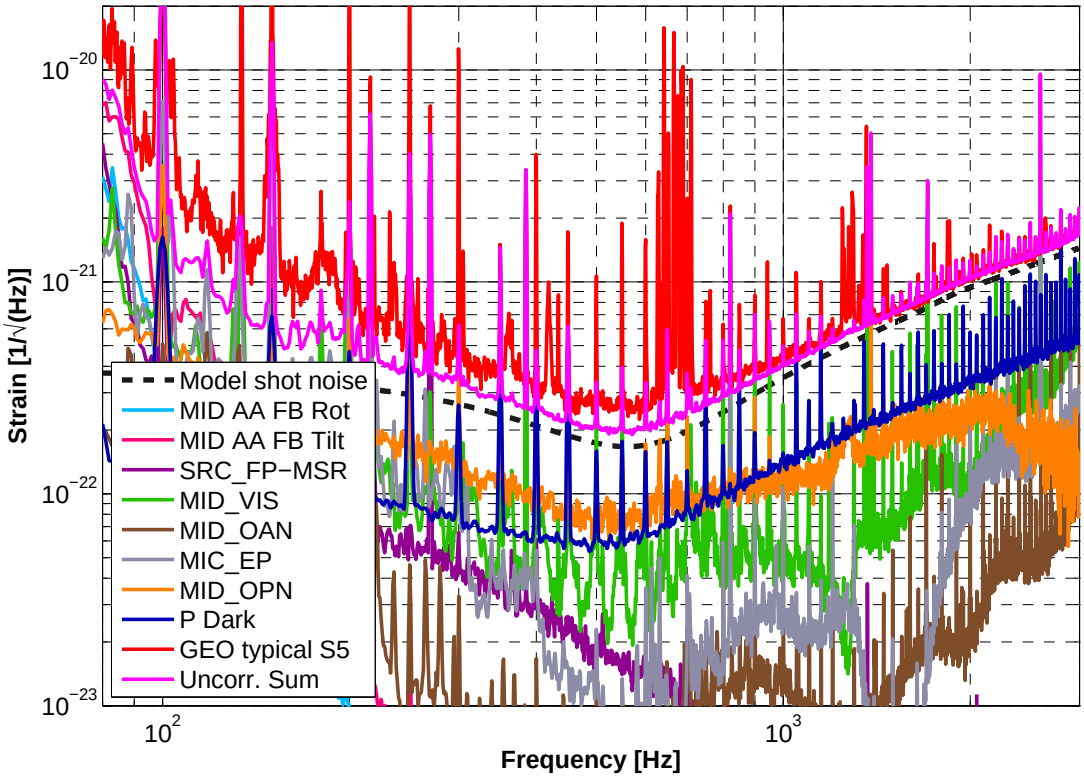

Figure 6.2.: Noise projections for a time of S5. The pink curve represents the uncorrelated sum of the individual noise contributions. The red trace shows a snapshot of the actual sensitivity. Above 400 Hz the uncorrelated sum is mainly dominated by the modelled shot noise (explanation is given in the text). The near-future plan is to increase the circulating light power by about a factor 4 in order to decrease shot noise by a factor of 2. Then the sensitivity between 500 and 2000 Hz would be limited to roughly equal shares by shot noise, oscillator phase noise (MID_OPN) and electronic noise of the main photodiode (P Dark). All three of these noise contributions will potentially be decreased by changing over from a heterodyne to a DC-readout scheme.

frequencies above 500 Hz is to decrease the shot noise contribution by means of increasing the circulating light power. As soon as the light power is increased by a factor of 4, which would bring the shot noise (black dashed line in Figure 6.2) down by a factor of 2, the sensitivity of GEO 600 would be limited above 500 Hz by roughly equal shares of three noise sources:

- Shot noise
- Oscillator phase noise of the modulation used for creating control signals for the differential arm length of the Michelson interferometer and the gravitational wave readout (MID_OPN, orange trace in Figure 6.2).
- Electronic noise of the main photo diode (P Dark, blue trace in Figure 6.2).

If we want to increase the sensitivity of GEO 600 by more than a factor of two at frequencies above 500 Hz we have to attack all three of the noises listed above. The concept of DC-readout implies the wonderful chance to reduce all three of these noises at once.

6.2.1. Shot noise

When going from the currently used heterodyne read out scheme to a DC-readout scheme the signal to shot noise ratio will be increased by a factor between $\sqrt{1.5}$ and $\sqrt{2}$ [Buonanno03], [Harms06]. This depends on the balancing of the two Michelson sidebands at the dark-port. The sensitivity will be increased by between a factor of $\sqrt{1.5}$ for balanced sidebands and a factor of $\sqrt{2}$ for completely unbalanced sidebands. This can in an easy picture be understood by looking at the individual shot noise contributions at the dark-port. Amongst others we find in the heterodyne case shot noise contributions from frequencies, 2ω, corresponding to two times the heterodyne modulation frequencies (see Appendix B). It is worth noting that this improvement in sensitivity is achieved by only changing the readout scheme and does not require any increase of light power.

for the different propagation of signal and shot noise in a FINESSE-mixer (for a detailed description see [Finesse], page 61). The second factor, $\sqrt{2}$, accounts for additional shot noise in a heterodyne readout with respect to a homodyne readout [Buonanno03], [Harms06].

6.2.2. Oscillator phase noise

The oscillator phase noise is a serious problem for all heterodyne readout techniques. Even though this noise is usually classified as a technical noise source we are now already close to the limits, even though a low phase noise crystal oscillator is currently used in GEO 600. One way to reduce the oscillator phase contribution would be to reduce the coupling factor by going to tuned signal recycling (see Section 2.6). However, when going from a heterodyne to a DC-readout scheme it would be possible to derive the GW signal without an RF demodulation of the main output photodetector. By that we would completely eliminate any oscillator phase noise contribution.[3]

6.2.3. Electronic noise of the main photo diode

The electronic noise of the main photodiode can also be reduced by changing over to DC-readout. At the moment the diode is required to have a large dynamic range and to be capable of detecting large RF signals at the same time. This requirement restricts the maximal possible conversion factor for the photo current to voltage transformation [Grote]. However, as in a DC-readout scheme the photodiode does not have to detect RF signals, the electronic noise of the photodiode can be significantly reduced by increasing the photocurrent to voltage conversion factor and an additional gain increase of the first amplification stage.

6.3. Determination of the optimal dark fringe offset

The most important question we have to answer is, what is the optimal offset from the dark fringe for a DC-readout scheme for GEO 600? The dark fringe offset, ξ_{df}, is defined as:

$$\xi_{\mathrm{df}} = \frac{|\Delta L_{\mathrm{n}}| + |\Delta L_{\mathrm{e}}|}{2}, \tag{6.1}$$

where $\Delta L_{\mathrm{e}} = -\Delta L_{\mathrm{n}}$ are the intentionally added offsets in the distance between the beam splitter and the end mirrors MCE and MCN, respectively. In the following, FINESSE simulations [Freise04] are used to find the optimal dark fringe offset. The

[3] It is a noteworthy fact, that in recent times the relative stability of the light in the interferometer is better than the relative phase noise achievable with excellent RF technique.

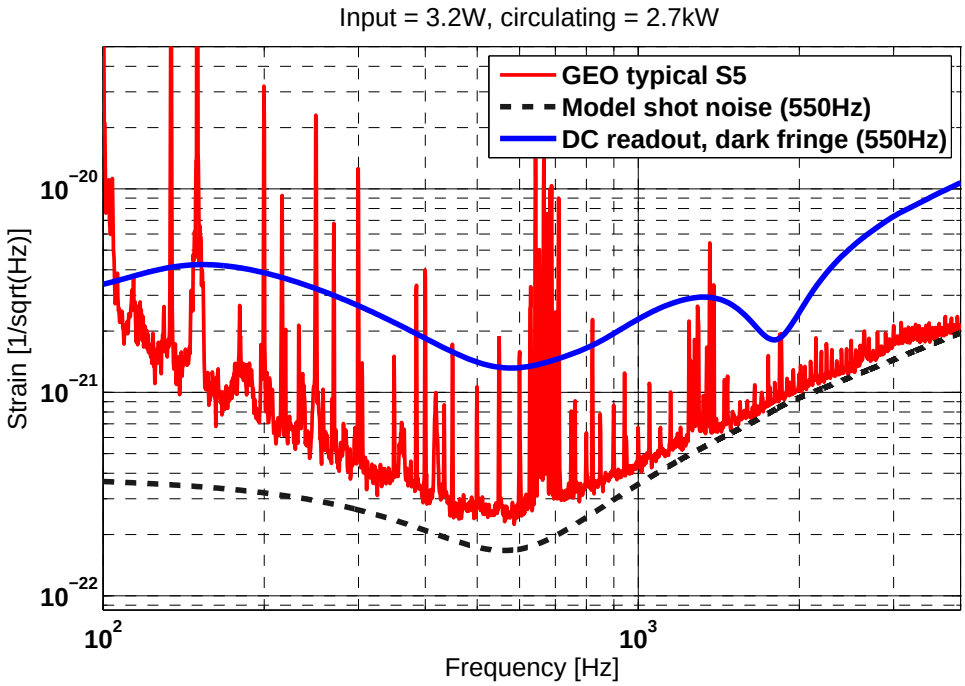

Figure 6.3.: Heterodyne versus DC-readout for GEO 600 in S5 configuration: The red trace shows the typical sensitivity of GEO 600 of S5. The blue trace corresponds to the shot noise limited sensitivity for using the DC light level of main photo detector, $\mathcal{P}_{\mathrm{DC}}$. For this simulation the nominal modulation indices of S5 have been used and the operating point was chosen to be the dark fringe. The black dashed curve represents the modelled shot noise.

first simulation that was carried out is shown in Figure 6.3. The blue line represents the sensitivity that can in principle be obtained in the current configuration of GEO 600 (nominal S5 parameters) by using the DC light of the main photo detector. As already presented in Chapter 5.3 the DC light of the main photo detector, $\mathcal{P}_{\mathrm{DC}}$ is sensitive to gravitational wave signal as well. This originates from the fact that for the Michelson modulation sidebands the Michelson interferometer is not at the dark fringe, i.e. the sideband strength at the output port is to some extent proportional to the differential arm length of the interferometer. With respect to the actual sensitivity of GEO 600 (red trace in Figure 6.3), the blue trace shows a maximal sensitivity around 1.8 kHz. The bump around 1.8 kHz can also be found in the measurement of the transfer function from differential arm length to $\mathcal{P}_{\mathrm{DC}}$ shown in Figure 5.12.

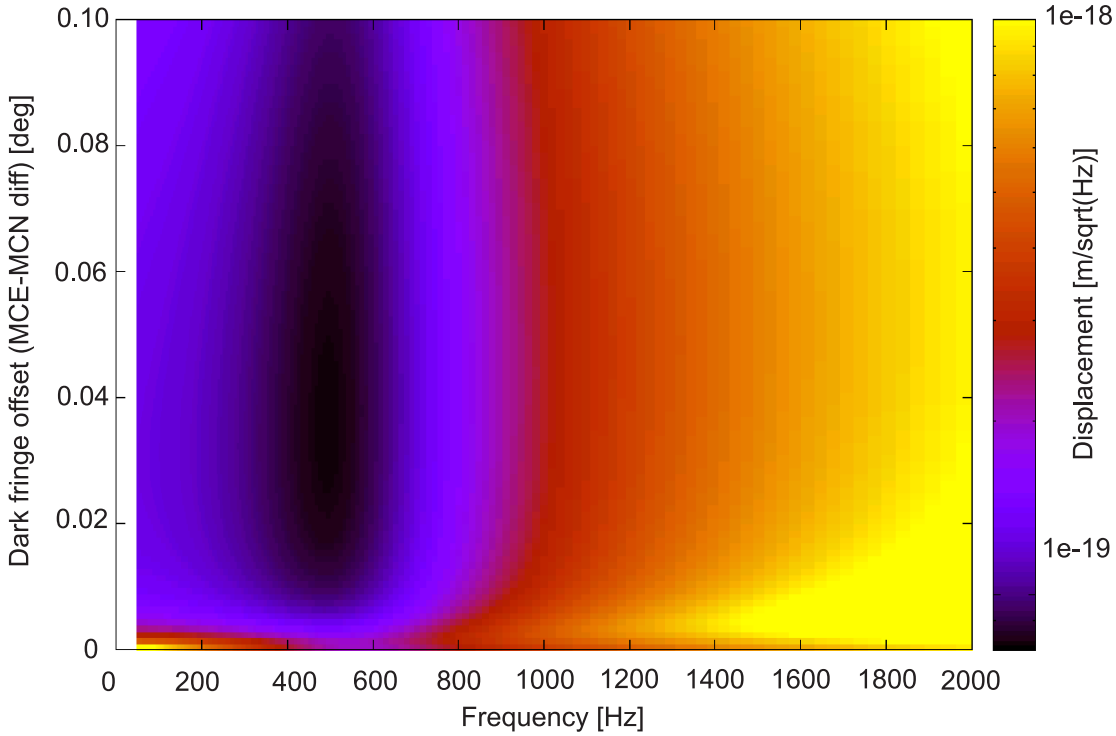

Figure 6.4.: Simulated displacement sensitivity of GEO 600 with DC-readout versus the offset from the dark fringe, ξ_{df}. The offset from the dark fringe was realized in this simulation by adding a differential phase offset to MCE and MCN. The modulation index of the Michelson sidebands was set to 5 % of the nominal S5 value. The best peak sensitivity is found for ξ_{df}= 0.036 deg.

Currently a modulation index for the Michelson modulation of 0.38 is used. For the DC-readout scheme it is desirable to get rid of all RF contributions at the output port light field in order to not spoil the measurement. The strength of the sidebands at the dark port is planned to be decreased in two steps. First it seems reasonable to decrease the applied modulation by a factor of two and still get reasonable control signals. In a second step it is planned to insert an output mode cleaner (OMC) into the main detection path which is assumed to suppress the Michelson sidebands by another factor of ten. Overall this would give a reduction by a factor of 20 of the Michelson sidebands at the main photo detector. In the following simulations this sideband suppression is realized by turning down the modulation in front of the interferometer from the nominal S5 value of 0.38 to 0.019[4].

With the reduced Michelson sideband strength we can now find the optimal offset from the dark fringe. Figure 6.4 shows the simulated displacement sensitivity versus the dark fringe offset, ξ_{df}. The offset from the dark fringe was implemented in this simulation by adding a differential phase offset (given in degree) to the end mirrors of the Michelson interferometer, MCE and MCN. ξ_{df} given in degrees can be converted into ξ_{df} given in meters by

$$\xi_{\mathrm{df}}\,[\mathrm{m}] = \frac{\lambda}{360\,\mathrm{deg}}\,\xi_{\mathrm{df}}\,[\mathrm{deg}], \tag{6.2}$$

where $\lambda = 1064\,\mathrm{nm}$ is the wavelength of the laser. The optimal dark fringe offset giving the best peak sensitivity is found for a ξ_{df} of 0.036 degrees, which is equivalent to ξ_{df}= $1.06 \cdot 10^{-10}\,\mathrm{m}$. The slope of the sensitivity improvement is found to be very steep for small offsets from the dark fringe, $\xi_{\mathrm{df}} < 0.01\,\mathrm{deg}$, and is nearly flat for larger offsets. That is why already for half the optimal dark fringe offset, $\xi_{\mathrm{df}} = 0.018$ degrees, which is equivalent to a dark fringe offset of about 50 pm, the achieved sensitivity is nearly optimal[5]. The FINESSE input file used for this simulation can be found in Appendix H.

Since many potential problems connected to a DC-readout scheme, such as noise couplings, increase with the dark fringe offset, a smaller offset, giving nearly the same sensitivity, is actually preferable. Figure 6.5 shows the spectra of the shot noise limit

[4] In contrast to an output mode cleaner this scenario gives a slightly increased circulating light power inside the interferometer, as now ratio of carrier and Michelson sidebands is increased. However, this effect influences the following simulations only on a scale of a few percent.

[5] This relation is also illustrated in a more obvious way in Figure 6.5.

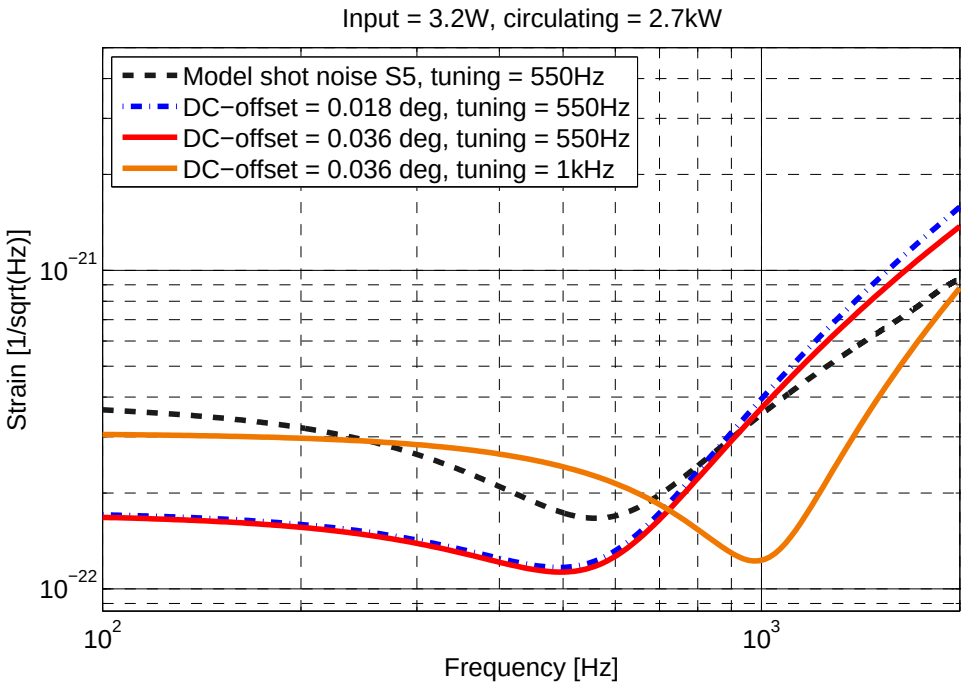

Figure 6.5.: Shot noise limited sensitivity achievable with DC-readout versus the modelled shot noise of S5: The red and the blue dashed-dotted trace represent the sensitivity with a DC-readout scheme for two different ξ_{df}. Even though an optimal ξ_{df}= 0.036 deg was determined from Figure 6.4, half of that dark fringe offset (ξ_{df}= 0.018 deg) already gives a sensitivity only marginally worse. An improvement of the peak sensitivity by about a factor 1.5 is achievable with respect to the modelled shot noise of S5. For the currently used input power of 3.2 W a peak sensitivity of about $1.1 \cdot 10^{-22}/\sqrt{\mathrm{Hz}}$ is obtained. The orange trace shows the sensitivity for a signal recycling tuning frequency of 1 kHz.

achievable with DC-readout versus the modelled shot noise of S5. The red and the blue dashed-dotted trace represent the sensitivity with a DC-readout scheme for two different ξ_{df}. Even though an optimal ξ_{df}= 0.036 deg was determined from Figure 6.4, half of that dark fringe offset (ξ_{df}= 0.018 deg) already gives a sensitivity only marginally worse. An improvement of the peak sensitivity by about a factor 1.5 is achievable with respect to the modelled shot noise of S5. For the currently used input power of 3.2 W a peak sensitivity of about $1.1 \cdot 10^{-22}/\sqrt{\mathrm{Hz}}$ is obtained.

The orange trace shows the simulated shot noise limited sensitivity with DC-readout for a signal recycling tuning frequency of 1 kHz. Again a peak sensitivity of about $1.2 \cdot 10^{-22}/\sqrt{\mathrm{Hz}}$ is obtained. At a frequency of 1 kHz this sensitivity is a factor of roughly 3 better than the S5 sensitivity of GEO 600 with the currently used signal recycling tuning of 550 Hz.

6.4. Technical realization

The technical implementation of a pure DC-readout scheme for GEO 600 would require some major changes, such as finding a new locking procedure or developing good in-vacuum photodiodes. Before the implementation of DC-readout into a running gravitational wave detector can be considered, a challenging R&D project needs to be carried out, which can probably be best done at a small prototype interferometer.

Nevertheless, a mix-scenario of a heterodyne and a DC-readout scheme for GEO 600 might be easy to implement and would give the chance get a sensitivity improvement at least at high frequencies. The idea is to keep the GEO detector as it is and only implement two changes: The first change would be to introduce an offset from the dark fringe of 50 pm. The second change would be to install an output mode cleaner (OMC) in front of the main photo detector (HPD), see Figure 6.6. Since in GEO 600 the Michelson sideband frequency is about 15 MHz, an OMC with a pole frequency of 1.5 MHz is required in order to give a suppression factor of 10 for the MI sidebands. The locking procedure and the full angular and longitudinal control of the interferometer would stay the same as it is now, except that the signal for the Michelson differential arm length is no longer derived from the main photo detector, but from an auxiliary detector (PDOQ) that is currently only used for lock acquisition and during the down-tuning procedure. For the DC-readout of the GW wave signal still the main photo

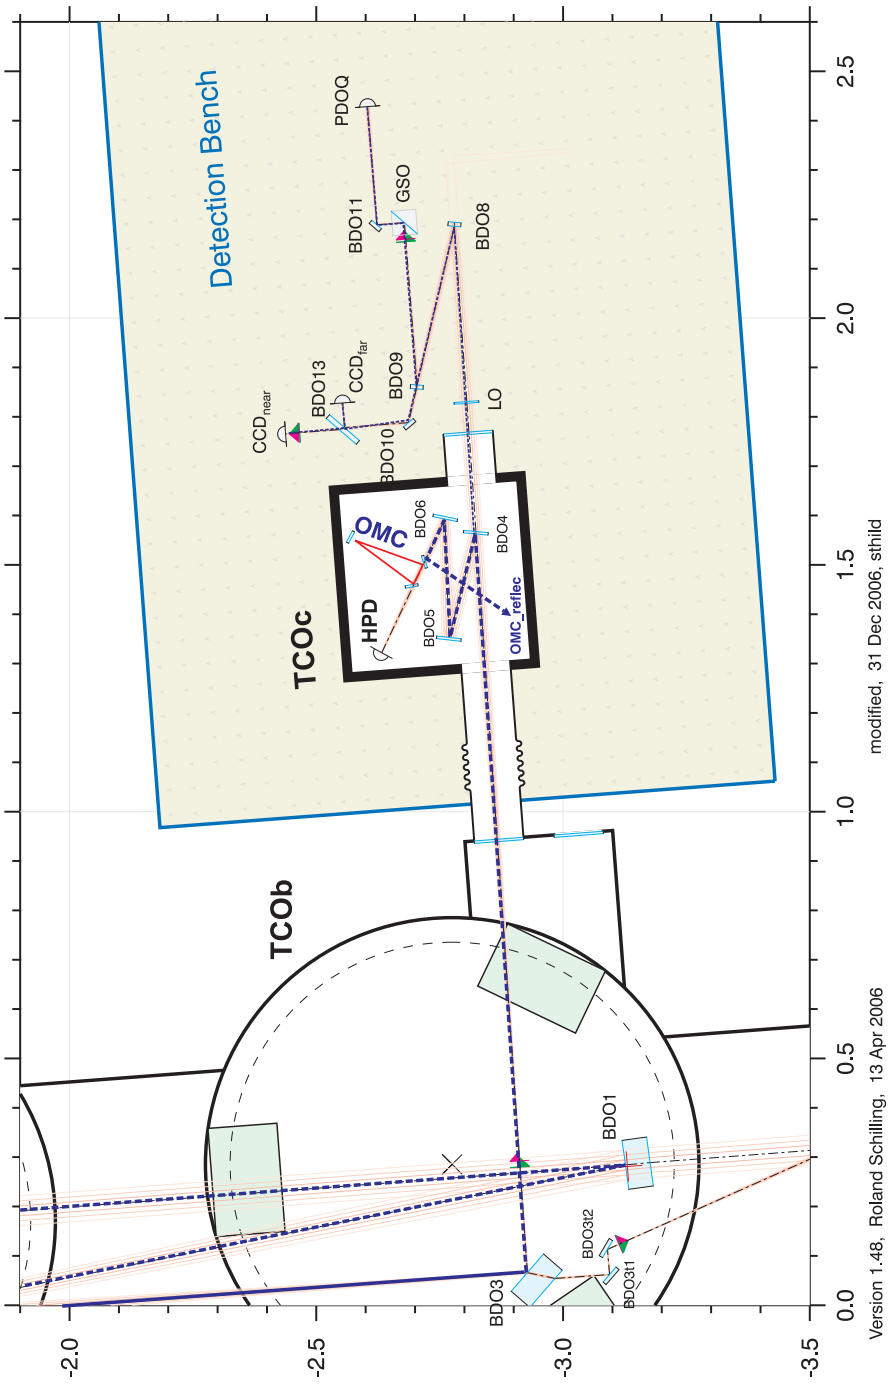

Figure 6.6.: Optical layout of the main detection bench of GEO 600. In front of the main photodiode (HPD) an output mode cleaner (OMC) needs to be added in order to suppress the Michelson sidebands (blue dashed lines) at the HPD. A more detailed explanation of a first realization of a DC-readout scheme can be found in the text.

detector would be used.

Figure 6.6 shows an optical layout of the detection bench. The output beam from the interferometer leaves TCOb and enters the small output vacuum chamber, TCOc, which is currently used at atmospheric pressure and only serves as acoustical enclosure. The beam is split by BDO4 (reflectivity = 0.98) into the so called *high power path* going to HPD and the so called *quadrant path* going to PDOQ. In the high power path an output mode cleaner is added. This filter cavity needs to be designed in a way that the carrier light can be transmitted, while the Michelson RF sidebands are reflected. The 2 % of the light in the quadrant path still contain the MI sidebands and can therefore be used for deriving control signals.

With the setup described above, at least at frequencies above 500 Hz, there is a chance to see the improvement in shot noise with respect to the heterodyne readout. Below 500 Hz the sensitivity will probably be limited by feedback noise introduced by the electronic noise of the quadrant diode. Hence in a next step it would be desirable to use the homodyne signal derived from the HPD for differential arm length control. In a DC-readout scheme a multitude of low frequency noise is expected to originate from acoustical and seismic excitation. That is why in a following step this setup could further be improvement by putting the output mode cleaner into vacuum (TCOc is already installed) and suspending the OMC.

6.5. Summary and outlook

In this chapter a possible new readout scheme of GEO 600 was introduced, combining a heterodyne scheme for control of the detector with a DC-readout scheme. With the aid of simulations a dark fringe offset of about 50 pm was found to be optimal. Without any change of the circulating light power a shot noise limited peak sensitivity can be obtained that is a factor of 1.5 improved with respect to currently modelled shot noise. However, the simulations shown in this chapter are not comprehensive and should be seen as an example of what we may find with GEO 600.

In case it will be decided to change the GEO 600 readout to the here described DC-readout scheme, further investigations have to be carried out in order to successfully enter this new and challenging field of GW detector design.

Appendix A.

The suspended output telescope of GEO 600

The output beam of GEO 600 transmitted through the signal recycling mirror has a diameter of about 2 cm. Such a large beam cannot easily be handled in the complex detection pathes (see Figure 6.6 for example). Therefore it is desirable to convert the large interferometer beam to a smaller beam by the use of an output telescope. Up to May 2004 the GEO 600 output telescope consisted of 3 mirrors rigidly connected to optical tables, with most of the beam path being in air.

In May 2004 a new output telescope, shown in Figure A.1, was installed. It consists of three suspended mirrors, BDO1, BDO2 and BDO3, of which the first one is curved in order to focus the beam. Each suspension consists of a vertical isolation stage, realized by cantilever springs, passively damped by eddy currents, and a horizontal stage, realized by a single pendulum stage. The mirrors are suspended in steel wire loops (127 microns) and the length of the pendulums was chosen to be 460 mm. The position of the mirror is read out by shadow sensors and feedback is applied via four coil magnet actuators each.

The new output telescope provides for the following benefits:

- **In-vacuum beam path:** Since the beam is inside the vacuum, the chance of stray light originating from dust is significantly reduced (see Section 5.3). In addition air induced beam distortion is avoided as well as acoustical excitation of the telescope mirrors.
- **Seismic isolation:** The seismic isolation of the three mirrors reduces the beam

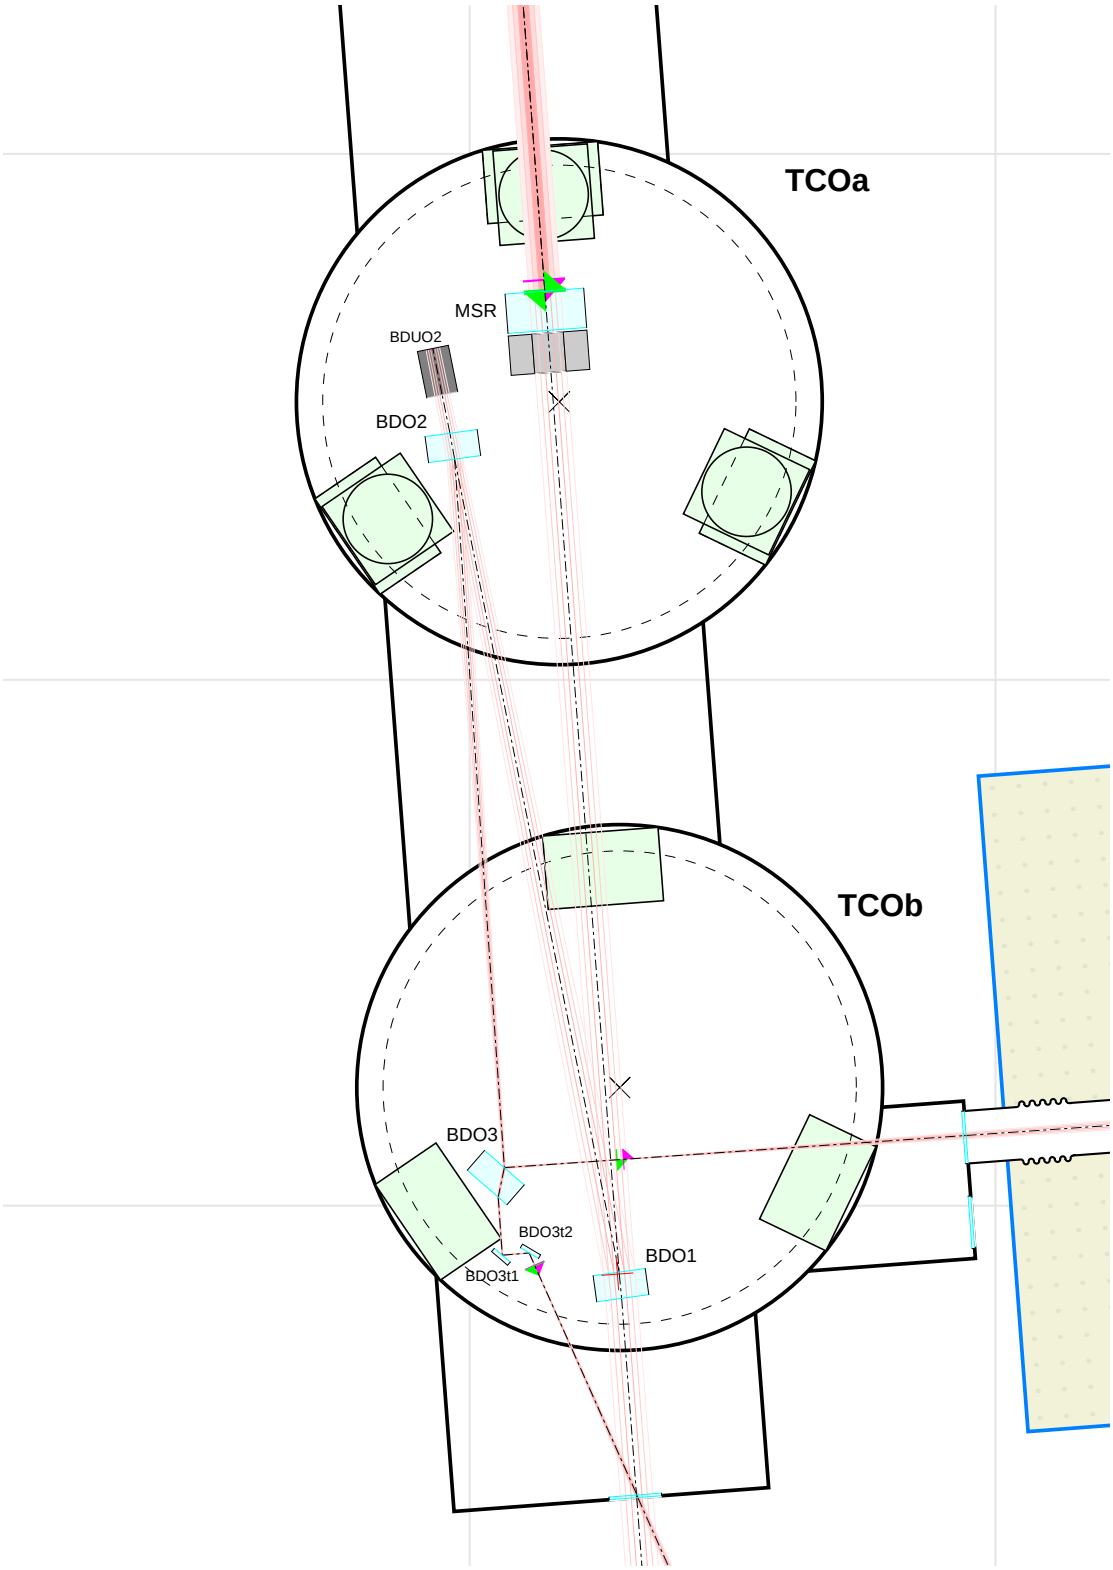

Figure A.1.: OPTOCAD layout of the GEO 600 output telescope, consisting of the three suspended mirrors BDO1, BDO2 and BDO3.

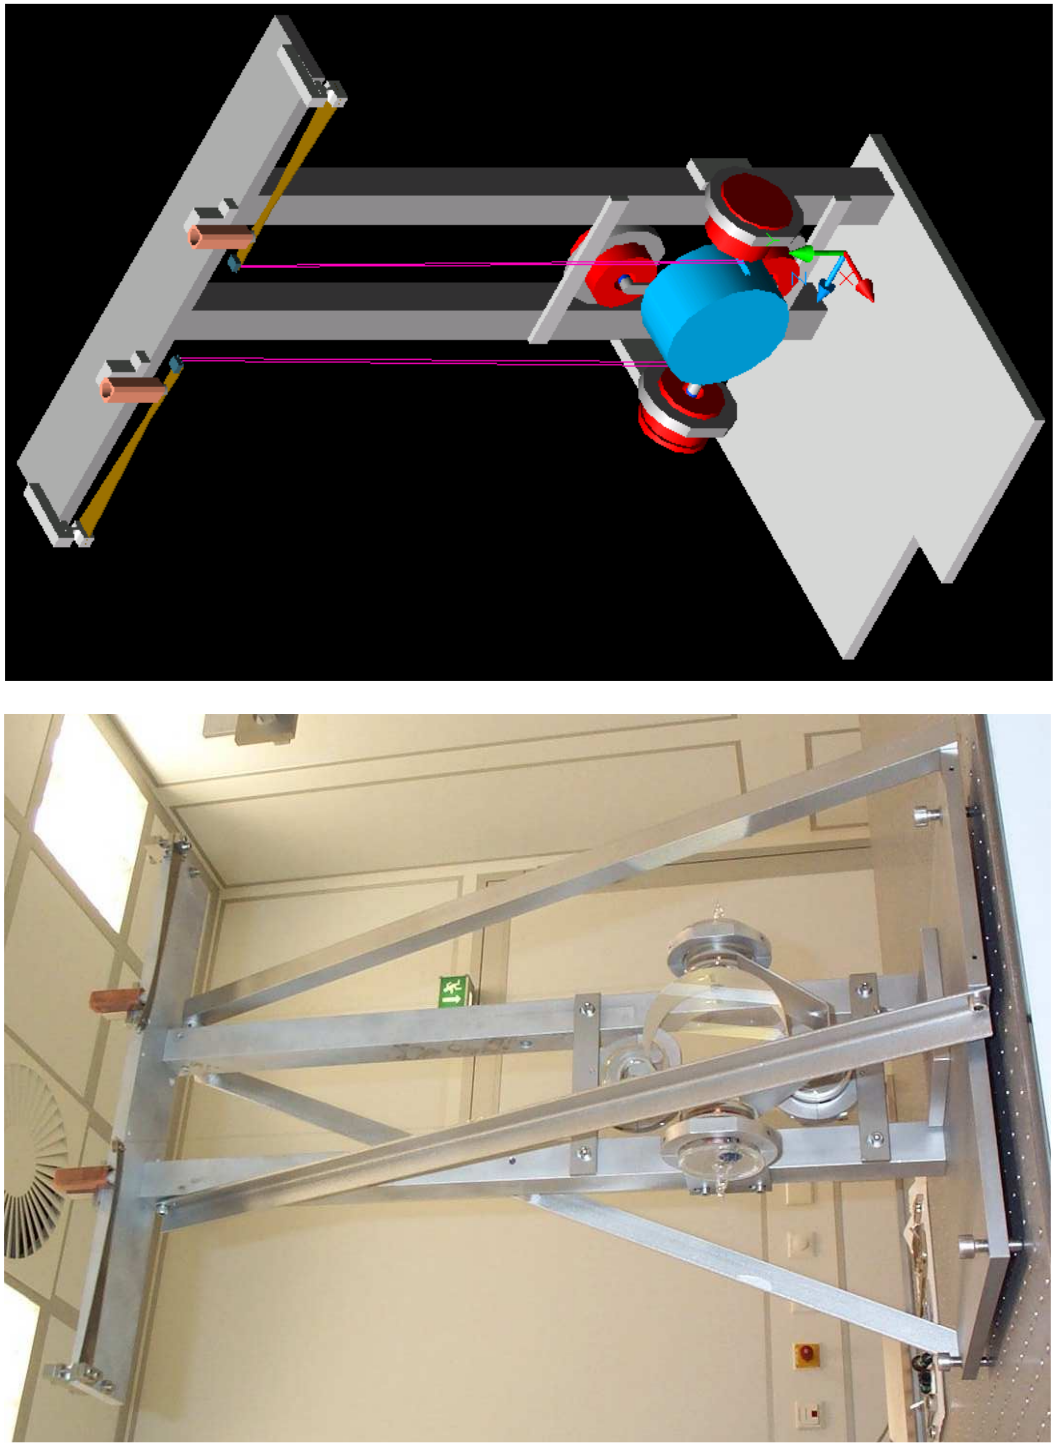

Figure A.2.: Suspension of BDO2. For BDO2 a stand alone Suspension is used which is clamped onto the bottom plate of TCOa.

Figure A.3.: The suspensions for BDO1 and BDO3

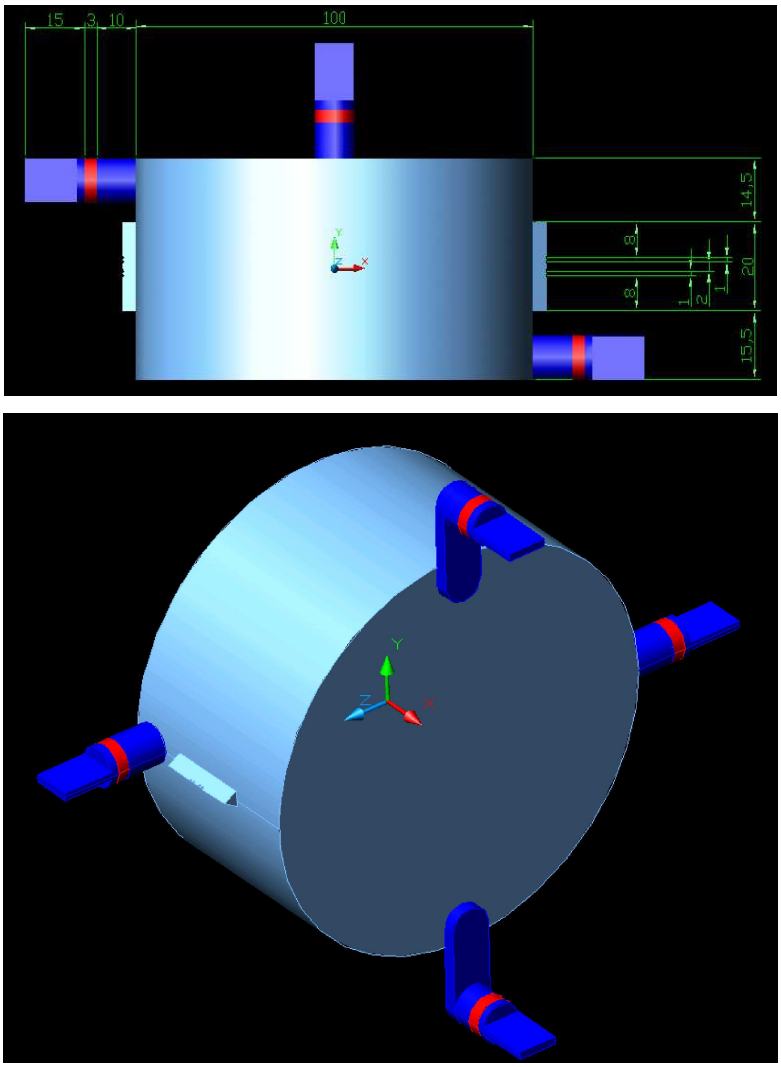

Figure A.4.: AutoCAD drawing of a BDO mirror with glued on break-off-bars, magnets (red) and flags, used for the local controls.

jittering at the main photo detector.

- **Auto-alignment of the output beam:** The suspended telescope mirrors can be used for auto-alignment of the main output beam. The position of the beam transmitted through BDO3 and the position of the beam close to the main photo detector are sensed with quadrant diodes and stabilized by feeding back to the local controls of the output telescope mirrors.

The following table gives an overview of the most important optical and mechanical parameters of the three telescope mirrors.

	BDO1	BDO2	BDO3
Transmission of HR coating (normal incidence)	**1.0 %**	**0.1 %**	14 %
Transmission of HR coating (45°)	7 %	1.3 %	**0.1 %**
Focal length	3.35 m	planar	planar
Thickness	49.8 mm	49.6 mm	49.7 mm
Diameter	99.7 mm	99.9 mm	99.8 mm
Separation of wire loops	2 mm	2 mm	3 mm

Table A.1.: Optical and mechanical parameters of the mirrors used for the output telescope.

Appendix B.

Light fields at the output port for detuned signal recycling

Figure B.1 shows the optical power of the different light fields present at the output of GEO 600, derived from measurements done with a scanning Fabry Perot cavity. Only three light fields are observed in this measurement: The two Michelson sidebands (MI+, MI-) and the carrier (C). As already shown in Figure 2.3 the two Michelson sidebands show a significant asymmetry, which contributes to the complex noise couplings described in Chapter 2.

For the reconstruction of the the total output field, E, we have to take three individual light fields into account, namely the lower Michelson sideband (E_-), the carrier (E_c) and the upper Michelson sideband (E_+). In general we can describe these fields in the following way,

$$E_- = a_- e^{i\omega_- t} \quad \text{with} \quad a_- = A_- e^{i\phi_-} \tag{B.1}$$

$$E_c = a_c e^{i\omega_c t} \quad \text{with} \quad a_c = A_c e^{i\phi_c} \tag{B.2}$$

$$E_+ = a_+ e^{i\omega_+ t} \quad \text{with} \quad a_+ = A_+ e^{i\phi_+} \tag{B.3}$$

where ω_i is the frequency of the light and a_i is complex and contains the amplitude A_i and the phase ϕ_i of the corresponding field. The total output field is just the sum of the three fields

$$E = E_- + E_c + E_+. \tag{B.4}$$

The actual by the photodiode detected property is the power, P of the output field

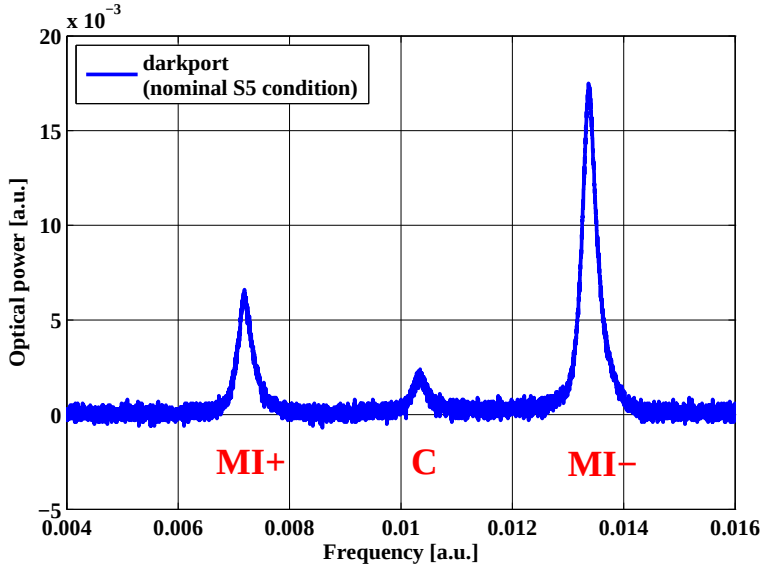

Figure B.1.: Power measurement of the light fields present at the output port of GEO 600. A strong asymmetry of the Schnupp modulation sidebands (MI+, MI-) used for the control of the differential arm length of the Michelson interferometer is observed. The measurement was done using a scanning Fabry Perot cavity.

given by

$$\begin{aligned} P &= EE^* \\ &= a_- a_-^* + a_- a_c^* e^{i(\omega_- - \omega_c)t} + a_- a_+^* e^{i(\omega_- - \omega_+)t} + a_c a_-^* e^{i(\omega_c - \omega_-)t} + a_c a_c^* \\ &\quad + a_c a_+^* e^{i(\omega_c - \omega_+)t} + a_+ a_-^* e^{i(\omega_+ - \omega_-)t} + a_+ a_c^* e^{i(\omega_+ - \omega_c)t} + a_+ a_+^* \end{aligned}$$

Now we can try to simplify this expression by introducing the following definitions. We use the frequency of the carrier light as reference which we define as zero, $\omega_c = 0$ and now redefine the frequencies of the sidebands to be:

$$\omega_- = -\omega \qquad \text{and} \qquad \omega_+ = +\omega \tag{B.5}$$

In addition we also use the phase of the carrier field as reference and define it to be zero, $\phi_c = 0$. With this the whole expression forms to

$$\begin{aligned} P &= A_-^2 + A_- A_c e^{i(-\omega t + \phi_-)} + A_- A_+ e^{i(-2\omega t + \phi_- - \phi_+)} + A_c A_- e^{i(\omega t - \phi_-)} \\ &\quad + A_c^2 + A_c A_+ e^{i(-\omega t - \phi_+)} + A_+ A_- e^{i(2\omega t + \phi_+ - \phi_-)} + A_+ A_c e^{i(\omega t + \phi_+)} + A_+^2 \end{aligned}$$

Now we group the terms by frequency. The DC component, P_{DC} is given by

$$P_{\mathrm{DC}} = A_-^2 + A_c^2 + A_+^2. \tag{B.6}$$

Second we get a contribution at the modulation frequency ω

$$P_{\mathrm{f}} = A_- A_c e^{i(-\omega t + \phi_-)} + A_c A_- e^{i(\omega t - \phi_-)} + A_c A_+ e^{i(-\omega t - \phi_+)} + A_+ A_c e^{i(\omega t + \phi_+)} \tag{B.7}$$

$$= 2A_- A_c cos(\omega t - \phi_-) + 2A_c A_+ cos(\omega t + \phi_+) \tag{B.8}$$

And finally from the beat of the lower and the upper Michelson sideband we also get a contribution at twice the modulation frequency:

$$P_{\mathrm{2f}} = A_- A_+ e^{i(-2\omega t + \phi_- - \phi_+)} + A_+ A_- e^{i(2\omega t + \phi_+ - \phi_-)} \tag{B.9}$$

$$= 2A_- A_+ cos(2\omega t - \phi_- + \phi_+) \tag{B.10}$$

Appendix C.

Design for an AR coated window for quadrant diodes

The standard windows of the quadrant diodes used in GEO 600 have been found to be of poor quality and a source of stray light (see Section 3.5). Therefore the housing of the diodes was cut and the window removed. A new encapsulation for the diodes was designed: The diode is clamped in between two copper plates (see Figures C.1 and C.2). In order to encapsulate the diode surface from dust an AR coated 1" window is glued onto the front-plate.

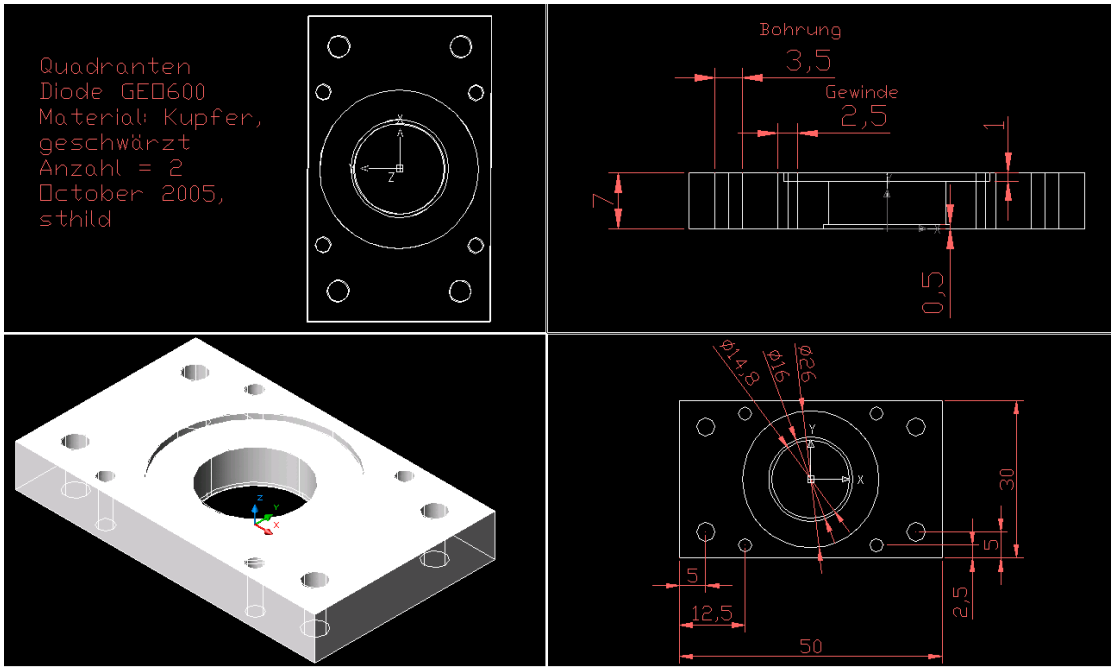

Figure C.1.: Front plate of the new quadrant diode encapsulation.

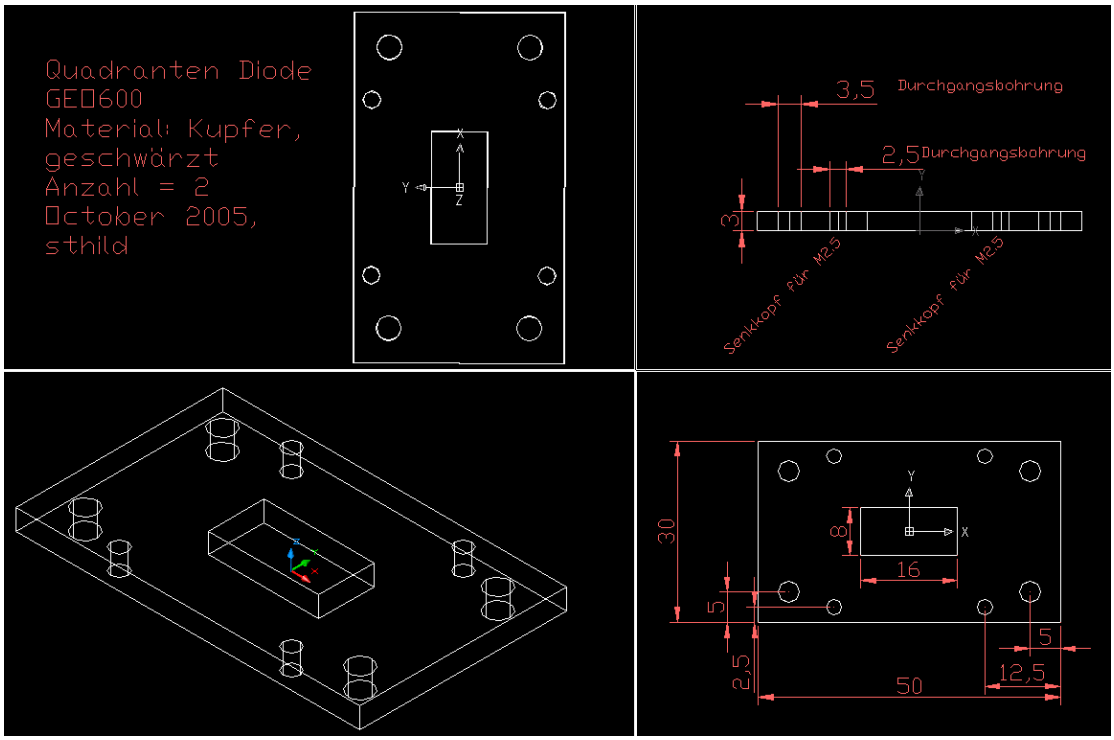

Figure C.2.: Back plate of the new quadrant diode encapsulation.

Appendix F.

A gravity calibrator for GEO 600

The gravity calibrator is a concept that could provide a calibration that is independent from any subsystem involved in the official calibration. The idea is to use a rotating system of masses, installed closely behind one of the test masses. This will yield, at the position of the testmass, a varying gravity gradient, which can be used as an independent actuator.

Figure F.1 shows the geometry of a possible 3-mass gravity calibrator. In order to find out which force can be applied to the testmass, we have to compare two different states of the gravity calibrator, which represent the two extreme cases of gravity force to the mirror. The first case is shown in the left part of the figure. We can simply calculate the force to the mirror by adding up three forces,one for each calibrator mass. The mirror is assumed to move only perpendicular to its surface.

The gravitational force F_G between two masses m_1 and m_2 separated by a distance of r is known as

$$F_G = G\frac{m_1 m_2}{r^2}, \tag{F.1}$$

where $G = 6,672 \cdot 10^{-11}\mathrm{m}^3/\mathrm{kg\ s}^2$ is the Gravity constant. Therefore the force F_1 on the test mass m_{tm} caused by calibration mass1 (m_{cal}) is given by

$$F_1 = G\frac{m_{tm} m_{cal}}{(r-R)^2}. \tag{F.2}$$

Due to the off axis position of calibration mass 2 and 3, their forces look slightly more complicated:

$$F_{2,3} = \cos(\beta) G\frac{m_{tm} m_{cal}}{(r + R\sin(\alpha))^2 + (R\cos(\alpha))^2}. \tag{F.3}$$

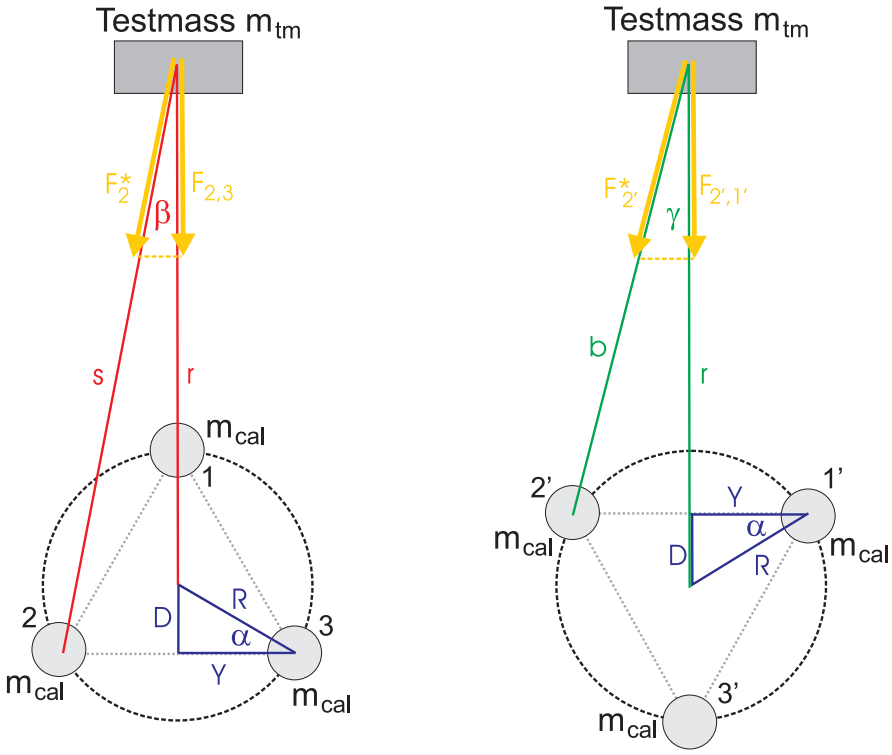

Figure F.1.: Geometry of a 3-mass gravity calibrator.

The cosine is present because we only allow the mirror to move perpendicular to its surface, leading to $F_2 * \cos\beta = F_{2,3}$. The sum of these three forces gives

$$F_A = G \cdot m_{tm} m_{cal} \left(\frac{1}{(r-R)^2} + \frac{2\cos(\beta)}{(r + R\sin(\alpha))^2 + (R\cos(\alpha))^2} \right) \tag{F.4}$$

Now we consider that the calibrator is rotated 60 degrees. Now the calibration masses 1 and 2 are off axis and mass 3 is placed behind the testmass. This configuration is shown in the right part of Figure F.1.

The force caused by the calibration masses $1'$ and $2'$ is given as

$$F_{1',2'} = \cos(\gamma) G \frac{m_{tm} m_{cal}}{(r - R\sin(\alpha))^2 + (R\cos(\alpha))^2} \tag{F.5}$$

and for mass $3'$

$$F_{3'} = G \frac{m_{tm} m_{cal}}{(r+R)^2}. \tag{F.6}$$

The resulting force, F_B is larger than F_A, because in this case two of the calibration masses are near to the mirror.

$$F_B = G \cdot m_{tm} m_{cal} \left(\frac{1}{(r+R)^2} + \frac{2\cos(\gamma)}{(r - R\sin(\alpha))^2 + (R\cos(\alpha))^2} \right) \tag{F.7}$$

The effective force seen by the mirror, ΔF, is given by the difference of F_A and F_B.

$$\Delta F = F_A - F_B \tag{F.8}$$

We simplify this expression by using the fact that α is 30 degrees in the current setup. This reduces the denominators as follows:

$$(r \pm R\sin\alpha)^2 + (R\cos\alpha)^2 = r^2 \pm rR + R^2. \tag{F.9}$$

With this we get

$$\Delta F = G \cdot m_{tm} \cdot m_{cal} \left[\frac{1}{(r+R)^2} + \frac{2\cos\beta}{r^2 - rR + R^2} - \frac{1}{(r-R)^2} - \frac{2\cos\gamma}{r^2 + rR + R^2} \right] \tag{F.10}$$

Now we can take some reasonable numbers for the different parameters:

- $r = 1\,\mathrm{m}$
- $R = 0.2\,\mathrm{m}$

- $m_{tm} = 5.6\,\mathrm{kg}$
- $m_{cal} = 2.0\,\mathrm{kg}$

which leads to a force:

$$\Delta F \approx 6.71 \cdot 10^{-10}\mathrm{N}. \tag{F.11}$$

This force corresponds to a strain amplitude of $h_{\text{grav-cal}} = 6 \cdot 10^{-20}/\sqrt{\mathrm{Hz}}$. Assuming the gravity calibrator rotates with a frequency of 30 Hz (that is the frequency a common washing machine motors provides), a signal at 90 Hz, $h_{\text{grav-cal}}$, would be generated. Comparing $h_{\text{grav-cal}}$ to the actual sensitivity of GEO 600 (see Figure 1.3), we find the gravity calibrator signal to show up in the detector sensitivity with a snr of about 5 for an integration time of one second.

Appendix G.

Matlab script: Statistical veto with amplitude consistency-check

```
%  Script for applying a statistical veto with amplitude
%  consistency check in the full GEO veto pipeline.
%  Actual case: MIDVIS_veto for Sep 2006.

%  Input:
%  - 2 Sets of triggers:  MIDVIS and H
%  - veto list for science, nullstream and CHi^2
%  - Amplitude ratio of H and MIDVIS
%  Output:
%  - List of veto intervals

Measurement of the bulk-absorption of the GEO 600 beam splitter

I.1. Introduction

The four large-scale laser-interferometric gravitational wave projects, LIGO [Waldman06], VIRGO [Acernese06], TAMA 300 [Ando05] and GEO 600 [Hild06c], have dedicated much effort to commissioning the detectors and improving their sensitivity. Soon the initial projects will have reached a sensitivity limited by fundamental noise sources like, for instance, shot noise. Second generation projects such as Advanced LIGO [AdvLIGO], Advanced VIRGO [AdvVIRGO] and GEO HF [Willke06] aiming at strain sensitivities in the region of 10^{-23} to $10^{-24}/\sqrt{\text{Hz}}$ will operate at much higher light powers than the initial detectors, in order to reduce the influence of shot noise. Accordingly, one major problem will be the absorption of laser light in the optical elements like beam splitters and test masses. Even though techniques for thermal correction and compensation have been developed (e.g., [Lück04, Lawrence02]), the use of low-absorption materials is a key point of future detector research.

The beam splitter substrate currently installed in GEO 600 was manufactured by Heraeus, Hanau [Heraeus] and consists of Suprasil 311 SV which provides extremely low bulk absorption due to an OH-content of less than 50 ppm [Loriette03]. Recent measurements of OH-reduced fused silica showed an absorption below 0.5 ppm/cm which was the lowest absorption of fused silica reported so far [Loriette03]. Therefore it is of great interest to obtain a lower absorption value, as presented in this work.

In Section I.2 I will explain the principle of a new method for a more sensitive estimation

of the bulk absorption in the beam splitter by using the GEO 600 interferometer itself as a measuring tool. Realization and details of this measurement are described in Section I.3 while the result is discussed in Section I.4.

I.2. A new method for measuring bulk absorption

Large Michelson interferometers such as GEO 600 working at high optical powers can be used to measure small effects of thermally induced distortion of their optical elements [Ottaway06]. One of the most sensitive optical components in GEO 600 is the beam splitter which is placed inside a high-finesse cavity: the power-recycling cavity (Figure I.1.1). The absorption of the bulk material causes a weak lens building up inside the beam splitter [Winkler91, Strain94]. This lens disturbs mainly the beam passing through the beam splitter substrate, whereas the beam reflected to the other arm (in case of GEO 600 this is the north arm) is only slightly influenced (Figure I.1.3). This means that depending on the strength of the lens we see a change in the interference pattern at the ports of the interferometer. Since GEO 600 is operated on a dark fringe at the output port, this effect can most easily be visualized there, using, for example, a CCD camera.

Due to the fact that the thermal lens does not build up instantaneously, we can compare the beam pattern at the output port for a cold state and a hot state of the beam splitter (as shown in Figure I.2). The high gain of the alignment control system guarantees a stable alignment and good suppression of first order higher modes [Grote04a]. Using GEO 600 parameters we can reproduce the pattern of the cold state using a FINESSE [Freise04] simulation. Now we can add to the simulation an additional lens inside the beam splitter and vary its focal length until it matches the experimentally observed beam pattern for the hot state. If the light power transmitted through the beam splitter is known, an estimate of the bulk absorption can be derived from the focal length of the simulated thermal lens as described below.

Absorption of light power from the transmitted beam heats the substrate non uniformly. Because of the temperature dependence of the index of refraction a path difference δs occurs between a light path measured along the beam axis and a light path measured

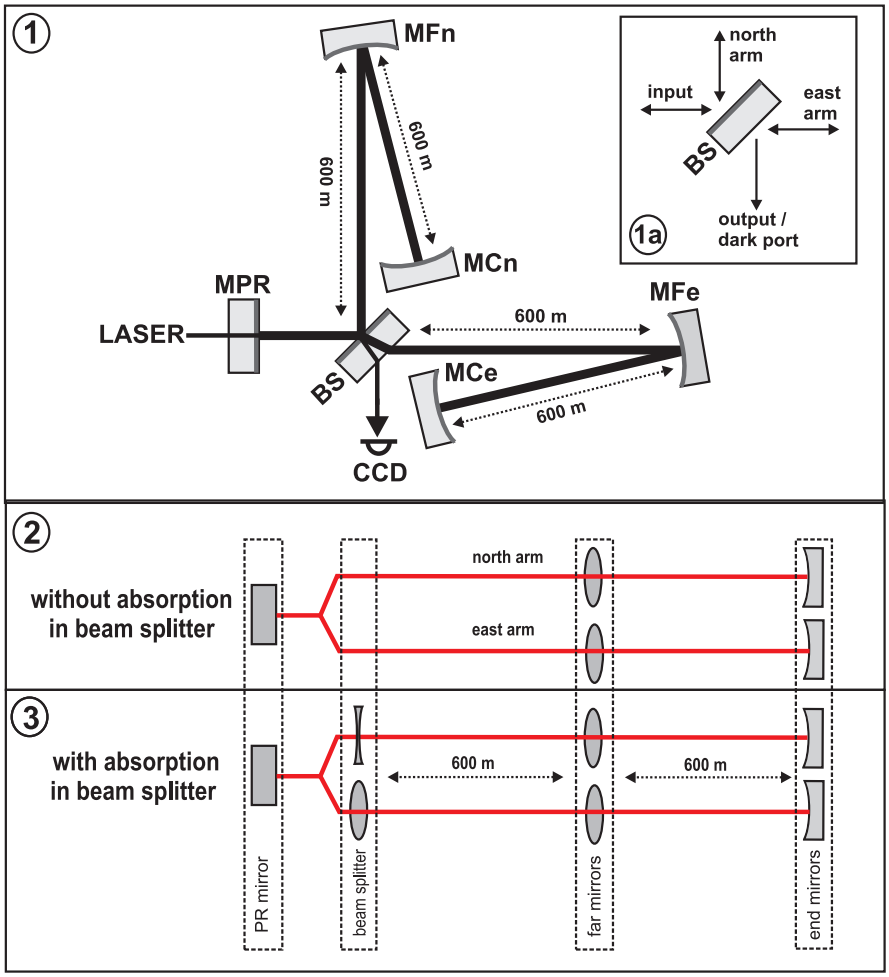

Figure I.1.: **1**. Simplified optical layout of the GEO 600 main interferometer with folded arms. The Laser beam enters the Michelson interferometer through the power-recycling mirror (MPR), gets split at the beam splitter and transverses the two folded arms, each of 2400 meter round trip length. At the output port of the interferometer the beam pattern is observed using a CCD camera. **2**. Optical imaging inside the interferometer arms expressed in an equivalent lens diagram for the case of no absorption inside the beam splitter substrate. **3**. Bulk absorption inside the beam splitter can be modelled by an additional convex lens inside the east arm (dominant effect) and an concave lens in the north arm.

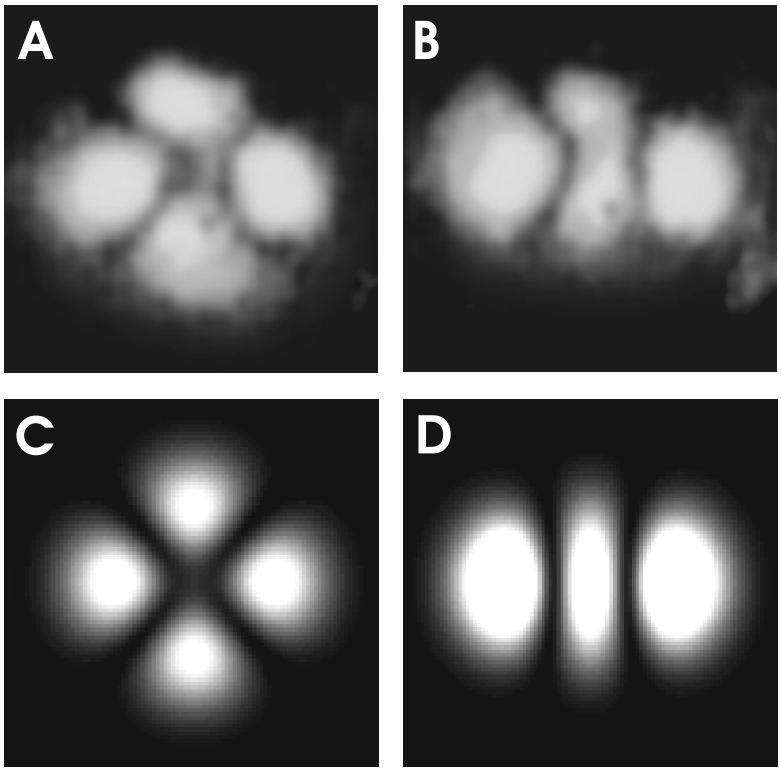

Figure I.2.: Beam pattern of the GEO 600 dark port for the case of a power-recycled Michelson interferometer. **A**: Observed dark port pattern for a cold beam splitter. **B**: Observed dark port pattern for a hot beam splitter, i.e., thermal lens present. **C**: Corresponding simulation of the cold beam splitter. **D**: Corresponding simulation of the hot beam splitter, i.e., thermal lens present.

along the $1/e^2$ point of the intensity distribution [Winkler91].

$$\delta s = 1.3 \cdot \frac{\beta}{4\pi\kappa} \cdot p_a \cdot d \cdot P \tag{I.1}$$

Here κ is the thermal conductivity, p_a is the absorption per unit length, P is the light power and d is the geometrical path length inside the substrate. The temperature dependence of the index of refraction is given by $\beta = dn/dT$. Expressing δs by the focal length of the thermal lens induced in the beam splitter as $f_{\mathrm{therm}} = w^2/2\delta s$, where w is the beam radius at the beam splitter, Equation (I.1) transforms to

$$p_a = \frac{4 \cdot \pi}{2.6} \cdot \frac{w^2 \cdot \kappa}{\beta \cdot d \cdot P \cdot f_{\mathrm{therm}}}. \tag{I.2}$$

Up to here we only took absorption inside the beam splitter and the corresponding thermo-refractive effect into account. Of course, in reality the optical imaging in GEO 600 is also slightly influenced by two other effects: the thermal expansion and the absorption of the dielectric coatings. Nevertheless ignoring these two effects still gives a valid upper limit for the bulk absorption of the beam splitter, as we will show in the following sections.

The principle of our absorption measurement relies on the thermally induced change in the difference of the wavefront curvature of the two interferometer arms. Therefore we can neglect absorption at any coating of the four main interferometer mirrors (MFe, MFn, MCn and MCe in Figure I.1) and the corresponding thermal deformation of the mirror surfaces, because this effect would influence the wavefront curvature similarly in both interferometer arms (assuming symmetric absorption in both arms of the interferometer). Nevertheless we can give a rough estimate of the change in radius of curvature of the mirror and the resulting change in the beam diameter caused by coating absorption of the four main interferometer mirrors. In that respect the far mirrors (MFe, MFn) are the most critical ones. Assuming a coating absorption at one of the far mirrors of 2 ppm, would increase the radius of curvature which is 666 m by about 10 cm. The beam diameter w which is about 8.8 mm would change by roughly 6 microns. Therefore the coating absorption of the main interferometer mirrors is totally negligible.

Assuming symmetrical absorption in the two arms of the interferometer the beam splitter is the only optical component that can change the wavefront curvatures of the two arms differentially. In the case of the bulk absorption it is reasonable to neglect the thermal

expansion because it is first of all ten times smaller than the thermo-refractive effect and second would enhance the strength of the thermal lens.

Finally we have to consider light absorption at the two dielectric coatings of the beam splitter and the related thermal effect. For the east arm these effects can be modelled by adding an additional convex lens, while in the north arm we have to insert a concave lens.

All of the effects discussed above would cause a differential change of the two wavefront curvatures, which would increase the strength of the observed thermal lens and by this lead to a smaller value of the bulk absorption p_a. Hence Equation I.2 gives a valid upper limit for the bulk absorption inside the beam splitter.

I.3. Setting an upper limit for the bulk absorption in the GEO 600 beam splitter

To investigate the thermal lensing of the beam splitter, the GEO 600 detector was used in the configuration of a power-recycled Michelson interferometer. To avoid the influence from mode healing [Grote04b], the signal-recycling mirror was misaligned, such that it can just be considered as an attenuator at the dark port. Figure I.2A shows the dark port image for a cold state beam splitter, i.e., immediately after lock acquisition. Figure I.2C shows the result from a FINESSE simulation for the same configuration using our best estimate of the parameters of the GEO 600 detector.

The cross shape of the dark port image is caused by an astigmatic mismatch of the radii of curvature from the two far mirrors (MFe and MFn in figure I.1.1) [Lück04]. Due to this astigmatism the dark port image changes quite strongly with the beam splitter's lensing, which makes it easier to match measurements and simulations. Furthermore this fact also makes our method more accurate in obtaining the focal length of the thermal lens.

Figure I.2B shows the dark port image for the hot state of the beam splitter, after the lens has fully developed and the beam splitter is in thermal equilibrium, which takes about 30 minutes. The result of the corresponding simulation is shown in Figure I.2D. An additional thermal lens with a focal length of $f_{\mathrm{therm}} = 13\,\mathrm{km}$ best matches the simulation to the observed dark port shape.

The light power inside the beam splitter for this measurement was $P = 1.4$ kW. The beam radius is $w = 0.88\,\mathrm{cm}$ and the geometrical path length inside the beam splitter is $d = 9\,\mathrm{cm}$. Using these parameters and $\beta/\kappa = 10^{-5}\mathrm{m/W}$ for Suprasil [Takke] Equation (I.2) gives an upper limit for the bulk absorption of the GEO 600 beam splitter of

$$p_\mathrm{a} = 0.25 \pm 0.1\,\mathrm{ppm/cm}. \tag{I.3}$$

The main contributions to the error budget are uncertainties in the measurement of the radii of curvature of the far mirrors, the intra-cavity power, P, and the beam radius w.

I.4. Conclusion

A new method was developed to estimate the bulk absorption of beam splitter substrates in a large scale power-recycled Michelson interferometer. Using this method we obtained an upper limit of the bulk absorption of the GEO 600 beam splitter of $p_\mathrm{a} = 0.25 \pm 0.1$ ppm/cm. This is, to the knowledge of the author, the lowest value ever measured for absorption in fused silica at a wavelength of 1064 nm.

Acknowledgement

Joining the GEO-project, then seeing and feeling it grow and proceed was an exciting experience for me and I would like to thank all the people who contributed to GEO 600.

First I would like to thank Karsten Danzman for giving me the chance to work right at the core of the GEO 600 detector. It is unusual for a nearly unexperienced student to get the opportunity to 'play'with such an exciting device as GEO 600.

The people who contributed most to this work are the members of the GEO commissioning team: Hartmut Grote, Harald Lück, Martin Hewitson, Joshua Smith, Ken Strain and Benno Willke have been for me an infinite supply of motivation, creativity and knowledge. I am happy and proud to be a member of such an great team. I'm very grateful to these people for sharing their knowledge and work with me, - nearly everything I know about building, commissioning and running a gravitational wave detector I learned from these bunch of scientists. Finally I want to add that working at GEO was not only scientifically interesting, but also always good fun and I enjoyed the familiar atmosphere in Ruthe very much. Thank you !!!

Furthermore I would like to thank many people from outside the Ruthe-team who contributed to this work: Keita Kawabe for introducing me to the 'real-live'interferometry at the Garching prototype interferometer. Stefan Goßler for teaching me how to build a proper suspension. Andreas Freise for many fruitful discussions and his help in doing simulations. Iain Martin, Stuard Reid and Jim Hough for providing the FEM analysis of the photon pressure induced mirror deformation. Peter Kalmus, Rick Savage and Brian O'Reilly for interesting discussions about the photon pressure calibrators used in GEO and LIGO. Simon Chelkowski for motivating me to use 3D AutoCAD. Ajith Parameswaran for giving me a background in veto analysis. Andreas Weidner and Heiko zur Mühlen for help in building electronics. Walter Winkler and Roland Schilling for sharing their knowledge with me and answering endless rows of questions. All members of the ILIAS Working group 1 for the interesting discussions and the nice atmosphere at all the meetings we had. Finally I thank Andre Thuering, not only for sharing an office in Hannover with me, but also for always being a friend.

For proof reading of this thesis I thank: Andreas Freise, Jan Harms, Hartmut Grote, Martin Hewitson, Harald Lück, Kasem Mossavi, Joshua Smith, Ken Strain and Benno Willke. However, I am of course responsible for all remaining mistakes in this thesis.

I am deeply grateful to Marion for all her patience and love.

(57) **ABSTRACT**

A gravitational wave generation device comprising an ensemble of energizable elements involving magnetic, electrical and electromechanical functions that are under the control of a computer and attendant computer software system. The magnetic and electrical force elements, when energized as directed by the computer, operate in concert to produce a rapid third-time-derivative motion of a mass. This action causes the generation of high-frequency gravitational waves that can be modulated and shaped in order to be utilized for communication, propulsion, and various physics experiments. The energizable elements can be very small coils or coil sets encased in a computer chip, current-carrying conductors, or small electromechanical devices. The mass acted upon by the coil elements can be a permanent magnet or magnets, or electromagnets. In the electromechanical-element configuration the device can be used both for the generation of gravitational waves and their detection.

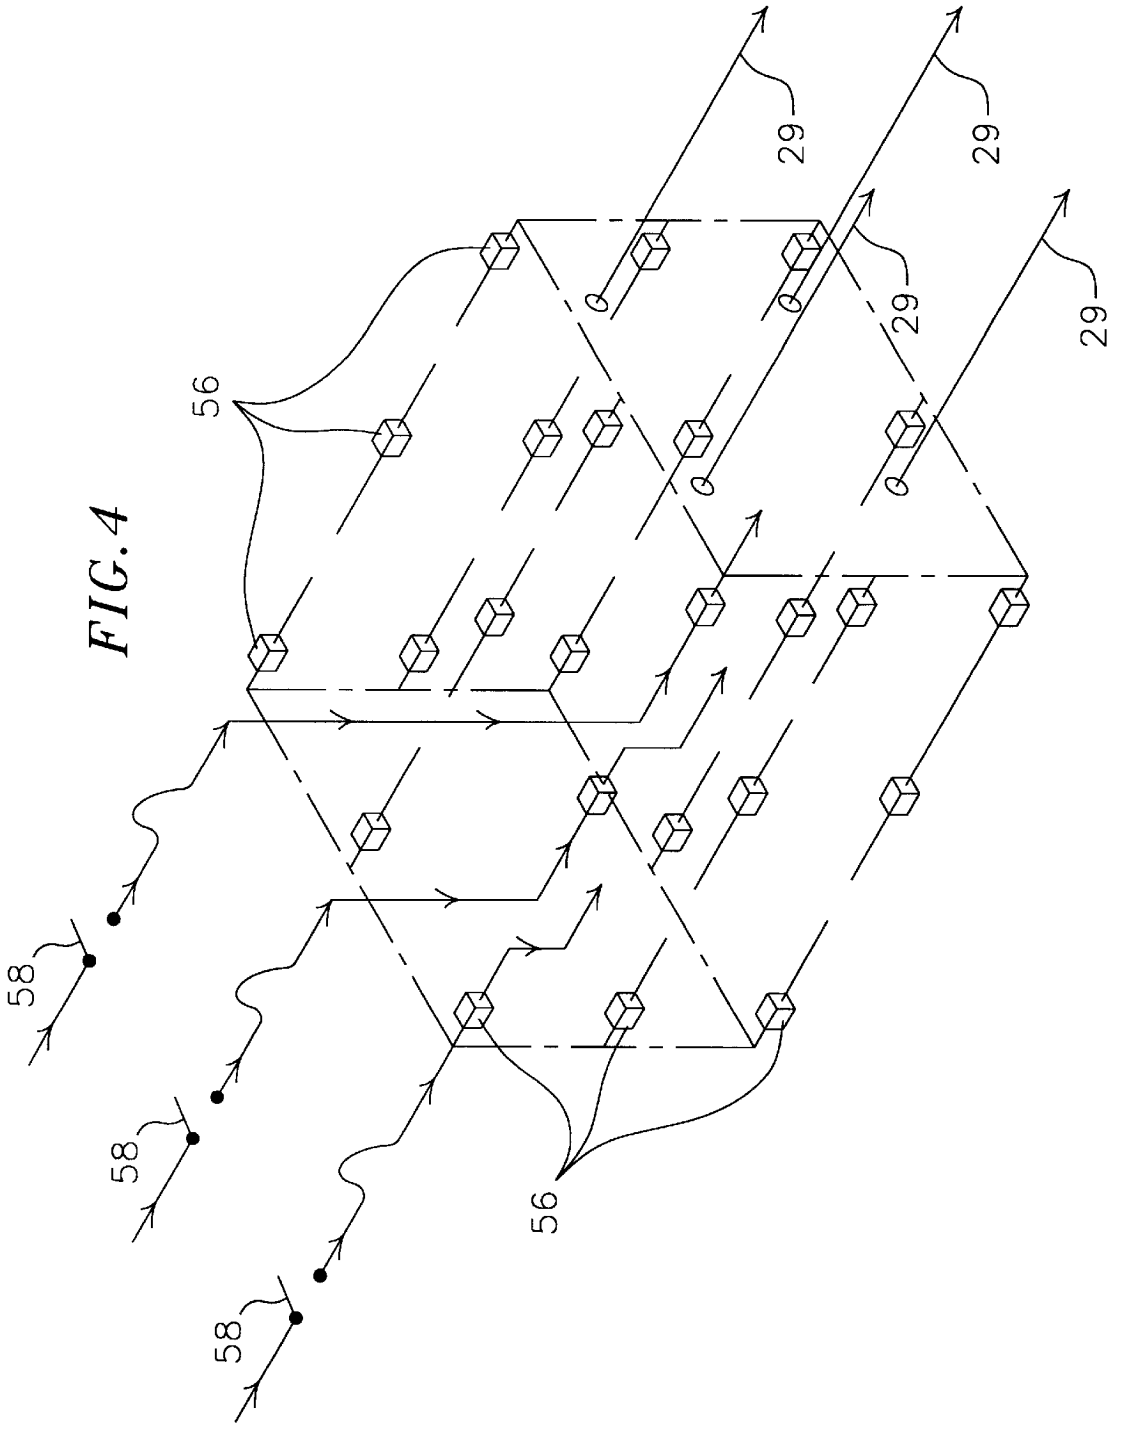

FIG. 4

GRAVITATIONAL WAVE GENERATOR

REFERENCE TO RELATED INVENTION

The present application is a continuation-in-part of application Ser. No. 09/443,527, filed Nov. 19, 1999, now U.S. Pat. No. 6,160,336 entitled Peak Power Energy Storage Device and Gravitational Wave Generator which is incorporated herein by reference.

BACKGROUND OF THE INVENTION

This invention relates to the generation of high-frequency gravitational waves that can be modulated and utilized for communication, propulsion and for the purpose of testing new physical theories, concepts, and conjectures. More particularly this invention relates to a combination of small energizable elements operatively connected to a computer working in concert to produce a third-time-derivative motion of a nearby mass or electromechanical elements that generates a high-frequency gravitational wave. The invention also relates to the detection of gravitational waves.

DESCRIPTION OF THE PRIOR ART

Albert Einstein in his General Theory of Relativity predicted gravitational waves (GW). Such waves have never been detected, but an extra-terrestrial source of low-frequency GW, namely a neutron double star pair, has been observed to coalesce at a rate exactly as predicted if it radiated GW. The production of GW having a high frequency and generated by relatively strong magnetic, electrical and electromechanical forces acting on relatively small masses rather than by the relatively weak gravitational forces acting on large celestial masses is not known.

The prior art indicates that gravitational-wave generators are theorized although not reduced to practice. Joseph Weber in "Detection and Generation of Gravitational Waves", *Physical Review*, Volume 117, Number 1, January, 1960, p. 313 has proposed electromechanical-force-produced GW by use of piezoelectric crystals: "Waves one meter long could be radiated by a crystal with dimensions about fifty centimeters on a side. If it is driven just below the breaking point, each crystal would radiate $\approx 10^{-20}$ [watts], assuming P_{max} to be its static published value." No one has, however, put such a device in practice.

According to Robert L. Forward a gravitational-wave generator could be constructed by means of a tube in which very dense Newtonium (element 127) is caused to move up-and-down the tube at high-speed (not really a dipole since as Joseph Weber indicated {"Gravitational Waves" in *Gravitation and Relativity*, Chapter 5,W. A. Benjamin, Inc., New York, 1964, p. 91} the lowest order of gravitational radiation from a system cannot be a dipole, but must be a quadrupole). However no drawings or other descriptions of such a generator are known that are sufficiently specific to enable a person skilled in the art to practice the generator.

As described in the parent patent, there is considerable prior art in the detection of gravitational waves including U.S. Pat. No. 5,646,728, which involves a very low amplitude interferometer instrument suitable for detecting gravitational waves. This prior art involves only the detection of low-frequency (below a MHz) gravitational waves generated by natural processes, such as astrophysical or celestial events. It is believed that there is no prior art in the detection of high-frequency gravitational waves that are artificially generated for communication or other purposes.

SUMMARY OF THE INVENTION

The present invention relies upon the fact that the rapid movement or "jerk" of a mass or the rapid change or "jerk" in angular momentum with time, over a period of time such as a picosecond caused by the operation of the present invention, will produce a quadrupole moment and generate a sequence or train of useful high-frequency, for example Tera Hertz (THz), gravitational waves (GW). The device described will accomplish this GW generation in several alternative ways based upon the device's rotating and non-rotating, symmetrical and non-symmetrical masses acted upon by means of relatively strong magnetic, electrical and electromechanical forces. Such forces are produced by an ensemble of very small, sub-millimeter, energizable elements operating in concert under the control of the device's computer. As noted, this process is substantially different from the extra-terrestrial generation of low-frequency GW by very large rotating and non-rotating celestial masses acted upon by relatively weak gravitational forces.

Gravitational waves are absorbed differently and propagate differently through matter and space than do electromagnetic waves. Thus gravitational waves may offer advantages over electromagnetic waves in that they can be transmitted through material opaque to electromagnetic waves and their intensity may fall off less rapidly with distance than electromagnetic waves. Up to now man-made machines in use do not generate significant or measurable GW.

BRIEF DESCRIPTION OF THE DRAWINGS

The foregoing features and advantages of the present invention will be more fully understood by reference to the following detailed description of the invention when considered in connection with the accompanying drawings in which:

FIG. **1**A and FIG. **1**B are schematic views of coil sets **56** embedded in or imprinted on a silicon chip **57** and connected to transistors or ultra-fast switches **58** in order to generate current pulses **59** in the magnetic field of the permanent magnets **60**;

FIG. **2** is a schematic view of a single-sector or linear-motor embodiment of a gravitational-wave-generator device. The sector refers to the sector of the annulus of the plan view of the rim of the spindle device shown in the parent patent, U.S. Pat. No. 6,160,336 and is, therefore, a single, isolated segment of the rim. A sheath **68** of coils, embedded in semiconductor chips **57** individually or collectively connected to computer controlled transistor or ultra-fast switches, surrounds a central magnetic-mass composed of magnetic sites **57** incorporated with core, piston, or barrel **63**;

FIG. **3** is a schematic view of infinite-radius coils evolved into parallel plate conductors **66**, which may have ballast **67** attached in order to vary their masses, connected to fast switches **58** in order to generate current pulses **59** acting in concert to generate a train of gravitational waves **29** (which propagate in both directions from the jerk since there is a square associated with the kernel of the quadrupole equation (3)—so there is no preferred direction along the axis of the jerk); and

FIG. **4** is a schematic view of the utilization of electromechanical elements **65** that act in concert to generate and detect gravitational waves **29**.

Analysis of Binary Pulsar PSR 1913+16

Since the observation of the binary pulsar PSR 1913+16 represents the only experimental confirmation of GW, the features and advantages of the present invention will be

better understood by the analyses of such a double-star system. This pair of neutron stars will coalesce in 3.5×10^8 years due to GW radiation and produce a rather continuous GW until that time. According to J. H. Taylor, Jr. in "Binary pulsars and relativistic gravity", *Reviews of Modern Physics*, Volume 66, Number 3, July, 1994, pp. 711–719, the period of their mutual rotation is 7.75 hours (or 2.79×10^4 [sec]), periastron is 1.1 solar radii (one solar radius is 6.965×10^8 [m]), and apastron is 4.8 solar radii. It's radius of gyration is essentially the semi-major axis=(1.1+4.8)/2=2.95 solar radii=(2.95) $(6.965\times10^8)=2.05\times10^9$ [m]. The neutron stars exhibit a mass of about 1.4 solar masses so that together their mass is (2) (1.4) $(1.987\times10^{30})=5.56\times10^{30}$ [kg]. Thus the moment of inertia of the binary-pulsar system is approximately (5.56×10^{30}) $(2.05\times10^9)^2=2.34\times10^{49}$ [kg-m^2]. The current angular rate of the system=$2\pi/2.79\times10^4=2.25\times10^{-4}$ [radians/sec]. Thus the angular momentum of the system is currently, $I\omega=(2.34\times10^{49})$ $(2.25\times10^{-4})=5.27\times10^{45}$ [kg-m^2/sec]. According to a perusal of binary-star catalogs by John Mosley of the Griffith Observatory, the binary pulsar PSR 1913+16 is at a distance from our Sun of 23,300 light years. If there was little or no GW diffraction, then the reference area is a circular ribbon or strip having a width of the diameter of a neutron star, 3×10^4 [m]. Thus the reference area equals (3×10^4) (2π) (2.33×10^4) $(9.5\times10^{15}$ meters per light year)=4.17×10^{25} [m^2].

In the case of a binary star pair such as PSR 1913+16 the GW power, P, is computed from the quadrupole moment, which for two masses on orbit about one another is given, for example, by an equation on p. 356 of L. D. Landau and E. M. Lifshitz, *The Classical Theory of Fields*, Forth Revised English Edition, Pergamon Press, 1975. They give the time-variable factor in P as a function of the true anomaly, v, and orbital eccentricity, e, as

$$(1+e\cos v)^4([1+\{e/12\}\cos v]^2+e^2\sin^2 v)/(a[1-e^2])^5. \quad (1)$$

In conventional astrodynamic/celestial-mechanics notation this factor is

$$p/r^6+(dr/d\tau)^2/12\mu r^4, \quad (2)$$

where p is the orbital "parameter" or semilatus rectum [AU], r is the radial distance between the two masses [AU], τ is the characteristic time measured in $k_s$days or in units of 5.0022×10^6 [s] for heliocentric-unit systems, and μ is the sum of the two masses [solar masses]. Note that one AU (astronomical unit)=1.496×10^{11} [m] and one solar mass=1.987×10^{30} [kg]. The $dr/d\tau$ term is related to $dI/d\tau$ $(=2\mu t[dr/d\tau])$, $d^3I/d\tau^3$ $(=-2\mu^2[dr/d\tau]/r^2)$, $d^2v/d\tau^2$ $(=-\sqrt{\mu p}[dr/d\tau]/r^3)$, and $d^3v/d\tau^3$ $(=-2\mu\sqrt{\mu p}[1/r-1/a-4\{dr/d\tau\}^2/\mu]/r^4)$, where a=the semi-major axis of the orbit [AU] and for a circular orbit $dr/d\tau=0$. These time derivatives are directly related to the embodiments of the invention.

The GW power radiated, P, which causes a perturbation in the semi-major axis, a, (and an attendant secular decrease in the orbital period) is obtained by integrating the time-variable factor, Eq. (2), over the orbital period using the mean anomaly, M, which is directly proportional to the time (that is, M=n [t-T], where n is the mean motion [=ω in Landau and Lifshitz's {ibid, p. 357} notation] and T is the time of periastron passage). The value of the average GW power, P, is computed from observations that define the eccentricity (based primarily upon Doppler-shift determination of the range rate at periastron and apastron), semi-major axis, and orbital orientation angles of PSR 1913+16. The error in the computed value of P is related to the observational error leading to the determination of the orbital elements as well as the determination of the masses of the pair of neutron stars, $\mu=m_1+m_2=1.4+1.4=2.8$ [solar masses]. For example, a 0.1 percent change in the measurement of range rate at periastron results in a 0.28 percent change in GW power, P, and a 0.1 percent change in the mass of the stars results in a 0.33 percent change in GW power.

The observed accumulated shift in the times of periastron passage, T, caused by the secular shortening of the orbital period of PSR 1913+16, compares closely, within observational error, to that predicted by General Relativity and confirms the existence of GW radiation. Likewise is confirmed the existence of a $dr/d\tau$ component, which is related to $d^2\omega/dt^2$ $(\approx d^3v/d\tau^3)$ and d^3I/dt^3, that are involved in the GW-generator embodiments of the invention

The average GW power, P, established by Landau and Lifshitz (ibid, p. 357) by analytically integrating and given as a function of eccentricity, e, is for e=0.641, 9.28×10^{24} [watts] so for the disk reference area the GW flux at the Sun's distance=$9.28\times10^{24}/4.17\times10^{25}=0.222$ [watts/m^2]. If the GW is totally diffracted and the propagation is spherically isotropic, then the GW flux at the Sun's distance=$9.28\times10^{24}/(4\pi[2.33\times10^4\times9.5\times10^{15}]^2)=1.51\times10^{-17}$ [watts/m^2]. By numerically integrating (see, for example, an algorithm found in R. L. M. Baker, Jr., *Astrodynamics, Applications and Advanced Topics*, Academic Press, New York , 1967, pp. 263–272) over the mean anomaly (directly proportional to time) the average GW power, P, is 9.296×10^{24} [watts]. The peak GW power, 1.73×10^{26} [watts] occurs at the time of periastron passage (every 7.75 hours) and at the Sun's distance would result in a GW flux of $1.73\times10^{26}/(4\pi[2.33\times10^4\times9.5\times10^{15}]^2)=2.81\times10^{-16}$ [watts/m^2] if the GW were totally diffracted and the propagation were spherically isotropic. If GW detectors were sensitive enough to detect such an intensity and they did not, then it would lend credence to the disk-like propagation of GW waves or at least to diffraction of GW less than 45 degrees from the orbit plane of PSR 1913+16 at the Sun's distance.

Individual Independently Programmable Coil System (IIPCS)

Of fundamental importance to the operation of the present invention is the Individual Independently Programmable Coil System (IIPCS) described and illustrated in parent patent U.S. Pat. No. 6,160,336. This system, is enabled by a computer and associated computer software, to control a system of either transistors or of ultra-fast switches. The switches rapidly turn off or on a myriad of sub-millimeter coils, current-carrying conductors and/or electromechanical elements and generate magnetic (or electromechanical) force to produce a third time derivative or "jerk" or, alternatively, a harmonic oscillation of a mass or masses.

For a very large number of ultra-small, sub-millimeter coil elements involved in some of the embodiments of this invention a miniaturized integrated circuit can be utilized. They are embedded in or imprinted on a silicon chip, organic material, or in connection with polymer-based devices. They consist of multiple layers, with appropriate sequencing time delays to ensure near simultaneity of the magnetic field's interaction with individual elements, as in FIG. **1A**, or as the direct-current train of approximately one-picosecond pulses, which traverse each coil set on the chip levels, as in FIG. **1B** and possibly integrated in the chip with the ultra-fast switches or transistors or other semi-conductors. Although switches or transistors having picosecond capability are utilized in the various numerical examples, much slower switches or transistors could be utilized to successfully practice the invention. A preferred embodiment utilizes

conventional computer chips, containing the IIPCS circuit elements about 18 micrometers or less apart, synchronizing clock, input/output ports, and sub-millimeter coils on 50 to 100 micrometer centers. The chips are about 6 mm to 9 mm square and are obtained from silicon wafers. These chips are sewn into a circuit-board roll with an approximately 25-micrometer-diameter gold thread. Several layers of this roll (for example, 25) are connected in a fixed location or band adjacent to the moving spindle's rim and form the IIPCS in the spindle rim's magnetic field. Such rolls are routinely fabricated by French-owned Oberthur Card Systems (plant in Rancho Dominguez, Calif.), French-based Gemplus, Schlumberger (Paris and New York), and California-based Frost & Sullivan.

In the miniaturized integrated circuit situation, as exhibited in FIG. **1**A, there will be a very large number of small, sub-millimeter coil sets or elements **56** embedded in or imprinted upon a silicon chip **57** in multiple layers. Ultra-fast switches or transistors of the IIPCS **58** will launch a series of current pulses **59** of approximately picosecond duration moving at the electron's mobility speed, c, that will be timed to reach the individual coil sets or elements almost simultaneously along several individual wire conductors, as in FIG. **1**A, or one single wire conductor per line, as in FIG. **1**B, and thereby interact with the magnetic field **60** in concert. This interaction will result in a third-time-derivative motion or jerk of the magnetic mass to generate a train of gravitational waves. The ultra-fast switches are preferably semiconductor-based, such as a semiconductor optical amplifier (SOA) or a semiconductor nonlinear interferometer such as a nonlinear Sagnac interferometer on a phosphide semiconductor chip, etc. (see, for example, D. Cotter, et al, "Non-linear Optics for High-speed Digital Information Processing", *Science*, Volume 286, Nov. 19, 1999, pp. 1523–1528). In FIG. **1**B, the IIPCS and its array of ultra-fast switches is programmed to launch a train of current pulses or intervals of approximately a picosecond duration **59** such that each member of the pulse train will reach each of the coils or coil sets at the same time. The pulse train can consist of stretches of constant or zero current. The duration of the pulses will be such to completely energize any given coil set as it passes through it in order to produce a magnetic field interaction. The interaction will result in a third-time-derivative lateral motion or jerk of a cylindrical, central magnetic core **63** shown in FIG. **2** and, as will be discussed, generate a GW train **29**, which propagates both in the direction of and opposite to the direction of the jerk as illustrated in FIGS. **8**A and **8**B of U.S. Pat. No. 6,160,336. This core, piston, or barrel **63** is surrounded by and immediately adjacent to a sheath **68** of IIPCS-controlled coil sets **64**. In the case of the current-pulse train on a single conductor wire interconnecting a line of coils or coil sets, there will be a build up of impulses to full value as the current-impulse train progresses down the line of coil sets. Use of a single conductor wire for each line of coils or coil sets reduces the resistive power loss. In order to transmit information, all pulses in the train may not be present or they may be at different amplitude thereby modulating the GW. Portions or stretches of the pulse train could also be intervals of constant current. In each line of coils set in series along one conductor wire **61** there will be time delays **62** between coil sets to ensure simultaneity of the current pulses reaching any given coil set.

In FIG. **3**, ultra-fast switches or transistors of the IIPCS **58** will launch a series of current pulses acting in either direction **59** of approximately picosecond duration moving at the electron's mobility speed, c, along individual conductors or single interconnecting conductor wires in order to produce current pulses **59**, acting in concert to generate a modulated gravitational wave **29**. The current pulses will be timed to reach individual parallel-plate conductors **66**, which may have different masses or may have ballast **67** attached and/or carry different current and/or have different modulus of elasticity and/or are constructed differently in their mounting for the purpose of exhibiting high-frequency asymmetrical mass displacements.

In FIG. **4**, ultra-fast switches or transistors of the IIPCS **58** will launch a series of current pulses **59** of approximately picosecond duration moving at the electron's mobility speed, c, along individual conductors or single interconnecting conductor wires that will be times to reach individual, sub-millimeter electrical or electromechanical-force elements **55** in sequence to reinforce the build up or modulation of a GW beam **29**. The ensemble of electrical or electromagnetic force elements will be embedded in or imprinted on a silicon chip **57** in multiple layers.

Quadrupole Moment

Although the specific relationship for GW generation will be an outcome of the experimental use of the invention; as an example of that relationship consider the standard GW quadrupole Eq. (110.16), p. 355 of L. D. Landau and E. M. Lifshitz (opcit) or Eq. (1), p. 463 of J. P. Ostriker, ("Astrophysical Sources of Gravitational Radiation" in *Sources of Gravitational Radiation*, Edited by L. L. Smarr, Cambridge University Press, 1979) which gives the GW radiated power [watts] as

$$P=-dE/dt=-(G/45c^5)\,(d^3D_{\alpha\beta}/dt^3)^2\ [\text{watts}] \qquad (3)$$

where

E=energy [joules],

t=time [s],

$G=6.67423\times10^{-11}$ [m^3/kg-s^2] (universal gravitational constant),

$c=3\times10^8$ [m/s] (the speed of light, approximately the electron's mobility speed in the conductor), and

$D_{\alpha\beta}$ [kg-m^2] is the quadrupole moment-of-inertia tensor of the mass of the device, and the

α and β subscripts signify the tensor components and directions.

Note especially the third time derivative in the squared term or kernel (that is, $(d^3D_{\alpha\beta/dt}{}^3)^2$) of Eq.)3). Such a time-rate-of-change of the second derivative ("acceleration") is often referred to as a "jerk". Because the factor of this kernel is so small, 1.76×10^{-52}, the kernel and hence the jerk must be very large. In the following examples of GW generation by various devices, we shall often cite astrophysical analyses of the same GW formulation. It should be recognized, however, that although kernels are analogous in the invention and in the celestial astrophysical systems (or events) their operation is quite different. In most cases the astrophysically generated GW rely on rather slow-moving, low-frequency events (a fraction of a Hertz to possibly a MHz) and weak gravitational forces. On the other hand, the various embodiments of the invention rely on vary fast-moving, high-frequency events (in the THz range) and relatively strong magnetic, electrical or electromechanical forces.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

In order to understand the various embodiments of the invention it is useful to refer to the historical roots of GW

generation. From Eq. (1), p. 90 of Joseph Weber (opcit, 1964) one has for Einstein's original formulation of the gravitational-wave (GW) radiated power of a rod spinning about an axis through its midpoint, having a time-constant moment of inertia, I [kg-m^2], and an angular rate, ω [radians/s]:

$$P=-(G/45c^5)\ ([\sqrt{\{2\times12\}}][I\omega^3])^{2=-G(I\omega3)^2}/5(c/2)^5[\text{watts}]. \quad (4)$$

Equation (4) is an approximation and is, strictly speaking, only valid for lengths very much less than the GW wavelength and speeds of the rod's rotation less than c.

This is the same equation as that given for two bodies on a circular orbit (also exhibiting a time-constant moment of inertia) on p. 356 of Landau and Lifshitz, opcit ($I=\mu r^2$ in their notation) where ω=n, the orbital mean motion, and similar to all of the equations associated with the various embodiments of the invention. Although Eqs. (3) and (4) result from relativistic mechanics, classical mechanics (such as the use of the conventional moment of inertia in Eq. (4)) will be utilized herein to provide useful results.

Spindle-Device GW Generation Embodiment

It is reasonable (by appealing to simplicity, that is, by Ockham's Razor) to suggest that for the spin up/down of a spindle device, as referred to in the parent application, (referred to herein as the "$(Id^2\omega/dt^2)^2$ formulation or component"):

$$P=-G\ \kappa_{I\omega2dot}(Id^2\omega/dt^2)^2/5(c/2)^5[\text{watts}] \quad (5)$$

where

$\kappa_{I\omega2dot}$=a dimensionless constant or function to be established by experiment and

$d^2\omega/dt^2$=second time derivative of the spindle's angular velocity, ω, or third time derivative of it's angle, termed, a "jerk". In fact, as noted by M. S. Turner and R. V. Wagoner "Gravitational Radiation from Slowly Rotating 'Supernova' Preliminary Results," in *Sources of Gravitational Radiation*, Edited by L. L. Smarr, Cambridge University Press , 1979, p. 383 that "If the angular velocity ω . . . is non-uniform, octupole (post-Newtonian) radiation is generated (in addition to the quadrupole (Newtonian) radiation . . . " (emphasis added) and on p. 385 they state "This radiation is generated not by non-spherical distribution of matter . . . , but by internal motions."

This third derivative, $d^2\omega/dt^2$, is computed by introducing the equation of motion for a rotating body

$$Id\omega/dt=rf \quad (6)$$

where

r=radius of the spindle's rim [m] and

f=force tangential to the rim [N].

The derivative is approximated by

$$Id^2\omega/dt^2\cong\Delta(Id\omega/dt)/\Delta t=\Delta(rf)/\Delta t=r\Delta f/\Delta t; \quad (7)$$

in which Δf is the nearly instantaneous increase in the force tangential to the rim or jerk caused by the magnetic field when it is turned on or turned off or pulsed by the transistors or ultra-fast switches of the Individual Independently Programmable Coil System (IIPCS), that is, a tangential jerk. Thus

$$P=-1.76\times10^{-52}(\kappa_{I\omega2dot}r\Delta f/\Delta t)^2[\text{watts}]. \quad (8)$$

(1) Numerical Example

As a numerical example, (for a spindle GW-generation device slightly different from the exemplar spindle shown in U.S. Pat. No. 6,160,336) set $\kappa_{I\omega2dot}=1$ (subject to experimental determination later), r=1000 [m], $\Delta f=1.8\times10^7$ [N], and $\Delta t=10^{-12}$ [s]. These numbers arise as follows: The rim is a thin (approximately one cm thick) band of Alnico 5 permanent magnets (or electromagnets) facing radially outward. In general, permanent magnets exhibit irregular magnetic fields and associated forces. As a rule of thumb such a band of juxtaposed magnets will produce in excess of 30 pounds per 1.75 inches (or 206 pounds per foot) of tangential rim force. Each 1.75-inch magnet has a flux density, B, of about 2,600 gauss or 0.26 [Tesla] developed every 4.4 cm. The kilometer-radius rim is a large hoop connected to a central spindle/hub as described in the parent patent. The IIPCS coil sets at the rim's periphery, when switched on generate a 0.26 [Tesla] flux density every 0.044 [m] and produce in excess of a 200 pound per foot or 3000 [N/m], which is defined as Δf/Δl, or impulse of tangential force every meter on the rim (that is, a force built-up almost to full value during spin up in approximately a picosecond and a similar build up of retarding force during spin down) . Since the rim's circumference is 2π (1000) (3.28 feet per meter)= 20,600 feet, the tangential rim force produced when the coils are fully energized is 4.1×10^6 pounds or 1.8×10^7 [N]. The 10^{-12} [s] intervals, with the coils turned turn on and then off, will generate a train of direct-current, approximately one-picosecond pulses. In each line of coils there will be an ultra-fast switch (such switches could be located near to the coils and each one energizing a large number of coil sets or else co-located with a central IIPCS control computer).

Inserting the numbers in Eq. (8) for the spindle's gravitational-wave (GW) power for the tangential jerk yields

$$P=-1.76\times10^{-52}(2\times10^3\times1.8\times10^7/10^{-12})^2=-2.3\times10^{-7}[\text{watts}]. \quad (9)$$

The reference area of the 1 cm thick rim is (0.01) 2π(1000)= 63 [m^2], so that the GW energy flux is 3×10^{-9} [watts/m^2]. For a time-constant value of I there may be a somewhat less simple, $\kappa_{I\omega d\omega\omega}([d\omega/dt]\omega)^2$, formulation or component of the GW power for spin up/down, but as will be seen, for most applications it is expected to result in a smaller power than the larger of the $\kappa_{I\omega2dot}(Id^2\omega/dt^2)^2$ or $(I\omega^3)^2$ formulations or components.

Note that the coil sets must be very close together. In order for the coils fields to interact with the whole rim's magnetic field and impart the mechanical impulse or jerk, they must be spaced no more than 0.3 mm or 300 [micrometers] apart (the distance light and, hence, the magnetic field and resulting impulse on the permanent magnets, travels in a picosecond). If all coil sets in a line of coil sets are connected in series by the same conductor, then each member of the pulse train traverses a 300-micrometer-length coil set, separated from the next coil set by a time delay circuit. Such a time-delay circuit could be simply a 300-micrometer-long jumper (see **62** in FIG. **1**B) between coil sets. In this connection it is noted that if each coil set is connected by its own unique conductors as in FIG. **1**A, instead of one single conductor wire along each line of coils, then the communications lines or conductors to all of the coil switches from the logic circuits of the control computer must be equal to better than 0.01 mm or 10 [micrometers] in order to ensure near simultaneity or proper timing. That is, the electrons must reach all of the coils sets at the appropriate time in less than approximately a fraction of a picosecond of time difference.

(2) Magnetic Field Build Up and Heat Loss

Although of little concern in most applications, the length of time to "build-up" the magnetic field of the coils is

important here. The electrons must complete sufficient coil turns (moving at the electron's mobility speed or about light speed) in approximately a picosecond to "launch" most of the magnetic field that produces the impulsive force, "hammer blow" or jerk when it interacts with the static magnetic field of the permanent or electromagnets carried around by the rim or other magnetic mass. Thus, they must be very tightly wound with each coil "set" having a total length of less than 0.3 mm (0.0003[m] or 300 micrometers). If each of the ultra-small, sub-millimeter coil sets consist of two coils or turns, as exhibited in FIGS. **7**A, **7**B, **7**C, **7**D, **7**E, **7**F, **7**G, and **7**F, of the parent patent, then their diameters are on the order of d=0.3/2π=0.05[mm]=50 [micrometers] or less. The coil wire could be made of gold having about a 0.015-mm or 15-micrometer diameter. The resistance for such wire at room temperature is about 135 [ohms/m]—high-temperature superconducting material would be useful here. In the spin-up mode the IIPCS will need to build up 0.26 [Tesla] flux density every 0.044 [m] (the requirements for the spin-down mode are essentially the same, but reversed). Thus

$$B=\mu_o ni/l[\text{Tesla}] \tag{10}$$

where $\mu_o=4\pi\times10^{-7}$ (permeability of free space), n is the number of coil turns, i is the current through the coils [amps], and l is the length of the coil conductors [m]. The double coil sets will be placed on 50 to 100 [micrometer] centers, so that there will be about $2\times100\times100=2\times10^4$ coil turns on each square-centimeter level of the stack of 25 coil levels or layers. With l=0.044 [m] and B=0.26 [Tesla], $ni=9.1\times10^3$ [amp turns]. For $n=25\times2\times10^4=5\times10^5$, $i=9.1\times10^3/5\times10^5=0.018$ [amps] or 18 milliamperes. The total length of 15-micrometer-diameter gold wire across any given layer or level is 100(rows)×100(coil & jumper/time-delays)×(600 micrometers)=6 [m]. For the 25 layers or levels there will 150 [m] of wire with a resistance of $150[m]\times135[ohms/m]=2.025\times10^4$ [ohms]. Since on average every other pulse or current interval across a conductor wire will carry no current, since in order to modulate the GW some pulses or current intervals in the train will be missing, the heat loss per centimeter of chip stack or semi-conductor layers is

$$(1/2)i^2R=3.28[\text{watts}]. \tag{11}$$

This heat loss can be reduced by 32% by using 25-micrometer-diameter wires for the time-delay jumpers, but high-temperature superconductors for this purpose are contemplated. In addition there may be some energy loss or resistance occasioned by electromagnetic radiation (EM) generated during the GW generation process. Such a loss can be reduced by the design of the energizing, for example coil, elements and controlling the direction of current pulses by the IIPCS. By the way, EM radiation can be easily screened out by means of interposing a conductor in the GW path, which is opaque to EM radiation but transparent to GW.

The spin-up/down of the entire rim is not instantaneous and is anticipated to progress at the speed of light in the rim from the juxtaposed permanent-magnet sites on the rim acted upon by the coil-magnetic fields. (Spin up/down does not progress at the local speed of sound, but rather it is expected to progress at the speed of light like a signal being transmitted by pushing a frictionless rod. That is, all of the ferromagnetic molecules comprising the magnets on the periphery of the rim move in concert, as the GW crest moves through the magnets at light speed, impelled by their magnetic fields. On the other hand, impulsive stresses in the spindle or dumbbell device are propagated inwardly at the speed of sound in the material of the device rather than at the speed of light.) Thus, for example, at a one picosecond cycle or switching rate an in-rim light speed of 3×10^8 [m/s] some $(10^{-12})(3\times10^8)=0.0003$ [m] or 0.3 [mm] or 300 micrometers of the rim on each side of the juxtaposed coil/magnet activity sites will respond (spin up or down) during each picosecond after coil activation. This process, in the case of a dumbbell-shaped rim, will generate an ever widening fan of gravitational waves, 51 as exhibited in FIG. **8**B of the parent patent. Many more than the 4,290 coil sites of the exemplar device of the parent patent could be distributed around the rim (perhaps over only a single sector or selected sectors adjacent to the rim; thereby greatly reducing the required number of coils and "focusing" the GW). A large number of ultra-fast switches, preferably semiconductor based, would be activated simultaneously by the IIPCS coil-control computer, with communication lines of nearly equal length to all switches.

(3) Rim Material Accelerations

A random series of positive and negative jerks tend to build up a positive acceleration over time by random walk. Consider an extreme case, however, in which the maximum jerk builds up rim acceleration (spin up, or deceleration, spin down) continuously over a length of time, $\delta t=10^{-7}$ [s] or 100 nanoseconds. The mass per unit length of the magnetic mass of the rim for the exemplar device of the parent application is $\Delta mass/\Delta l=3.83$ [kg/m]. The jerk is

$$da/dt=d^3S/dt^3=([\Delta f/\Delta l]/[\Delta mass/\Delta l]/\Delta t= (3000[N/m]/3.8[kg/m]/10^{-12}=7.89\times10^{14}[m/s^3], \tag{12}$$

where S is the displacement. Therefore, in δt=100 nanoseconds (10^{-7} [s]) of continuous and constant jerk, da/dt, the acceleration, a, would build up to

$$a(t)=\int_o^{\delta t}(da/dt)dt=(7.89\times10^{14})(10^{-7})=7.89\times10^7[m/s^2], \tag{13}$$

(of course, control of the jerks by the IIPCS would never allow such a high build up of acceleration) the speed would build up to

$$dS/dt=\int_o^{\delta t}(da/dt)dt=(da/dt)\delta t^2/2=(7.89/2)\times 10^{14}\times(10^{-7})^2=3.9[m/s], \tag{14}$$

and the displacement would build up to

$$S=\int_o^{\delta t}(ds/dt)dt=(da/dt)\delta t^3/6=(7.86/6)\times10^{14}\times (10^{-7})^3=1.315\times10^{-7}[m]. \tag{15}$$

The angular rate build up over 100 nanoseconds is 3.9[m/s]/1000[m]=3.9×10^{-3}[radians/s] versus, for example, the mean motion of double star PSR1913+16 of 2.25×10^{-4} [radians/s]. Thus there is considerable "motion" in the magnetic mass, but essentially the mass goes only a very short distance. In this regard, as already noted, the IIPCS can be programmed to ensure that there is not a secular increase or accumulation of magnetic-mass displacement beyond a certain prescribed limiting value. For example, if the jerk were reversed every two seconds (reciprocating) then the acceleration would build up to less than 200 [g's]. The stress moves away from the magnetic mass at sound speed (for example, 5000 [m/s]) or about 500 micrometers in 100 nanoseconds. They represent microscopic shock waves that will dissipate.

Radial-Jerk GW Generation Embodiment

In the case of the radially directed pulses or displacements of the rim or rim sector or sectors, they result in a time-

variable value of the moment of inertia, I. These displacements are built up in the radial direction by the sequential activation of radial arcs of coils in a given, single wedge-shaped sector or juxtaposed sectors of the rim or dumbbell. Under the control of the IIPCS, radially oriented strips of the aforementioned circuit-board or computer-chip rolls are sequentially activated to build up or generate a $(d^3I/dt^3)^2$ formulation or GW component as the GW moves outward at light speed. The radial displacements should be asymmetrical (as controlled by the IIPCS) in order to produce a quadrupole moment or so that the GW will not cancel out. The astrophysical analogy here is a vibrating white dwarf star emitting GW (see, for example, D. H. Douglas, p.491, of L. L. Smarr, opcit).

As is well known and noted in specifics by Geoff Burdge, Deputy Director for Technology and Systems of the National Security Agency (written communication dated Jan. 19, 2000) "Because of symmetry, the quadrupole moment can be related to a principal moment of inertia, I, of a three-dimensional tensor of the system and . . . can be approximated by

$$-dE/dt \approx G/5c^5(d^3I/dt^3)^2=5.5\times10^{-54}(d^3I/dt^3)^2." \quad (16)$$

In which k in Burdge's notation is G and the units are in the MKS system [watts] not the cgs. In this case

$$P=-G\kappa_{I3dot}(d^3I/dt^3)^2/5c^5[\text{watts}] \quad (17)$$

where $I=\delta m\ r^2$ [kg-m^2],

δm=mass of an individual rim sector or a number of sectors (or dumbbell) [kg], and

r=half of the distance between opposing δm [m]. Thus

$$d^3I/dt^3=\delta m\ d^3r^2/dt^3=2r\delta m\ d^3r/dt^3+\ldots \quad (18)$$

and d^3r/dt^3 is computed by noting that

$$2r\delta m\ d^2r/dt^2=2rf_r[\text{N-m}] \quad (19)$$

where f_r=radial force on a single rim sector, rim sectors, or dumbbell. (This single-sector embodiment of the invention can also be visualized as a linear motor.)

The derivative is approximated by

$$d^3I/dt^3=2r\Delta f_r/\Delta t, \quad (20)$$

in which Δf_r is the nearly instantaneous increase in the radial force on the rim caused by the magnetic field when it is turned on and off or pulsed by the transistors or ultra-fast switches of the IIPCS, that is, a radial jerk. In this regard the coils are sequenced radially outward by the IIPCS (at the speed of light) in order to generate or build up the high-frequency gravitational waves. Thus

$$P=-5.5\times10^{-54}\kappa_{I3dot}(2r\Delta f_r/\Delta t)^2[\text{watts}]. \quad (21)$$

Again, κ_{I3dot} will be a function determined experimentally to account for the fact that r may not be less than the GW wavelength for most high-frequency GW of interest.

As a numerical example, for a spindle similar to the one mentioned in the prior numerical example, but with a one-meter wide apron of peripheral magnets and IIPCS coil sets both top and bottom (thus 2×100 cm/m=200 times more force per meter along the rim's periphery), $\kappa_{I3dot}=32$, $\Delta f=3.6\times10^9$ [N], r=1000 [m] and $\Delta t=10^{-12}$ [s], so that (pending experimental verification)

$$P=-1.76\times10^{-52}(2\times1000\times3.6\times10^9/10^{-12})^2=-9.12\times10^{-3}[\text{watts}] \quad (22)$$

Again the reference area is 63 [m^2], so that the GW energy flux near the device is about 1.45×10^{-4} [watts/m^2].

Single-Sector or Linear-Motor, Tangential-Jerk GW Generation Embodiment

The single-sector or linear-motor embodiment of the invention (sometimes referred to as a linear induction motor or LIM) is the most preferred embodiment of the invention. It can be visualized to involve a single sector of the rim with the impulsive forces being tangential rather than radial. Alternatively, it can be conceptualized as the rim magnets and adjacent coils being peeled off from the rim and laid out flat. In this case an exemplar device would be 2000 [m] in length and 3 [m] in diameter. The approximately one-centimeter-wide chip rolls would be placed longitudinally along the sides of central, cylindrical, permanent- (or electro-) magnetic core, piston, or barrel as shown in FIG. **2**. Each meter-long segment of the roll would produce about 3000 [N] of longitudinal force, f_l, and all together they form a sheath of sub-millimeter coils surrounding the central magnetic core, piston, or barrel consisting of magnetic sites. Note that in this case the motion of the magnetic mass is asymmetrical (either "in" or "out") so that there is a quadrupole and the GW do not cancel and become null. The IIPCS controlled current can proceed in either direction and in the single-interconnecting-line-of-coils embodiment of the invention alternative coil lines can be energized by pulse trains moving in opposite directions to vibrate the magnetic mass. The magnetic mass itself can be composed of electromagnets, with or without cores, that can be controlled by the IIPCS to augment the GW generation.

(1) Numerical Example

As a numerical example, there would be about one roll or 25-layer strip of chips spaced around and adjacent to the barrel in a longitudinal direction (parallel to the barrel axis) every 2 centimeters forming the sheath. Thus there would be π×3[m]×100[cm/m]/2[cm]=471 strips, 2000 [m] long or

$$\Delta f_l=(471)\ (2000[\text{m}])\ (3000[\text{N/m}])=2.83\times10^9[\text{N}] \quad (23)$$

and with $\kappa_{mr3dot}=32$ (to be established experimentally),

$$P=-1.76\times10^{-52}(2\times2000\times2.83\times10^9/10^{-12})^2=-2.26\times10^{-2}[\text{watts}]. \quad (24)$$

Thus, with the reference area of the two 3 [m] diameter ends, $2\pi(1.5)^2=14$ [m^2], (GW propagating in both directions) the generated GW flux is about 1.6×10^{-3} [watts/m^2].

(2) Sector-Material Accelerations

In this case the jerk is obtained from

$$(da/dt)_{per\ unit\ area}=(\Delta f/\Delta t)/(\Delta\text{mass}/\Delta A) \quad (25)$$

where $\Delta f=\Delta f_i$ [N]/(2000[m]×3[m]π)=$2.83\times10^9/1.885\times10^4=1.5\times10^5$ [N/m^2], so that

$$\Delta f/\Delta t=1.5\times10^5/10^{-12}=1.5\times10^{17}[\text{N/m}^2\text{-s}] \text{ and} \quad (26)$$

Δmass/ΔA=mass per area (3.8 [kg/m] of strip) (471 strips per meter)=1.79×10^3 [kg/m^2], so that $da/dt=1.5\times10^{17}/1.79\times10^3=8.38\times10^{13}$ [m/s^3]. Therefore, in 100 nanoseconds of continuous jerk the acceleration would build up to

$$a=d^2S/dt^2=(da/dt)\delta t=(8.38\times10^{13})\ (10^{-7})=8.38\times10^6[\text{m/s}^2]. \quad (27)$$

As already noted, the IIPCS would be programmed so that accelerations would never approach this value! As an example, for a one THz alternating jerk the acceleration would only build up to $(8.38\times10^{13})\ (10^{-12})=83.8$ [m/s^2]=8.6 [g's] (alternating or reciprocating "hammer blows" acting on a single mass or masses (such as magnetic sites); not harmonic oscillation of two masses). In the extreme case of 100 nanoseconds of continuous jerk in the same direction, the speed would build up to

$$dS/dt=(da/dt)\delta t^2/2=(8.38\times10^{13})\times10^{-14}=0.42[m/s] \quad (28)$$

and the displacement of the magnetic mass (magnetic surface of single sector, piston, or barrel) is

$$S=(da/dt)\delta t^3/6=(8.38\times10^{13}/6)\times\mathbf{10}^{-12}=1.40\times10^{-8}[m]. \quad (29)$$

Again there is considerable "motion" of the magnetic mass, but it goes a very small distance before the IIPCS reverses the built-up acceleration, speed, and displacement.

Infinite-radius Coil GW Generation Embodiment

For comparison with the foregoing embodiments of the invention, consider the evolution of coil pairs or coil sets into flattened-out pairs of parallel wires (that is, infinite-radius coils) situated very close to each other and carrying a large current in the same direction (and, therefore, attracting each other). This current, which can go either way, is to be pulsed by a large number of ultra-fast switches or transistors **58** (FIG. **3**) about every picosecond by the IIPCS to produce pulses of electrical current through the wires. For simplicity, as an example consider the wires to be flat, one-meter square plates (therefore a one-square-meter GW reference area or smaller (e.g., in order to achieve $r<<\lambda_{GW}$) down to a current-pulse wavelength across or made larger by constructing a mosaic of individual plate pairs) as exhibited schematically in FIG. **3**. As a numerical example, let each plate carry a one-thousand ampere current and the plates in the pairs are situated one-micrometer (10^{-6} [m]) apart and the pairs are separated at a greater distance, say, 0.1 [mm]. In order to achieve asymmetrical mass displacement (to produce a quadrupole moment) one plate of each pair or of each "coil set" could be considerably more massive than the other, that is, exhibit a considerably larger cross section or be joined to a ballast **67** in FIG. **3** or carry a much larger current than the other or have different modulus of elasticity or be constrained differently in their mountings. If the IIPCS pulsed these conducting plates with picosecond-duration pulses, then during each cycle the attractive, impulsive force (lateral jerk) for each coil pair or set of coil pairs would be

$$\Delta f=(\mu_o/2\pi)\ (1000[amps]\times[1000[amps])/10^{-6}[m]=2\times10^5[N]. \quad (30)$$

The IIPCS-controlled switches **58** in FIG. **3**, will sequence the current pulses **59** moving approximately at light speed, c, to build up a gravitational wave **29**.

Let GW-radiated power be given by

$$P=G(md^3r^2/dt^3)^2/5(c/2)^5\ G(\Delta f/\Delta t)^2/5(c/2)^5=1.76\times10^{-52}(\Delta f/\Delta t)^2\ [watts], \quad (31)$$

where $\Delta f/\Delta t=2\times10^5/10^{-12}=2\times10^{17}$ [N/s]. Thus, pending experimental verification:

$$P\ 1.76\times10^{-52}(2\times10^{17})^2=7.04\times10^{-18}[watts] \quad (32)$$

and since the reference area is two square meters (GW propagates into and out of the plates) the GW flux=3.5×10^{-18} [watts/m^2]. The product of the amperage of, say, two plates would need to go up by a factor of about 10^5 (to about one-million amperes) or the distance between the plates reduced by the same factor (to ten picometers or 10^{-11} [m]), or the number of plate pairs increased by a factor of a thousand, or a mosaic of many plate pairs per level (and multiple levels), or some combination thereof in order to approach the GW-flux values for the other embodiments of the invention. Such a current is, however, exceeded by the eighteen-million-ampere current passed through the Sandia Laboratory Z-pinch machine (A. Wilson, "Z Mimics X-rays from Neutron Stars", *Science*, Volume 286, Dec. 10, 1999, p. 2059). The current-produced jerk of this machine would be expected to generate a GW pulse as its tungsten wires collapse on each other, if they do so in an asymmetrical manner.

Electromechanical-force GW Generation Embodiment

At one THz the GW wavelength is 3×10^{-4} [m] or 300 micrometers so that the half wavelength and the optimum crystal dimension according to Joseph Weber, p. 313, 1960 opcit, is 150 micrometers and, of course, even smaller for the approximate quadrupole equation to hold. If the ensemble of electromechanical elements, for example, piezoelectric crystals, were controlled by the IIPCS and replaced the coils, and were on 160 micrometer centers in the chips, then there would be about $60\times60=3.6\times10^3$ per square centimeter. If there were 25 chip levels or layers, then there would be about $25\times3.6\times10^3=9\times10^4$ crystals per square centimeter or 9×10^9 per [m^2] as shown schematically in FIG. **4**. The energy would be 10^{-20} [watts] per crystal (if each driven just below its breaking point as enhanced by low-temperature and high-frequency operation) multiplied by 9×10^9 (crystals)$\cong10^{-11}$ [watts] (subject to experimental verification) . With the crystals properly oriented and programmed by the IIPCS to propagate GW radiation out of the side of the centimeter-thick, one-meter-square crystal array (whose area is about one centimeter by one meter, that is a reference area of 2×10^{-2} [m^2]) the GW flux would be $1/2\times10^{-11}/10^{-2}=5\times10^{-1C}$ [watts/m^2]. As noted by Joseph Weber (ibid), such a system could be employed " . . . to generate and detect gravitational radiation." (Emphasis added.) With regard to detection, the crystals would represent very small resonators whose natural frequencies were in the terahertz range. Alternatives to the preferred embodiment of the invention using piezoelectric crystals (or piezoelectric polycrystalline ceramics), include, but are not limited to either P or N processed strain-gage silicon semiconductors, thin-film piezoelectric resonators, electromechanical nanomachines, capacitors, dielectric resonators, solenoids and piezoelectric polymers. Electromechanical nanomachines are such devices as piston actuators, motors, vibrators and pumps. For specific design details either G. L. Wojcik, et al, "Electromechanical Modeling Using Explicit Time-Domain Finite Elements", *IEEE* 1993 *Ultrasonics Symposium Proceedings*, Volume 2, pp. 1107–1112 or Jan Kocback's "Finite-Element-Modeling Analysis of Piezoelectric Disks,—Method and Testing", Master of Science Thesis, Department of Physics, University of Bergen, Bergen, Norway, can be utilized.

As discussed in detail in the 1960 and 1964 Joseph Weber articles referred to above, the passage of a gravitational wave deforms an object or set of objects as it passes through them. For example, a piezoelectric polymer, a silicon semiconductor, a thin-film piezoelectric resonator, a piezoelectric-crystal functioning as a collector element is deformed by a GW and produces a small electrical current. Likewise, the plates of a capacitor functioning as a collector element are slightly moved relative to each other and thereby produces a signal. In fact, these elements are both energizable and generate GW and also are collectors and detect GW through the same conductors. The nanomachine collectors operate in a similar fashion. A nanomachine is a microscopic or molecular sized machine, for example, a microscopic version of the dumbbell motor/generator of the parent patent. As a GW passes through the collector, the dumbbell moves slightly and submicroscopic coils respond to this motion and generate a small current. Likewise, energizing the microscopic coils in the motor mode will generate GW due to dumbbell motion. Electrical transducer or micro strain gauge nanomachines respond to the defor-

mation occasioned by the passage of a GW in exactly the same fashion as it does to a mechanically induced strain and thereby function as a GW collector. The nanomachine pressure transducer collector element responds to a slight change in pressure of a set of particles comprising a fluid as the GW passes through it. The location of the collector elements and their connection with ultra-fast switches or transistors is identical to the location of the energizer elements, shown in FIG. **4** and, as already noted may be one and the same element acting as either an energizer or a collector.

Communication Utilizing GW

As an approximate numerical example related to a possible gravitational-wave detector for a train of high-frequency, THz, gravitational waves, consider the absorption cross section, a [m^2], for such antennas as given by Joseph Weber (opcit, 1964, p.99)

$$\sigma=15\pi GIQ\beta^2N^2/8\omega c[m^2] \quad (33)$$

where $G=6.67423\times10^{-11}$ [m^3/kg-s^2] (universal gravitational constant),

I=moment of inertia or quadrupole moment of the detector element(s) [kg-m^2],

Q=π times the number of oscillations a free oscillator undergoes before its amplitude decays by a factor of e,

$\beta=2\pi/\lambda$ [1/m] (propagation constant),

$\lambda=c/\nu$ [m] (gravitational-wave wavelength),

N=the number of quadrupoles coupled together in the antenna (see Eq. (2.9A), p.62, of *Gravitational Radiation and Relativity*, Edited by J. Weber and T. M. Karade, World Scientific Publishing Co., Singapore, 1986),

$c=3\times10^8$ [m/s] (the speed of light),

ν=frequency of gravitational radiation [1/s or Hz], and

ω=angular frequency (or mean motion) [1/s].

For $Q=10^6$ (as noted by Joseph Weber opcit, 1960, p. 308, "A practical antenna might be expected to have $Q\approx10^6$." A large Q implies that a long time is required for the quadrupole element to reach thermal equilibrium. Also, the detection devices that Weber had in mind were large isolated aluminum cylinders, suspended and well isolated from the environment. The collector elements for the present device will probably be contained on a chip with damping constraints and a much smaller Q is likely).

$\nu=10^{12}$ [Hz] or one [THz], and

$\beta=2\pi\nu/c=2.09\times10^4$ [1/m], and

$\omega=\nu/2=5\times10^{11}$ [1/s]; see Weber, 1964, opcit p. 90, we have

$\sigma=1.15\times10^{-15}$ IN^2[m^2].

This value, depending upon I and the number of quadrupoles (with masses and characteristics nearly identical) coupled together in the antenna, N, compares favorably with $\sigma=10^{-20}$ [m^2] of the Weber Bar given on p. 102 of Weber , ibid.

An approximate estimate of what bandwidth a gravitational-wave (GW) communication system might achieve is obtained as follows: Suppose that the distance between the GW generating or transmitting device and the receiver or detector is about one Earth's radius, 7,000 [km] or 7000 rim radii. Also, suppose that we are transmitting through the Earth's mantle and that 10 percent of the GW energy gets through. Thus, for the tangential-jerk situation the "signal" obtained by modulating the current pulses by the IIPCS (some pulses missing and some forming a longer-duration pulse or pulses of different amplitudes) is using the power near the spindle device given by Eq. (9) and the average power flux of 2×10^{-9} [watts/m^2] there

$$S=(2\times10^{-9})\ (0.1)/7000=2.8\times10^{-14}[watts/m^2] \quad (34)$$

at the receiver or detector (assuming that the GW propagates in a single plane with little or no diffraction). For the radial-jerk spindle situation using the power near the device given by Eq. (22) and the average power flux of 1×10^{-4} [watts/m^2] there

$$S=(1\times10^{-4})\ (0.1)/7000=1.4\times10^{-9}[watts/m^2]. \quad (35)$$

For the longitudinal-jerk, linear-motor situation with average power from Eq. (24) (if there were a fall off with range in "rim" radii), with a 2000 [m] length or radius of gyration and a resulting average power of 1×10^{-3} [watts/m^2] we have,

$$S=(1\times10^{-3})\ (0.1)/7000=1.4\times10^{-8}[watts/m^2]. \quad (36)$$

Let us estimate the "noise" $N=10^{-20}$ [watts/m^2] in the THz band(probably not many GW sources there, but Brownian motion, thermal and quantum fluctuations, etc. may result in much more noise than this) and that the GW detector exhibits a sensitivity on this same order. It should be recognized, however, that the bandwidth of the long-baseline, interferometric GW detectors now under construction are at most about a few kHz and they are not designed for THz detection. Furthermore, a six to ten order-of-magnitude improvement of the sensitivity of the single-crystal detectors considered by Joseph Weber 42 years ago might need to be accomplished (sensitivity of about 10^{-10} [watts] as given on p. 313 of Weber opcit, 1960). More recently, however, Weber has speculated optimistically (opcit, 1986, p. 30) that there is " . . . no limit to the theoretical sensitivity of a (elastic solid) gravitational radiation antenna, and perhaps no limit to the number of novel methods for improving the sensitivity of existing antennas."

Using Shannon's classical equation (C. B. Shannon, *Bell Systems Technical Journal*, Volume 27, Number 379, p. 623, 1948), the maximum rate of information transfer, C, for the spindle's tangential-jerk GW embodiment is given by

$$C=B\log_2(1+2.8\times10^{-14}/10^{-20})\cong(10^{12})\ (20)=2\times10^{13}[bps], \quad (37)$$

for the radial-jerk GW embodiment

$$C=B\log_2(1+1.4\times10^{-9}/10^{-20})\cong(10^{12})\ (30)=3\times10^{13}[bps] \quad (38)$$

and for the longitudinal-jerk (linear-motor) GW preferred embodiment

$$C=B\log_2(1+1.4\times10^{-8}/10^{-20})\cong(10^{12})\ (40)=4\times10^{13}[bps]. \quad (39)$$

In each embodiment the bandwidth, B, is taken to be the IIPCS switch on-off or "chop" rate of about 10^{12} reciprocating "hammer blows" or jerks per second (one THz and multiple GW generators or "transmitters" could increase the bandwidth further).

There exists a useful figure-of-merit or trade-off function for the longitudinal-jerk (single-sector or linear-motor) preferred embodiment of the invention that relates to the received signal:

$$S\ ([2\pi rl\{l\Delta f_l/\Delta A\}/\Delta t]^2/[\pi r^2])\alpha \quad (40)$$

$$(l^2[\Delta f_l/\Delta A]/\Delta t)^2\alpha \quad (41)$$

(note that the radius of the single-sector cylindrical magnetic core, piston, or barrel, cancels out) where

S=signal at the detector (receiver) [watts/m^2],

r=radius of the single-sector magnetic core, piston, or barrel [m],

l=radius of the single-sector or length at magnetic core, piston, or barrel [m],

$\Delta f_l/\Delta A$=longitudinal force per unit area acting on the single-sector magnetic core, piston, or barrel [N/m^2],

Δt=impulse time [s],

α=attenuation due to intervening material between the GW generator (transmitter) and detector (receiver) [dimensionless],and assume that for the single-sector or linear-motor preferred embodiment of the invention, if there is little or no GW diffraction, then there is no range, ρ dependence (to be tested experimentally).

As a numerical example, consider the solution for the length, l,

$$l=\sqrt[4]{(S/\alpha)\times(\Delta t/[\Delta f_l/\Delta A])^2} \quad (42)$$

where

$S=4.5\times10^{-4}$ multiplied by the nominal=(4.5×10^{-4}) $(1.4\times10^{-8})=6.26\times10^{-12}$ [watts/m^2] (assume a $\{1/4.5\}\times10^4$ more sensitive detector or receiver),

α=10 multiplied by the nominal=(10) (0.1)=1 [dimensionless] (assume no attenuation),

$\Delta t=10^{-1}$ multiplied by the nominal=10^{-13} [s] (occasioned by the possible design of a 100 femtosecond ultra-fast switch and pulse duration), and

$\Delta f_l/\Delta A$=100 multiplied by the nominal=(100) $(5.64\times10^9/[2000\times3\pi])=(100)(3.0\times10^5)=3.0\times10^7$ [N/m^2] (assume increased magnet efficiencies due to, for example, use of high-temperature super conductors and electromagnets).

Thus, in this case the length of the GW generator would be (with the factor of 7000 rim radii removed; thus the factor of $10^{-3}/7$)

$$l=\sqrt[4]{([6.26\times10^{-12}/10][10^{-3}/7]/[100/0.1]^2)\ (2000)}=6.15\times10^{-3}[m]=6.15[mm]. \quad (43)$$

Equation (41) can be utilized by a person with average skill in the art to practice the inventions utilizing fast or ultra-fast switches or transistors having different capabilities, that is different Δt, different detection capabilities, S, different forces, Δf, and different lengths, l including lengths significantly smaller than GW wavelength.

Propulsion

No doubt high-frequency GW experiments will reveal many applications of GW to propel spacecraft by means of remote GW generators. In this regard, on p. 349 of Landau and Lifshitz (opcit), they comment: "Since it has a definite energy, the GW is itself the source of some additional gravitational field. Like the energy producing it, this field is a second-order effect in the h_{ik} (tensor describing a weak perturbation of the galilean metric). But in the case of high-frequency gravitational waves the effect is significantly strengthened . . . " (Emphasis added.)

The axis of rotation of a spindle GW-generation device defines a preferred, single, unique direction in space and also a preferred, single, unique plane. The axis of the single-sector, linear-motor GW generator device defines a preferred, unique direction in space as well. Thus there is an asphericity or pattern to the gravitational radiation, an anisotropy or focusing, that is analogous to a radio-antenna pattern of field strength. The concept that, as a part of this pattern, the gravitational waves are constrained to the "preferred" plane of the rim, or axis of the linear-motor's "preferred" line in space, without diffraction, will also be tested. These concepts have potential application to spacecraft propulsion either by remote "gravitational force field" generation or by placing anisotropic GW generators on board a spacecraft—a "Relativistic Rocket".

What is claimed is:

1. A gravitational wave generator utilizing a computer controlled logic system to produce gravitational waves by imparting a third time derivative to the motion of a mass or a system of masses.

2. A gravitational wave generation device comprising:

a plurality of energizable elements;

a plurality of electronic switches connected to the elements;

a computer-controlled logic system operatively connected to a power source for selectively energizing the elements; and

a transmitter operatively connected to the elements for selectively connecting the elements to an information processing device in a predetermined time sequence to generate gravitational waves.

3. A device according to claim **2** wherein the electronic switches are semiconductor based.

4. A device according to claim **2** wherein the plurality of elements are piezoelectric crystals.

5. A device according to claim **2** wherein the plurality of elements are silicon semiconductors.

6. A device according to claim **2** wherein the plurality of elements are thin-film piezoelectric resonators.

7. A device according to claim **2** wherein the plurality of energizable elements are piezoelectric polymers.

8. A device according to claim **2** wherein the plurality of elements are of a submillimeter size and incorporated into a semiconductor chip.

9. A device according to claim **2** wherein the plurality of energizable elements are of a submillimeter size and integrated with polymer-based devices.

10. A device according to claim **2** wherein a subset of the energizable elements are arranged in a line of such elements such that when energized by a train of current pulses, the duration of which allows the pulses to traverse a subsequent energizable element completely, and reaches the next energizable element in the line with time delays between the elements to ensure that the pulses can reach each of the elements in the line at an appropriate time to generate gravitational waves as the train of pulses progresses down the line.

11. A device according to claim **2** wherein the plurality of elements are of a submillimeter size and integrated with polymer-based devices.

12. A device according to claim **2** wherein the plurality of elements are nanomachines.

13. A device according to claim **12** wherein the nanomachines are piston actuators.

14. A device according to claim **12** wherein the nanomachines are motors.

15. A device according to claim **12** wherein the nanomachines are vibrators.

16. A device according to claim **12** wherein the nanomachines are pumps.

17. A device according to claim **2** wherein a mass or masses are is set in motion by the elements and exhibits a third-time-derivative motion of the mass or masses to produce a gravitational wave.

18. A device according to claim **17** wherein the mass or masses are a plurality of electromagnets.

19. A device according to claim **18** wherein a cylindrically shaped magnetic core mass is provided, surrounded by a

sheath composed of a plurality of very small coils or coil sets, each individually controlled by computer means.

20. A device according to claim **17** wherein the mass or masses are a plurality of permanent magnets located around the rim of a spindle.

21. A device according to claim **20** wherein to a plurality of conductive wire coils or coil sets adjacent to the spindle rim are segmented into one or more separate, juxtaposed sectors.

22. A device according to claim **20** wherein the plurality of magnets located around the periphery of the spindle rim are separated into one or more separate, juxtaposed magnets.

23. A device according to claim **2** wherein the plurality of elements are electrically energizable elements.

24. A device according to claim **23** wherein the plurality of electrically energizable elements are capacitors.

25. A device according to claim **23** wherein the plurality of electrically energizable elements are dielectric resonators.

26. A device according to claim **2** wherein the plurality of elements are small conductive wire coils or coil sets.

27. A device according to claim **23** wherein the plurality of conductive wire coils or coil sets are microscopic in size and integrated with polymer-based devices.

28. A device according to claim **26** wherein the plurality of small conductive coils or coil sets are individually sequenced radially outward by current pulses to generate gravitational waves resulting from a third-time-derivative motion or jerk of a time-variable moment of inertia or mass distribution of a magnetic mass.

29. A device according to claim **26** wherein the plurality of coils or coil sets along a predetermined line of such coils or coil sets are energized by a train of current pulses, the duration of which is controlled by computer means to cause the pulse to traverse a subsequent coil or coil set completely and reaches the coil set in the line via the same single conductor wire with predetermined time delays between the coils or coil sets to ensure that the pulses reach each of the coils or coil sets in the line at an appropriate time to generate gravitational waves as the train of pulses progresses down the line.

30. A device according to claim **23** wherein the plurality of conductive wire coils or coil sets are of a very small size and encased in or imprinted on a semiconductor chip.

31. A device according to claim **30** wherein the semiconductor chip, containing the plurality of very small coils or coil sets, is layered with circuit elements sequenced to launch a magnetic-field pulse of very brief duration which interacts almost simultaneously with the electromagnetic field of a magnetic mass to cause a sufficient third-time-derivative motion or jerk of the magnetic mass to generate gravitational waves.

32. A device according to claim **31** wherein the magnetic mass is a single magnet acted upon by the plurality of coils or coil sets adjacent to it.

33. A device according to claim **2** wherein the plurality of elements are electromagnetic-force elements.

34. A device according to claim **33** wherein the plurality of electromagnetic-force elements are solenoids.

35. A device according to claim **33** herein the electromagnetic force elements are coil sets that are flattened out into one or more parallel conductor pairs situated close to one another and are pulsed with a current by computer controlled switches to produce a gravitational wave.

36. A device according to claim **35** wherein the plurality of parallel conductor pairs are arranged in a mosaic pattern or in multiple layers of a mosaic pattern.

37. A device according to claim **35** wherein the plurality of parallel conductor pairs are of microscopic size and encased in or imprinted on a semiconductor chip or integrated with a polymer-based device.

38. A device according to claim **35** wherein the plurality of parallel conductor pairs along a predetermined line of such parallel conductor pairs are energized by a train of current pulses the duration of which is controlled by computer means to cause the pulse to traverse a subsequent pair of parallel conductors completely and reaches the parallel conductors in the line via the same single conductor wire with predetermined time delays between the pairs of parallel conductors to ensure that the pulses reach each of the pairs of parallel conductors in the line at an appropriate time to generate gravitational waves as the train of pulses progresses down the line.

39. A gravitational wave detection device comprising:

a plurality of collector elements;

a plurality of electronic switches connected to the elements;

a computer-controlled logic system operatively connected to an information processing device for selectively connecting the elements in a predetermined time sequence; and

a receiver operatively connected to the information processing device to indicate the detection of gravitational waves.

40. A device according to claim **39** wherein the plurality of elements are piezoelectric crystals.

41. A device according to claim **39** wherein the plurality of elements are silicon semiconductors.

42. A device according to claim **39** wherein the plurality of elements are thin-film piezoelectric resonators.

43. A device according to claim **39** wherein the plurality of elements are piezoelectric polymers.

44. A device according to claim **39** wherein the plurality of elements are capacitors.

45. A device according to claim **39** wherein the plurality of elements are of a submillimeter size and incorporated into a semiconductor chip.

46. A device according to claim **39** wherein the plurality of elements are nanomachines.

47. A device according to claim **46** wherein the nanomachines are piston actuators.

48. A device according to claim **46** wherein the nanomachines are generators.

49. A device according to claim **46** wherein the nanomachines are electrical transducers.

50. A device according to claim **46** wherein the nanomachines are pressure transducers.

Abstract. Physical properties of gravitational waves, belonging to the larger class of exact solutions of Einstein field equations which are invariant for a non-Abelian two-dimensional Lie algebra of Killing fields, are described. It is shown that in the would be quantum theory of gravity they correspond to spin $-$ 1 massless particles. The gravitational interaction of two pencils of light is analyzed.

Introduction

The aim of this talk is to illustrate some interesting and, in a sense, surprising physical properties of special solutions of Einstein field equations, belonging to the large class of Einstein metrics invariant for a non-Abelian two-dimensional Lie algebra of symmetries, which throw new light on the following problem.

A long time ago Tolman, Ehrenfest and Podolsky [30] and later Wheeler [33] analyzed the gravitational field of light beams and the corresponding geodesics in the linear approximation of Einstein equations. They discovered that null rays behave differently according whether they propagate parallel or antiparallel to a steady, long, straight beam of light, but they did not provide a physical explanation of this fact. The result was clarified in part by Faraoni and Dumse [14] using an approach based on a generalization to null rays of the gravitoelectromagnetic Lorentz force of linearized gravity. They also extended the analysis to the realm of exact *pp*-wave solutions of the Einstein equations.

Since the problem of the gravitational interaction of two photons is still unsolved, it appears necessary to take into full account the nonlinearity of Einstein's equations when studying the generation of gravitational waves from strong sources [12, 29].

On the other hand, some decades ago, Belinski and Zakharov have shown [4] that there exist metrics such that the corresponding vacuum Einstein field equations reduce to a system of non-linear partial differential equations, whose *generalized Lax form* is characteristic for integrable systems. Then, by using a suitable generalization of the *Inverse Scattering Transform*, they were able to find *solitary waves solutions*.

A geometric inspection of mentioned metrics shows that they are invariant under translations along the x, y-axes, i.e., they admit two Killing fields, ∂_x and ∂_y, closing on an Abelian two-dimensional Lie algebra $\mathcal{A}_2$. Moreover, the distribution $\mathcal{D}$ generated by ∂_x and ∂_y is two-dimensional and the distribution $\mathcal{D}^\perp$ orthogonal to $\mathcal{D}$ is integrable and transversal to $\mathcal{D}$.

Since a two-dimensional Lie algebra is either Abelian ($\mathcal{A}_2$) or non-Abelian ($\mathcal{G}_2$), it has been natural to consider [24–26] the problem of characterizing all gravitational fields g admitting a Lie algebra $\mathcal{G}$ of Killing fields such that

I the distribution $\mathcal{D}$, generated by vector fields of $\mathcal{G}$, is two-dimensional.

II the distribution $\mathcal{D}^\perp$, orthogonal to $\mathcal{D}$ is integrable and transversal to $\mathcal{D}$.

The condition of transversality can be relaxed [9, 10], so that in order to distinguish the different cases, the notation $(\mathcal{G}, r)$ is used. Metrics satisfying the conditions *I* and *II* are called *of* $(\mathcal{G}, 2)$*-type*. Metrics satisfying conditions *I* and *II*, except the transversality condition, are called *of* $(\mathcal{G}, 0)$*-type* or *of* $(\mathcal{G}, 1)$*-type* according to the rank of their restriction the leaves of $\mathcal{D}$ which are also called *Killing leaves*.

All the possible situations corresponding to a two-dimensional Lie algebra of isometries, are described by the following Table 1 in which the cases indicated with bold letters are essentially solved [2, 9, 10, 24–27] where a non integrable two-

Table 1

	$\mathcal{D}^\perp, r = 0$	$\mathcal{D}^\perp, r = 1$	$\mathcal{D}^\perp, r = 2$
$\mathcal{G}_2$	**integrable**	**integrable**	**integrable**
$\mathcal{G}_2$	**semi-integrable**	**semi-integrable**	**semi-integrable**
$\mathcal{G}_2$	**non-integrable**	**non-integrable**	non-integrable
$\mathcal{A}_2$	**integrable**	**integrable**	integrable
$\mathcal{A}_2$	semi-integrable	semi-integrable	semi-integrable
$\mathcal{A}_2$	non-integrable	non-integrable	non-integrable

dimensional distribution has been called *semi-integrable* if it is part (i.e., a suitable restriction) of a three-dimensional integrable distribution.

The study of $\mathcal{A}_2$-invariant Einstein metrics goes back to Einstein and Rosen [13], Kompaneyets [16], Geroch [15], Belinsky, Khalatnikov, Zakharov [3, 4], so that

some exact solutions already known in the literature [28] have been rediscovered. Nevertheless, the geometric approach allows to perform in a natural way the choice of coordinates, i.e., the coordinates adapted to the symmetries of the metrics, even if they do not admit integrable $\mathcal{D}^{\perp}$ distribution. Usually, the standard techniques to find exact solutions assume, from the very beginning, that there exist natural vector fields, surfaces forming, which simplify the choice of the coordinates system. These assumptions are strong topological constraints on the space-time. The method developed in [2, 9, 10, 24–27] can be applied also when such topological assumptions do not hold.

The paper is organized as follows. In Section 1 gravitational fields invariant for a non Abelian two-dimensional Lie algebra, when the commutator of generators of the Lie algebra is of *light-type*, are characterized from a geometric point of view. In Section 2, the canonical and the Landau energy-momentum pseudo-tensors are introduced and a comparison with the linearized theory is performed. The role of (realistic) sources for such gravitational waves is also described. Eventually, the analysis of the polarization leads to the conclusion that these fields are spin -1 gravitational waves. In Section 3, spin -1 and spin -2 gravitational waves are compared from a gravitoelectromagnetic perspective. Section 4 is devoted to the analysis of the photon-photon gravitational interaction.

1. Geometric Aspects

Let g be a metric on the space-time $\mathcal{M}$ and $\mathcal{G}_2$ one of its Killing algebras whose generators X, Y satisfy $[X, Y] = sY$, $s = 0, 1$. The Frobenius distribution $\mathcal{D}$ generated by $\mathcal{G}_2$ is two-dimensional and in the neighborhood of a non-singular point *adapted coordinates* (x, y, p, q) exist ([9, 10, 24–27]) such that

$$X = \frac{\partial}{\partial p}, \qquad Y = \exp(sp)\frac{\partial}{\partial q}\cdot$$

In these coordinates, the general solution of vacuum Einstein equations, in the case in which the Killing field Y is of *light type*, is given by

$$g = 2f(\mathrm{d}x^2 \pm \mathrm{d}y^2) + \mu[(w(x, y) - 2sq)\mathrm{d}p^2 + 2\mathrm{d}p\mathrm{d}q] \tag{1}$$

where $\mu = A\Phi + B$ with $A, B \in \mathbb{R}$, $\Phi(x, y)$ is a non-constant harmonic function, $f = (\nabla\Phi)^2\sqrt{|\mu|}/\mu$, $w(x, y)$ is the solution of the *Euler-Darboux equation*

$$\Delta_{\pm}w + (\partial_x \ln|\mu|)\partial_x w \pm (\partial_y \ln|\mu|)\partial_y w = 0$$

where $\Delta_{\pm}$ is the Laplace (d'Alembert) operator in the (x, y)-plane. Metrics (1) are Lorentzian if the orthogonal leaves are conformally Euclidean, i.e., the positive sign is chosen, and Kleinian otherwise. Only the Lorentzian case will be analyzed and these metrics will be called of $(\mathcal{G}_2, 2)$-*isotropic type*.

In the particular case $s = 1$, $f = 1/2$ and $\mu = 1$, the above (Lorentzian) metrics are locally diffeomorphic [7] to a subclass of the vacuum Peres solutions [20, 28], that for later purpose we rewrite in the form

$$g = \mathrm{d}x^2 + \mathrm{d}y^2 + 2\mathrm{d}u\mathrm{d}v + 2(\varphi_{,x}\mathrm{d}x + \varphi_{,y}\mathrm{d}y)\mathrm{d}u. \tag{2}$$

The correspondence between (1) and (2) depends on the special choice of the function $\varphi(x, y, u)$, which, in general, is harmonic in x and y. In our case

$$x \to x, \quad y \to y, \quad u \to u, \quad v \to v + \varphi(x, y, u), \quad h = \varphi_{,u}.$$

In the case $\mu = \mathrm{const}$, the Euler-Darboux equation reduces to the Laplace equation. For $\mu = 1$, in the harmonic coordinates system (x, y, z, t) defined in [6], the above Einstein metrics take the particularly simple form

$$g = 2f(\mathrm{d}x^2 + \mathrm{d}y^2) + \mathrm{d}z^2 - \mathrm{d}t^2 + \mathrm{d}(w)\mathrm{d}(\ln|z - t|). \tag{3}$$

This shows that, when w is constant, the Einstein metrics given by equation (3) are static and, under the further assumption $\Phi = x\sqrt{2}$, they reduce to the Minkowski one. Moreover, when w is not constant, gravitational fields (3) look like a *disturbance* propagating at light velocity along the z direction on the Killing leaves. In the following we will only consider the case $\Phi = x\sqrt{2}$.

More precisely, the wave character and the polarization of gravitational fields (2) can be checked by using the covariant Pirani's criterion. To use this criterion the Weyl scalars must be evaluated according to the Petrov-Penrose classification [19, 21].

To perform the Petrov-Penrose classification, one has to choose a *tetrad* basis with two real null vector fields and two real spacelike (or two complex null) vector fields. Then, according to the Pirani's criterion, if the metric belongs to type **N** of the Petrov classification, it is a gravitational wave propagating along one of the two real null vector fields. Since ∂_u and ∂_v are null real vector fields and ∂_x and ∂_y are spacelike real vector fields, the above set of coordinates is the right one to apply for the Pirani's criterion.

Since the only nonvanishing components of the Riemann tensor, corresponding to the metric (2), are

$$R_{iuju} = -\partial^2_{ij}\partial_u\varphi, \qquad i, j = x, y$$

this gravitational fields belong to Petrov type **N** [11, 34]. Then, according to the Pirani's criterion, the metric (2) does indeed represent a gravitational wave propagating along the null vector field ∂_u.

2. Physical Properties

In the following, physical properties of metrics (1) will be analyzed only in the case of Lorentzian signature. In previous section, the wavelike nature of gravitational

fields (1) has been checked [6] by using covariant criteria. Now, we will shortly review the most important properties of these waves which will turn out to have spin $-$ 1.

Let us remark that the definition and the meaning of spin or polarization for a theory, such as general relativity, which is non-linear and possesses a much bigger invariance than just the Poincaré one, deserve a careful analysis. It is well known that the concept of particle, together with its degrees of freedom like the spin, may be only introduced for linear theories. In these theories, when Poincaré invariant, the particles are classified in terms of the eigenvalues of two Casimir operators of the Poincaré group, P^2 and W^2 where P_μ are the translation generators and $W_\mu = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}P^\nu M^{\rho\sigma}$ is the **Pauli-Ljubanski polarization vector** with $M^{\mu\nu}$ Lorentz generators. Then, the total angular momentum $J = L + S$ is defined in terms of the generators $M_{\mu\nu}$ as $J^i = \frac{1}{2}\epsilon^{0ijk}M_{jk}$. The generators P_μ and $M_{\mu\nu}$ span the Poincaré algebra, ISO$(3,1)$. When $P^2 = 0$, $W^2 = 0$, W and P are linearly dependent of each other $W_\mu = \lambda P_\mu$; the constant of proportionality λ is given by $\lambda = \overrightarrow{P}\cdot\overrightarrow{J}/P_0$ and defines the *helicity* for massless particles like photons.

Let us turn now to the gravitational fields represented by equation (3). As it has been remarked, they represent gravitational waves moving at the velocity of light, that is, in the would be quantised theory, particles with zero rest mass. Thus, if a classification in terms of Poincaré group invariants could be performed, these waves would belong to the class of unitary (infinite-dimensional) representations of the Poincaré group characterized by $P^2 = 0$, $W^2 = 0$. Recall that, in order for such a classification to be meaningful P^2 and W^2 have to be invariants of the theory. This is not the case for general relativity, unless we restrict to a subset of transformations selected for example by some physical criterion or by experimental constraints. For the solutions of the linearized vacuum Einstein equations the choice of the harmonic gauge does the job [32]. There, the residual gauge freedom corresponds to the sole Lorentz transformations.

2.1. The Standard Linearized Theory

The standard analysis of linearized theory and the issue of the polarization will be analyzed. In particular, the usual transverse-traceless gauge in the linearized vacuum Einstein equations and the (usually implicit) assumptions needed to reduce to this gauge play an important role: the generality of the usual claim "the graviton has spin $-$ 2" (that, of course, is strictly related to the possibility of achieving this special gauge in any "reasonable" physical situation) is strictly related to these assumptions.

The gravitational field is said to be *weak* (in M') if there exists a (harmonic) coordinates system and a region $M' \subset M$ of space-time in which the following

conditions hold

$$g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}, \qquad |h_{\mu\nu}| \ll 1, \qquad |h_{\mu\nu,\alpha}| \ll 1. \tag{4}$$

As it is known, in the weak field approximations in a harmonic coordinates system the Einstein equations read

$$\Box h_{\mu\nu} = 0. \tag{5}$$

The choice of the harmonic gauge plays a key role in deriving equation (5). No other special assumption either on the form or on the analytic properties of the perturbation h has been done. It is commonly believed that, with a suitable gauge transformation preserving the harmonicity of the coordinate system and the "weak character" of the field, one can always kill the "spin $-$ 1" components of the gravitational waves. However, even if not explicitly declared, the standard textbook analysis of the polarization is performed for globally *square integrable* solutions of the wave-equation (5) (that is, solutions which are square integrable everywhere on M) but, as we will see in the following, some very interesting solutions do not belong to this class.

What is lacking in our case is, obviously, the global *square integrability* due to the presence of the harmonic function solution of the two-dimensional Laplace equation. Therefore, non-globally square integrable spin $-$ 1 perturbations are not pure gauge because they cannot be killed by infinitesimal diffeomorphisms. Even if global *square integrability* is lacking, there exist solutions of this form that far away the singularities are perfectly well-behaved. In other words, spin $-$ 1 perturbations which are square integrable on a submanifold $M' \subset M$ of the whole spacetime can be found: thus, in order to exist, spin $-$ 1 perturbations necessarily need some singularities and/or some region with non trivial topology.

A transparent method to determine the spin of a gravitational wave is to look at its physical degrees of freedom, i.e., the components which contribute to the energy. One should use the Landau-Lifshitz (pseudo)-tensor t^{μ}_{ν} which, in the asymptotically flat case, agrees with the Bondi flux at infinity [8].

It is worth to remark that the canonical and the Landau-Lifchitz energy-momentum pseudo-tensors are tensors for Lorentz transformations. Thus, any Lorentz transformation will preserve the form of these tensor; this allows to perform the analysis according to the Dirac procedure. A globally square integrable solution $h_{\mu\nu}$ of the wave equation is a function of $r = k_{\mu}x^{\mu}$ with $k_{\mu}k^{\mu} = 0$. With the choice $k_{\mu} = (1, 0, 0, -1)$, we get for the energy density t^0_0 and the energy momentum t^3_0 the following result

$$16\pi t^0_0 = \frac{1}{4}(u_{11} - u_{22})^2 + u^2_{12}, \qquad t^0_0 = t^3_0$$

where $u_{\mu\nu} \equiv \mathrm{d}h_{\mu\nu}/\mathrm{d}r$. Thus, the physical components which contribute to the energy density are $h_{11} - h_{22}$ and h_{12}. These amplitudes are eigenvectors of the

infinitesimal rotation generator $\mathcal{R}$, in the plane x–y belonging to the eigenvalues $\pm 2\mathrm{i}$. Thus, the components of $h_{\mu\nu}$ which contribute to the energy correspond to spin $-$ 2.

In the case of the prototype of spin $-$ 1 gravitational waves (3), for $f = 1/2$, we have

$$\tau_0^0 \sim c_1 (h_{0x,x})^2 + c_2 (h_{0y,x})^2, \qquad t_0^0 = t_0^3$$

where c_1 and c_2 are constants, so that the physical components of the metric are h_{0x} and h_{0y}. Following the usual analysis one can see that these two components are eigenvectors of $\mathrm{i}\mathcal{R}$ belonging to the eigenvalues ± 1. In other words, metrics (3), which are not pure gauge since the Riemann tensor is not vanishing, represent spin $-$ 1 gravitational waves propagating along the z-axis at light velocity.

This is related to the harmonic function of the transverse coordinates: in order to have an asymptotically flat wave, singularities or some sort of non triviality in the spacetime topology are necessary. The question is, can reasonable sources be found to smooth out the singularities? The answer is positive as we will see in more details in the next sections. Now we will show a simple and interesting example of such solutions.

As a simple example let us consider perturbations, as in equation (3), of the form $h = \mathrm{d}w(x,y) \cdot \mathrm{d}f(z-t)$ which are not globally square integrable. The metric

$$g = \eta + \mathrm{d}w(x,y) \cdot \mathrm{d}f(u), \qquad u = z - t, \qquad \left(\partial_x^2 + \partial_y^2\right) w = 0 \qquad (6)$$

being spatially asymptotically flat for a wide choice of harmonic functions w. Indeed, it represents a physically interesting gravitational field: gravitational waves propagating along the z-axis at light velocity. Besides to be a solution of the linearized Einstein equations on flat background, it is an exact solution of Einstein equations too.

It is trivial to verify that metric (6) is written in harmonic coordinates and has an *off-diagonal* form, that is, the perturbation h has only one index in the plane x–y orthogonal to the propagation direction z. For this reason the above gravitational wave has spin equal to one and is not a pure gauge [6]. With a suitable transformation it is possible to bring the above gravitational wave in the standard *transverse-traceless* form, however one can check that the new coordinates are not harmonic anymore.

Summarizing: *globally square integrable spin*-1 *gravitational waves propagating on a flat background are always pure gauge. Spin* $-$ 1 *gravitational waves which are not globally square integrable are not pure gauge*.

2.2. Asymptotic Flatness and Matter Sources

In the vacuum case, the coordinates (x, y, z, t) of the metrics (6) are harmonic. Being z the propagation direction, the physical effects manifest themselves in the x–y planes orthogonal to the propagation direction. In order these metrics be *asymptotically Minkowski* for $x^2 + y^2 \to \infty$, the function w is required to satisfy the condition

$$\lim_{x^2+y^2\to\infty} (w - c_1 x + c_2 y - c_3) = 0$$

where c_1, c_2 and c_3 are arbitrary constants and the behaviour of w can be easily recognized by looking at the Riemann tensor of the metrics (6)

$$R_{uiuj} = f_{,u} w_{,ij} \tag{7}$$

which depends on the second derivatives of the harmonic function w.

Therefore, to have an asymptotically Minkowski metric, the function w must be asymptotically close to a linear functions. But, due to standard results in the theory of linear Partial Differential Equations, this is impossible unless w is a linear function everywhere and this would imply the flatness of the metrics (6). However, if we admit δ-like singularities in the x–y planes, non trivial spatially asymptotically Minkowski vacuum solutions with $w \neq \text{const}$ can exist [7]. Of course, it is not necessary to consider δ-like singularities: it is enough to take into account matter sources. For example, in the presence of an electromagnetic wave propagating along the z axis, with energy density equal to ρ which vanishes outside a compact region of the x–y planes, the exact non vacuum Einstein equations for metrics (6) read (see, for example [7])

$$f_{,u} \left(\partial_x^2 + \partial_y^2 \right) w = \kappa \rho$$

where κ is the gravitational coupling constant. Thus, one can have non-singular spin $-$ 1 gravitational waves by considering suitable matter sources which smooth out the singularities.

From the phenomenological point of view, it is worth to note that these kind of wave-like gravitational fields, unlike standard spin $-$ 2 gravitational waves which can be singularities free even in the vacuum case, have to be coupled to matter sources in order to represent reasonable gravitational fields. The observational consequence of this fact is that spin $-$ 1 gravitational waves are naturally weaker than spin $-$ 2 gravitational waves [18]. Typically, if the characteristic velocity of the matter source is v, the spin $-$ 1 wave is suppressed by factors $(v/c)^n$ with respect to a spin $-$ 2 wave. It is worth to note that a gravitational field may also have a repulsive character. For instance, a Kerr black hole is "more repulsive" than a Schwarzschild black hole with the same mass. This is obviously related to the

angular momentum. Roughly speaking, this effect may be attributed to the "gravitomagnetic" part of the Kerr metric which, in our terminology, is the "spin $-$ 1" part. On the other hand, the Kaluza-Klein mechanism allows to construct in pure five-dimensional gravity, solutions with spin $-$ 1 excitations (which in four dimensions may be interpreted as electromagnetic and, therefore, *repulsive*-degrees of freedom. Of course, the Kaluza-Klein mechanism also works when reducing from four to three dimensions. Solutions we are calling *spin $-$ 1 gravitational waves* when reduced to three dimensions (considering as extra dimension the propagation direction of the wave) give rise to purely electromagnetic fields.

3. A Gravitoelectromagnetic Perspective

A different point of view, which is useful in clarifying the nature of spin $-$ 1 gravitational waves is provided by the *gravitoelectromagnetism*, henceforth GEM (see, for example, [17]). In this scheme one tries to exploit as much as possible the similarities between the Maxwell and the linearized Einstein equations. To make this analogy evident it is enough to write a weak gravitational field fulfilling conditions (4) in the GEM form (see, for example, [17, 22])

$$\mathrm{d}s^2 = c^2\left(1+2\frac{\Phi_{(g)}}{c^2}\right)\mathrm{d}t^2 + \frac{4}{c}\left(\mathbf{A}_{(g)}\cdot\mathrm{d}\mathbf{x}\right)\mathrm{d}t - \left(1-2\frac{\Phi_{(g)}}{c^2}\right)\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j \quad (8)$$

with

$$h_{00} = \frac{4\Phi_{(g)}}{c^2}, \qquad h_{0i} = -\frac{4A_{(g)i}}{c^2}$$

(in this section the speed of light c will be explicitly written). Hereafter, the spatial part of four-vectors will be denoted in bold and the standard symbols of three-dimensional vector calculus will be adopted. In terms of $\Phi_{(g)}$ and $\mathbf{A}$, the harmonic gauge condition reads

$$\frac{1}{c}\frac{\partial\Phi_{(g)}}{\partial t} + \frac{1}{2}\nabla\cdot\mathbf{A}_{(g)} = 0 \quad (9)$$

and, once the gravitoelectric and gravitomagnetic fields are defined in terms of GEM potentials, as

$$\mathbf{E}_{(g)} = -\nabla\Phi_{(g)} - \frac{1}{2c}\frac{\partial\mathbf{A}_{(g)}}{\partial t}, \qquad \mathbf{B}_{(g)} = \nabla\wedge\mathbf{A}_{(g)} \quad (10)$$

one finds that the linearized Einstein's equations resemble the Maxwell equations. Consequently, being the dynamics fully encoded in Maxwell-like equations, the GEM formalism describes the physical effects of the vector part of the gravitational field. The situations which are usually described in this formalism are, typically, static. In fact, when this assumption is dropped, GEM gravitational waves are also possible.

The energy-momentum content of gravitational fields of form in (8) is well described, in the asymptotically flat case, by the Landau-Lifshitz pseudo-tensor $t^{\mu\nu}$ [17].

Spin $-$ 1 gravitational waves, as one could expect on the basis of the Kaluza-Klein theory, can be put in an "almost" GEM form. This can be understood recalling that they have only one index in the plane transversal to the propagation direction. A generic spin $-$ 1 gravitational wave, propagating along the z axis on flat spacetimes, has the form in equation (2) with $u = z - t$ and $v = z + t$, and this is almost the same form of equation (8) provided one replaces the time-like index 0 with the light-like index u representing the propagation direction of the wave. The analogous of the gravitomagnetic potential reads in this case $\mathbf{A}_{(g)}(x, y, u) = (\varphi_{,x}, \varphi_{,y}, 0)$ and the harmonic gauge condition is

$$\nabla \cdot \mathbf{A}_{(g)} = \left(\partial_x^2 + \partial_y^2\right) \varphi = 0. \tag{11}$$

Thus, the analogue of the gravitoelectric and magnetic fields are

$$\mathbf{E}_{(g)} = -\frac{1}{2c}(\varphi_{,xu}, \varphi_{,yu}, 0), \qquad \mathbf{B}_{(g)} = (\varphi_{,yu}, -\varphi_{,xu}, 0) \tag{12}$$

and the Einstein equations reduce to

$$\nabla \cdot \mathbf{E}_{(g)} = -4\pi G\rho \tag{13}$$

so that, outside the matter sources, the harmonic gauge condition implies the vacuum field equations.

4. Back to Tolman-Ehrenfest-Podolsky-Wheeler Problem

A steady light beam lying along the z-axis is described by electromagnetic field $F_{\mu\nu}$ whose non vanishing components are

$$E_x = -F_{01} = E_0 \cos(kz - \omega t) = B_y = F_{31}.$$

The only non vanishing components of-the energy momentum tensor $T_{\mu\nu}$ are

$$T_{00} = T_{33} = -T_{03} = -T_{30} = E_0 2 \cos 2(kz - \omega t)/4\pi.$$

Taking the time average over a time grater than ω^{-1} and localizing the waves in a beam, we get

$$T_{00} = T_{33} = -T_{03} = -T_{30} = E_0 2\delta(x)\delta(y)/8\pi$$

where the Dirac delta-function δ has been introduced.

Thus, it is natural to consider a metric perturbation whose non vanishing components are

$$h_{00} = h_{33} = -h_{03} = -h_{30}, \qquad h^{\mu}_{\mu} = 0, \qquad \partial_t h_{\mu\nu} = \partial_z h_{\mu\nu} = 0.$$

Then, the gravitoelectric and the gravitomagnetic components of the metric are given by

$$E_{(g)\mu} = F_{(g)\mu 0}, \qquad B_{(g)_m} = -\varepsilon^{\mu ab} F_{(g)\alpha\beta}/2$$

where

$$F_{(g)}\mu\nu = \partial_\mu A_{(g)\nu} - \partial\nu A_{(g)\mu}, \qquad A_{(g)\mu} = -h_{0\mu}/4 = (\Phi_{(g)}, A_{(g)}).$$

It turns out that

- the first order geodesic motion for a *massive particle* in the light beam gravitational field is determined by the *force*

$$\mathbf{f}_{(g)} = -2\mathbf{E}_{(g)} - 4\mathbf{v} \wedge \mathbf{B}_{(g)}$$

  where $\mathbf{v}$ is the velocity of the particle.
- the first order geodesic motion for a *photon* propagating, in the light beam gravitational field, parallel(anti) to z-axis ($u_j = \pm\delta_{j3}$) is lightly different

$$\mathbf{f}_{(g)} = -4\left(\mathbf{E}_{(g)} + \mathbf{v} \wedge \mathbf{B}_{(g)}\right).$$

In previous section, we have seen that a gravitational wave generated by the light is described by the exact Einstein metric

$$g = \mathrm{d}x^2 + \mathrm{d}y^2 + 2\mathrm{d}u\mathrm{d}v + wu^{-2}\mathrm{d}u^2.$$

In that case, the perturbation is given by

$$h_{00} = h_{33} = -h_{03} = -h_{30} = wu^{-2}$$

and we have

$$\mathbf{E}_{(g)} = -\frac{1}{4}\left(w_x, w_y, \frac{w}{u}\right)u^{-2}, \qquad \mathbf{B}_{(g)} = \frac{1}{4}\left(w_y, -w_x, \frac{w}{u}\right)u^{-2}.$$

The gravitational force acting over a massless particle is given by

$$\mathbf{f}_{(g)} = -[w_x(1-v_z)\mathbf{i} + w_y(1-v_z)\mathbf{j} + (w_x v_x + w_y v_y)\mathbf{k}]/4u^2.$$

If the photon propagates parallel to the light beam, $\mathbf{v} = (0,0,1)$, then

$$\mathbf{f}_{(g)} = 0$$

and there is not attraction or repulsion. It is worth to address that this result holds at first order approximation; the analysis in the strong gravity regime will be exposed in a forthcoming paper [31].

Thus, if the photon propagates antiparallel to the light beam $\mathbf{v} = (0,0,-1)$, then

$$\mathbf{f}_{(g)} = -\nabla w/2u^2$$

and the force turns out to be attractive.

However, it is known from Quantum Field Theory that one consequence of spin $-$ 1 messengers is that particles with the same orientation repel and particles with opposite orientation attract.

Thus, the apparent lacking of attraction must be ascribed to the linear approximation since, according to our results, photons generate spin $-$ 1 gravitational waves and, as a consequence, two photons with same helicity must repel one another [31].

Are these effects observable?

It can be seen that the transversal acceleration per unit length for two laser beams in *VIRGO interferometer* ($W = 1$ watt, separation $d = 10\,\mathrm{cm}$) is only $\mathrm{d}v/\mathrm{d}l = 2.10^{-110}\,\mathrm{cm}^{-1}$ which is too small to be detected with the actual technology.

For a gravitational wave coming from *Virgo cluster* with dimensionless amplitude $h = 10^{-21}$ and frequency $\nu = 1\,\mathrm{KHz}$, it turns out that

$$\mathrm{d}v/\mathrm{d}l = h\nu/c = 3.3.10^{-29}\,\mathrm{cm}^{-1}.$$

Thus, even if the effects cannot be certainly observed in the Laboratory, they may be relevant at cosmic scale.

Directions for gravitational wave propulsion

Abstract

This paper summarizes results of past analyses, including proposed examples, in order to build a modern theoretical framework for Gravitational Wave Propulsion. The framework consists of families of generators of gravitational waves, which have been theorized but still require experimentation, and models of thrust generation. High efficiency generators are based on coherent sources, for instance synchronized MEMS oscillators, the HTSC Gaser, based on coherent spin-2 transitions in s-wave/d-wave superconductors, and the nuclear electromagnetic wave to gravitational wave up-converting transducer, based on dineutrons.
After gravitational wave generation is successfully proven in the laboratory, it will be possible to apply a concept developed in the field of cosmology. It was found that the background energy density may give mass to the graviton, which in turn may allow gravitons to produce thrust. Local background energy density can be increased by charging materials with high dielectric constant in close proximity to the wave generating elements. Focused Gravitational Waves may also produce singularities, where the radiation is converted into a coulomb-like gravitational field. Gravitational singularities will set an n-body gravitating system among themselves, the spacecraft, and the remaining bodies of the universe, with obvious propulsive effects. Applications of the present analysis will lead to a unique propulsion system capable of enabling the fast exploration of the solar system, the local star system, and possibly the whole galaxy.

INTRODUCTION

On a general basis, a vehicle traveling in space requires energy and a reaction mass to accelerate and reach useful speeds. Usually the reaction mass is the mass of the propellant, which in most circumstances has also the role of energy source. Vehicles that are not required to carry reaction masses are more efficient and lightweight, but conventional ones are limited in scope. It is a fact that, after extraordinary developments, space travel by rocket technology has reached its limits and a new paradigm is required to make a big step forward in space propulsion; a step that should enable the exploration of nearby star systems and possibly the whole galaxy. These goals may seem unreachable with the current understanding of physics. Anyway with an open mind and a pragmatic approach, it is well known that we are dealing with opinions that are often suggested by the lack of interdisciplinary approaches to complex problems. It often happened that when so called theoretical limits were found wrong, accidental discoveries have shown why the good theory was erroneously applied the first time. An alternative to accidental discoveries are pieces of knowledge gathered from hundreds of research papers from different disciplines combined in an unusual way to create new concepts. They are normally rejected by experts of their single research field, thus painstaking efforts are required to simply communicate the new concept and let it grow in the laboratories.
At the and of the last century numerous theoretical efforts have started to show that Gravitational Waves (GWs) have not only astronomical and astrophysical relevance, but they also have technological applications[1,2]. Among them, several theories have approaches identified for telecommunication, imaging, material processing, and space propulsion. All of them elaborate on the fact that gravitational waves do exist and are emitted according to a theoretical

framework, namely General Relativity, which looks correct to a high accuracy[3]. Unfortunately successful experiments are yet to occur. However, the emission of GWs by star systems has been observed, and celebrated by a Nobel Prize[4,5].

For developing gravitational wave propulsion, multiple results of this framework have been adopted, combined, and applied to technological devices and methods. This same framework is also currently adopted for developing detectors of GWs from astronomical studies[6]. The detection difficulties suffer by today's detectors' accuracy although they have motivations that will be certainly discovered in the near future and will possibly reveal new information and a new paradigm about the universe and regarding specific approaches to propulsion.

Conceptually, gravitational wave propulsion is based on a generator of gravitational waves, and on one or more methods, that can theoretically produce motion. No physical reaction mass is used. Almost all generators are based on the Nobel Prize tested quadrupole formula[3,5] applied to various GW generating elements; among them there are MEMS oscillators, couples of non-electromagnetically radiating electrons and couples of neutrons.

DISCUSSION

Generators of gravitational waves for propulsion

This section introduces various generators of GWs that appear suitable for propulsion applications. According to the following elementary analysis, it is possible to prove that starting with given mass, volume and mechanical properties for the emitting solid body, the process of splitting the body into smaller parts will permit to increase the frequency and the power emitted.

By considering two equal revolving point masses each with mass m, distance between the masses r, and Universal constant of Gravity G, the power emitted in GWs can be computed by Eq. (10.5.25) at page 272 of Ref.[3], by considering two masses at half distance from the center of rotation, the two equal masses revolving about one another:

$$P = \frac{8G}{5c^5} m^2 r^4 \omega^6 \quad (1)$$

Equation (1) indicates that the power emitted is proportional to the 6th power of the frequency ω; obviously, the higher the frequency, the higher the power. Note that the denominator involving the fifth power of the speed of light, c, implies that the gravitational waves will be very weak. For real world materials a different analysis is required. In fact the actual limit is the ability to keep the emitting object in rotation (and/or vibration) at the highest possible frequency and avoiding that it breaks apart because of excessive internal stresses. The analysis is the following.

For rotating objects, the centripetal force is:

$$F = mr\omega^2 \quad (2)$$

If we choose to keep our system at the limit for the structural integrity of the selected material, F will be bounded by a limiting constant; let's choose force units, or just normalize the expression, according to the properties of the selected material in order to have for this limiting constant $F_{lim}=1$ so that $mr\omega^2 = 1$. Therefore splitting our system in two identical smaller systems each defined by:

$$m_{split} = m/2 \text{ and } r_{split} = r/2 \quad (3)$$

substituting into Eq. (2), we have from the centripetal force limiting formula:

$$\omega_{split} = 2\omega \quad (4)$$

Using these changes in the quadrupole formula for equal masses in Eq. (1) and considering that we obtain two systems, for each of them we obtain:

$$Psplit = \frac{8G}{5c^5}(m/2)^2 (r/2)^4 (2\omega)^6 \quad (5)$$

explicitly it becomes:

$$Psplit = \frac{\frac{8G}{5c^5}(m)^2 (r)^4 (\omega)^6}{4 \cdot 16/64} = P \quad (6)$$

Therefore starting with a given mass (and volume) of a preferred emitting material at the limit of structural integrity and cleverly rearranging the mass distribution in order to keep it always at the limit structural integrity by increasing the frequency, the power emitted by each "small piece" is equal to the power emitted by the "originating" element. If the "small pieces" do not interact with each other, and considering N elementary generators, incoherent summation gives $P_{splitN}=N \cdot P$. If the system of N elementary generators is coherent[7], amplitudes will add up instead of the powers and the power summation will give $P_{splitN}=N^2 \cdot P$, the quadratic growth will proceed till the conversion efficiency of the generator will be near 100%, after that it will saturate. The analysis clearly indicates that it is necessary to arrange the given mass into the largest number of discrete sources that technology allows; this approach leads to High Frequency Gravitational Waves – HFGWs[1]. Moving at high frequency coherently will increase the conversion efficiency of the generator. Equation (6) is the first direction to follow for increasing the power emitted by a GW generator with given mass and/or volume. It follows that the first technical and scientific development for achieving high power and high frequency is the MEMS generator[8]. The MEMS generator is a composite ensemble of micromechanical devices; it can be produced using available technology.

Further developments capable of increasing the frequency and the emitted power in GWs as a function of generator mass may come from particle based and nuclear-based generators. Specifically, in this paper we consider electro-

magnetically shielded electrons and neutral nucleons. Theoretical models have been developed even for those more advanced systems therefore programs for advanced developments are possible.

The MEMS generator

The MEMS generator represents the first significant improvement above the fundamental rotating bar emitter of GW. It is proposed by Dr. Robert M. L. Baker Jr.[9] Because of its very reasonable complexity it will probably be the first one to be tested.

Dr. Baker and collaborators[10], suggested in a number of very detailed papers that commercially available film-bulk acoustic resonators (FBAR), can be arranged in phased arrays and excited by 2.5 GHz electromagnetic microwave generated by magnetrons like those employed in microwave ovens. The phased array will convert EM radiation at 2.5 GHz to 5 GHz High Frequency Gravitational waves (HFGWs).

In Figure 1, a simple MEMS generator is schematized by an array of microscopic GW sources excited in parallel by an electromagnetic field at microwave frequencies that couples to the resonators.

Two electrodes are used to confine the field in a small volume to achieve very high energy densities. In the schematization of Figure 1, the electromagnetic energy in

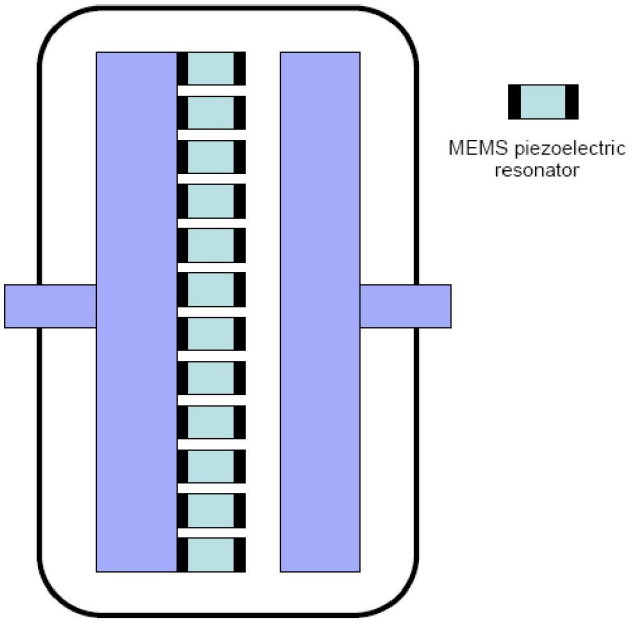

Figure 1 : Schematization of a MEMS generator of HFGWs.

the space surrounding the MEMS has a secondary purpose that will be discussed later.

More complex distributions are under development to improve the density of the microscopic emitters and the ability to drive them synchronously with microwaves and with the best possible use of the quantities appearing in Eq. (1) for each couple of associated masses of the elementary emitter. Among them there is a remarkable three-dimensional FBAR configuration recently proposed by Baker and Baker[9] shown in Figure 2.

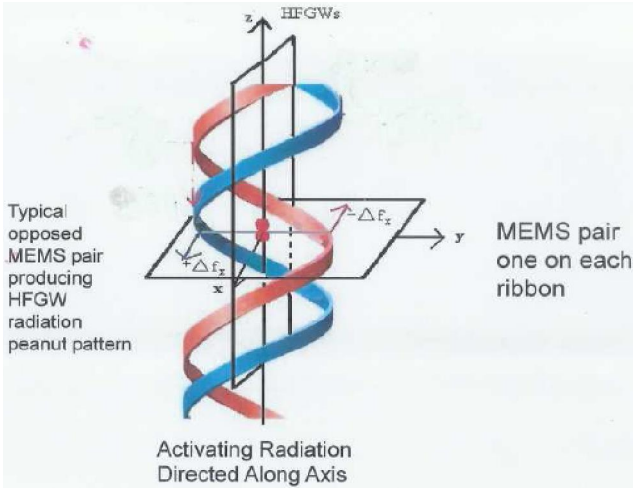

Figure 2 : The double helix MEMS generator of HFGWs.

The FBAR distribution is arranged on a double helix allowing dense packing, and efficient coupling to electromagnetic wave excitation. The configuration takes advantage of coherence and superradiance[9], by which the power emitted is proportional to N^2, where N is the number of elementary sources.

The HTSC gaser

The HTSC Gaser is a quantum source of GW in the THz range. First proposed by the author[11] in 1998, it was theoretically studied for more than a decade[12-15]. The HTSC Gaser promises to offer very high efficiency with directional and focusable GW beams.

The HTSC Gaser adopts electron couples for emitting HFGWs. Because electrons are charged, the whole HTSC Gaser technology is a method to make electron couples to start spinning coherently without emitting electromagnetic waves. The technology is based on early studies of L. Halpern and B. Laurent[16] on the emission of gravitational radiation from microscopic sources. The theory has to wait for the discovery of orthorombic cuprate high Tc superconductors, in which s-wave and d-wave cooper pairs were experimentally observed[17,18]. Transitions between s-wave and d-wave are gravitational *spin-2* transitions and may produce gravitational waves at THz frequencies. The HTSC Gaser depicted in Figure 3 operates by the injection of s-wave Cooper pairs generated in a low-Tc superconductor into the high-Tc superconductor. The injection process is well known and described in the literature with great detail[18]. The relatively new and relevant process is that transitions are linked to a gravitational phenomenon. The HTSC Gaser properly exploits the coherence of the order parameter of the superconductors and superrandiant effects in the very large num-

ber of Cooper pairs in the bulk superconductor.

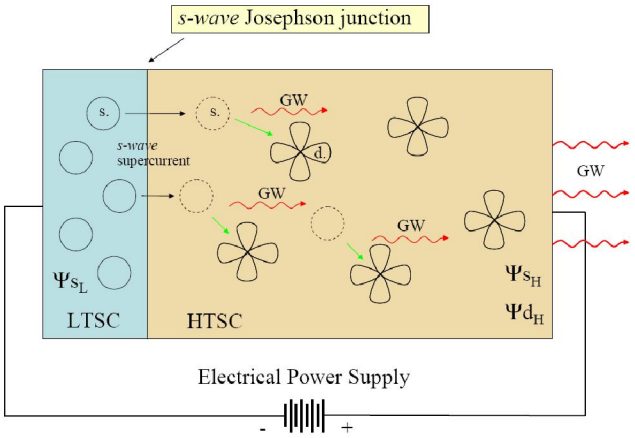

Figure 3 : Spin-2 transitions and HFGW emission in the HTSC gaser.

There are multiple advantages in the use of the HTSC Gaser. It converts DC current directly to HFGWs, it operates at submillimeter wavelengths, allowing easy productions of HFGWs beams. It is an efficient quantum device and allows the production of focused radiation because the junction can be constructed on a spherical dome with HFGWs focused at the center of the sphere. On the other hand it is a cryogenic device and requires special care and the use of very low temperature techniques.

Research should be directed towards the above mentioned potential discoveries because, in spite of the extremely large amount of data collected in more than twenty years, the real nature of high Tc superconductivity remains elusive; gravitational phenomena may be a key factor for a better understanding of the complete phenomenology.

To reach the ultimate goal of producing high intensity HFGWs and further increase the power, the frequency has to be increased as well as the mass of the emitting particles. Neutron mass is thousands of times higher than electron mass and they are electrically neutral. The clever point is how to induce controlled coherent motion to couples of neutrons and, most important, do stable couples of neutrons exist in nature?

It is possible to say yes to both questions.

The dineutron upconverting transducer

The Dineutron Upconverting Transducer (DUT) is the most complex and speculative device. First proposed by the author and Bernd Binder[19], it can convert nuclear excitations both from conventional X-ray sources and NMR signals to HFGWs at a much higher frequency respect to the excitation frequency. It is based on a nuclear model proposed by the late, two times Nobel laureate, Prof. Linus Pauling.

Pauling's nuclear model suggests a nuclear makeup of "spherons" that are protons, neutrons, alpha particles, and the more exotic dineutron[20-23]. Dineutrons are of great interest for this application. In fact dineutrons are ideal emitters of HFGWs. Dineutrons have nuclear densities, they are electrically neutral and the couple has a very small residual magnetic moment. According to Pauling, some nuclei, like for instance some stable isotopes of Gadolinium[21], may have one or two dineutrons floating almost in contact with the "surface" of the core nucleus as shown in Figure 4, under these conditions dineutrons are stable. According to detailed solutions of nuclear equations dineutrons do exist[24], and there are claims of their direct observation[25]. Dineutrons are dynamically coupled to the core of the nucleus by the highly "non linear" strong force. It is not necessary to know much about this dynamical system of nonlinearly coupled oscillators. Every system of nonlinearly coupled oscillators can be forced into a dynamic in which energy fully moves periodically from one oscillator to the other. Each oscillator oscillates at its own characteristic frequency. A well know example is the toy model "swinging spring"[26], which is indeed a simplified model of earth atmosphere. Another example is the multi pendulum marionette, a toy consisting of small pendulums appended to a bigger pendulum.

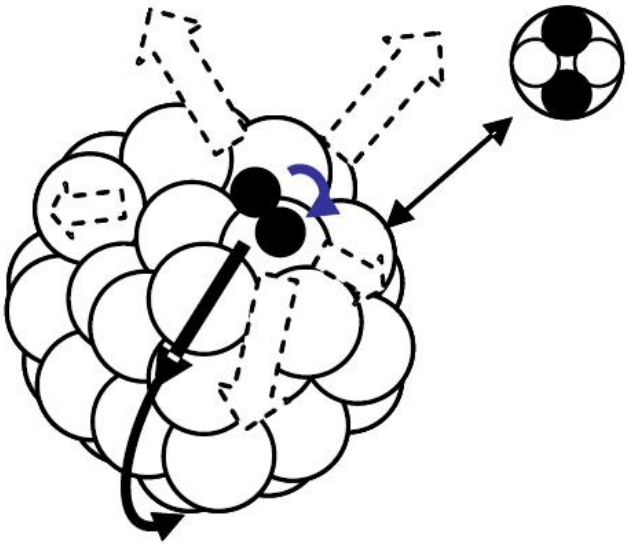

Figure 4 : The dineutron spins and orbits on the surface of the core nucleus, composed of alpha particles in this representation.

In our approach the system of coupled oscillators is composed by two or more spherons, one is the nucleus core, which being electrically charged can absorb electromagnetic waves. The others are the dineutrons that cannot absorb or emit electromagnetic waves; instead they can absorb and emit HFGWs. In Ref.[19], it is shown that according to the quadrupole formula the system can convert electromagnetic waves to HFGWs with high efficiency and at the same time coherently increase the frequency of HFGWs to high harmonics of the exciting electromagnetic radiation. It is the upconversion capability, mediated by the non-

linear "strong force" coupling that makes the efficient emission of HFGWs possible. The converter is estimated to absorb electromagnetic radiation at X-ray frequencies and emit HFGWs at gamma-ray frequencies.

In addition, according to a theory developed by Bernd Binder[27], dynamical instabilities may exist in some heavy nuclei capable of permitting the generation of energy by extracting it from the electromagnetic vacuum fluctuations. We observe that electromagnetic vacuum fluctuations will be converted to HFGWs of much higher frequency. The emitted HFGWs "should" be at the thermodynamic equilibrium with the gravitational quantum fluctuations, being this device an efficient transducer between the two radiation quantum fields. On the other hand, because our knowledge of gravitational quantum fluctuations is marginal at this time, electromagnetic quantum fluctuations might be converted by this device to HFGWs and allowed to propagate into an "almost empty and ultracold" gravitational radiation space, which is pure speculation but still remains a viable theoretical and experimental possibility and, certainly, create a direction to follow for future research. If this hypothesis is experimentally proved correct, a thermodynamic machine could extract useful work from the DUT, which could be therefore used as combined propulsor and useful energy generator.

Other nuclear generators

The DUT is the most complex, speculative, and potentially safe nuclear generator of HFGWs. Different generators were studied in past years and reported here for completeness, they may require nuclear reactions and may produce harmful radiation.

GW pulses could be emitted by the pulse of neutrons from a fission device[28], this is a one-shot concept that cannot be applied to GW propulsion. More recently Fontana and Baker[29] have proposed a HFGWs generating variant of the nuclear propulsion system in which neutrons or antiprotons may induce fission in a blanket of fissionable material. Layer by layer, in Rubbia's design[30], fission fragment may produce thrust.

We proposed an alternative approach in which the fissioning nucleus is prepared in a high rotational state (isomer), as shown in Figure 5; the rotational dynamics before the exact fission instant produces highly deformed nuclei that can emit HFGWs at X-ray and gamma-ray frequencies. By changing the angle between the wavefront of neutrons and the rotational axis of the isomers it is possible to match the speed of neutrons and the speed of HFGWs in order to produce high power pulses. This method is supported by theoretical papers on fission dynamics, on the other hand most energy is released as kinetic energy of fission products. Estimation of the power emitted in HFGWs is reported in Fontana and Baker[29].

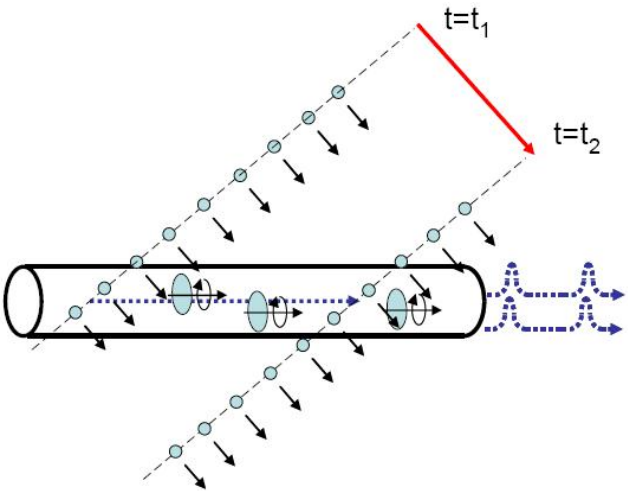

Figure 5 : Conceptual design of a traveling wave HFGW nuclear generator. Fissionable isomers are hit by wevefronts of neutrons. Pulses of HFGW are emitted.

ANALYSIS

Production of gravitons with mass

In the linearized approximation in flat space-time, GWs are purely transverse; therefore the interaction of GWs with matter is not useful for inducing longitudinal motion. In spite of this supposed inapplicability, the production of gravitons with mass is possible and it is the method that may permit propulsion by GWs[15,31]. If gravitons have mass while exiting the generator, propulsion by conservation of linear momentum is a straightforward possibility.

The existence of massive gravitons is predicted by General Relativity, which also gives some information on how to create the conditions required for giving mass to the graviton. The theory has been formulated by studying the propagation of *spin-2* fields in space-times with a background energy density.

While studying the propagation of GWs, it is normally assumed that space-time is flat and gravitational waves propagate as *spin-2* perturbation of flat space-time. Under these conditions gravitons are mass-less and travel at the speed of light. If there is a background energy density, like a cosmological constant, the background curvature and the graviton wave-packet curvature add non-linearly and the unbalance gives mass to the graviton (i.e. the positive perturbation "weights" more than the negative perturbation). Detailed analysis has provided a relationship between the mass of the graviton and the value of the background cosmological constant Λ in order to make propagation formally possible.

The relationship between the mass of the graviton m_g and background Λ, is, expressed in Planck units[32]:

$$mg^2 = \frac{2}{3}\Lambda \quad (7)$$

If the above relationship is not satisfied, the field is no longer a propagating radiation field. The theory was developed for large scale energy fields, like the cosmological constant, but it keeps validity at any scale above some wavelength of the selected GW. We promptly ask what happens if localized static high energy densities, for instance high electric energy densities in vacuum or in dielectrics, surround the GWs generator.

We expect that massive gravitons will be emitted, producing a back reaction on the generator, a thrust, and massive gravitons may possibly interact with distant matter, or maybe not very distant matter, because gravitons will leave the high energy density region where they are produced and will then propagate in "nearly" flat spacetime in which different propagation conditions apply[33]. Equation (7) can be rewritten in terms of energy density with the Einstein field equations:

$$mg^2 = \frac{2}{3}8\pi\rho \quad (8)$$

For engineering applications, the equation is converted to SI units by dividing the mass by the Planck mass. The energy density will be divided by the Planck energy and multiplied by the Planck volume:

$$\frac{m_g^{\,2}}{m_P^{\,2}} = \frac{16\pi}{3}\frac{\rho}{m_P c^2}\left(\frac{\hbar G}{c^3}\right)^{3/2} \Rightarrow m_g = \sqrt{\frac{16\pi m_P}{3}\frac{\rho}{c^2}\left(\frac{\hbar G}{c^3}\right)^{3/2}} \quad (9)$$

Substituting the SI values of the constants involved we have:

$$m_g = \sqrt{\frac{16\pi\cdot 2.17\cdot 10^{-8}}{3}\frac{\rho}{9\cdot 10^{16}}4.22\cdot 10^{-105}} = 1.3\cdot 10^{-48}\sqrt{\rho} \quad (10)$$

Focusing our attention only on the emission process, it is possible to adopt Eq. (10) to predict the amount of thrust that can be obtained from a GWs generator and the associated localized energy density. It is necessary to know the number of gravitons produced per second and the relationship between the energy density and the mass of the gravitons. According to Eq. (10) it is not necessary to know the frequency of the GW to define the mass of the graviton, the frequency must be sufficiently high for the gravitons to be generated in a beam that can resemble a rocket thrust, and therefore this section is developed following this specific approach.

To maximize the mass of the gravitons, it is necessary to employ dielectrics that may support high energy densities. Dielectrics are characterized by the dielectric constant ε higher than that of vacuum. Considering a plane capacitor with area A and armature distance d, the energy E of the electric field in the capacitor as a function of voltage V is:

$$E = 0.5CV^2 = 0.5\,\varepsilon\,V^2\,A/d \quad (11)$$

Dielectrics may suffer voltage induced breakdown if overstressed, and measurements can provide indications about the preferred materials and predicted performances. Table 1 of[34], suggests that $E_b = 10^6$ J/m^3 can be considered a standard high range value. Dielectrics are important for intra atmospheric travel, where air ionization must be reduced without reducing the background energy density. With $E_b = 10^6$ J/m^3, using SI units in the above formula we have:

$$m_g = 1.3\cdot 10^{-48}\sqrt{10^6} = 1.3\cdot 10^{-45}\,\text{kg} \quad (12)$$

It could be considered as a rest mass. To calculate the speed of the gravitons from an engineering point of view, it is possible to consider the Planck relationship applied, for instance, to high frequency gravitons. Let us choose $f = 5$ Ghz. The graviton energy is of the order of $hf = 3.3\cdot 10^{-24}$ J. The mass of the graviton is induced (produced) by the background energy density, being the particle massive and subluminal. It is possible to assume that its energy (most of it) is relativistic kinetic energy. With graviton mass of $1.3\cdot 10^{-45}$ kg, by using the relativistic kinetic energy E_k formula for massive objects, the graviton speed is 0.2 m/s less than the speed of light and the relativistic mass m_{gr} becomes of the order of $3.6\cdot 10^{-41}$ kg. If 10^6 W of GWs are produced by a generator, with $f = 5$ GHz, the number of gravitons per second is $3\cdot 10^{29}$. The amount of mass turns out to be about $1.1\cdot 10^{-11}$ kg/s expelled at nearly the speed of light. The momentum flow rate is $3\cdot 10^8$ m/s $\cdot 1.1\cdot 10^{-11}$ kg/s = $3.3\cdot 10^{-3}$ kg·m·s^{-2}, that is a measurable force.

With invariant GW power and invariant background energy density, reducing the frequency by adopting the generators discussed above, will increase the number of gravitons and reduce their relativistic kinetic energy. Relativistic effects combined with the background energy density that gives a "guaranteed rest mass to each graviton" turns out to be advantageous and with a frequency of 1 μHz, the thrust is 2000 kg·m·s^{-2}; 10^{-10} Hz will produce $2\cdot 10^5$ kg·m·s^{-2} thrust.

Gravitons with low frequency f_L can be produced by mixing two HFGW beams, with frequencies differing by f_L, within the the background energy density field. The method might be called gravitational wave mixing, and certainly will become a new research direction.

Gravitational wave focusing

The non-linearities of Einstein equations have also inspired a large number of theoretical papers on "colliding gravitational waves". Figure 6 shows a numerical solution of the collision of two impulsive gravitational waves[35].

The problem is usually described in u, v null coordinates (representing light propagation), expressed as: $v=t+r^*$; $u=t-r^*$; $r^*=r+2m\log((r-2m)/2m)$. The coordinate transformation is employed to represent space and time in a convenient

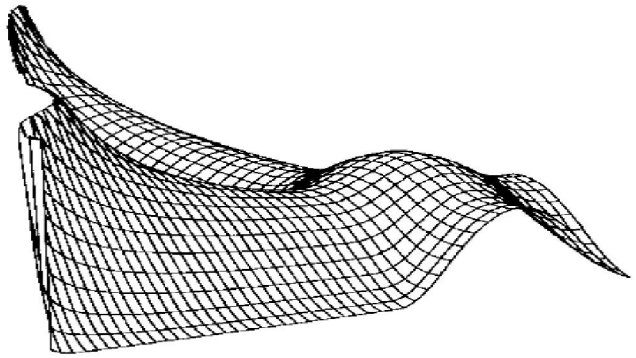

Figure 6 : Representation of the collision of two impulsive gravitational waves.

way, taking advantage of the symmetries of plane waves and "compressing" the space coordinates. The "bump" on the right of the picture represents the superimposing waves. The steep rise on the left of the picture is the effect of the non-linearity of Einstein equations and tends towards the singularity. The singularity does not appear by applying the linear approximation of Einstein equations.

Therefore, it has been shown theoretically and by numerical simulations, that, within the full theory of General Relativity, the singularity appears, accompanied by the diverging amplitude of the gravitational field.

The time (in Planck units) required for the creation of the singularity is a function of the amplitude of the waves A and the relative polarization α of the two waves[36,37].

$$\Delta t = \frac{1}{A^2}\sqrt{1+\sin\alpha} \qquad (13)$$

According to Eq. 13 focused HFGWs with amplitude $A=\Delta l/l=10^{-22}$ at the source may collapse to a singularity in about a second (SI units). This amplitude is relatively large but could even be generated by MEMS in double-helix configuration[9]. The result is equally valid with the more realistic beam-like gravitational waves[38], and the interaction of two graviton beams[39]. Colliding plane gravitational waves will produce a curvature singularity or a coordinate singularity, and the radiation is completely converted into a coulomb-like gravitational field[37].

The calculation of the gravitational potential of the resulting coulomb-like field as a function of the amplitude of the impinging waves would require an evaluation of the energy of the wave during the focusing process, the study of the accumulation process and the lifetime of the resulting singularity. Because of the curved space-time model, energy is not well defined in General Relativity and the lifetime of singularities is the very complex subject of quantum gravitational theories and Hawking radiation. Assuming that the energy of the wave is completely converted into a coulomb-like gravitational field and that no matter is created, all the energy will be converted into additional kinetic and potential energy of the n-body system composed by the spacecraft, the gravitational wave singularity and the remaining bodies of the universe[40]. Because n-body simulations[41] show that most energy exchange involves nearest bodies, if the gravitational singularity is produced near a spacecraft, the associated gravitational potential will mostly affect the kinetic energy of the spacecraft. This phenomenology can be intuitively described as a pulling effect, because the singularity co-moving with the spacecraft continuously pulls the spacecraft toward itself.

A large number of exact and numerical solutions are available for the n-body problem; therefore many solutions are possible, including librations, gravitational slingshots, complex orbital motions and chaotic motion.

It has been shown that a singularity appears also at the focus of a single, focused beam of gravitational radiation. The perfectly focused beam can be represented by a spherical gravitational wave, which has a singularity at the focus[42]. The focus may be the source of the wave or the absorber of the back-scattered wave, the second interpretation is the one of our interest. It is believed that the wave creates the singularity, which moves away at the speed of light. With the spherical gravitational wave, produced for instance, by a hemispherical array of synchronized microscopic sources or by a curved HTSC Gaser, the optical imperfections of the beam near the focus region could be spontaneously reduced by the intrinsic focusing behavior of the collision process. With focused gravitational waves the phenomena described by Eq. 13 will take place at the final stage of the process.

Gravitational wave generators may be external or onboard the spacecraft. Massless gravitons should be preferred in this case, because the direction of motion is reversed respect to the propulsion method described in the preceding two sections.

EXPERIMENTS

Various experiments were already made and patents already filed describing apparatuses and results that may fit the above framework. All of them are considered controversial, some of them were partially replicated, and some of them went completely ignored by physicists and rocket scientists. All of them report effects that are more intense than what can be theoretically predicted by the common elementary use of the theory. It is not the scope of this paper to evaluate the work of other scientists; on the other hand some of their results may fit to a high degree the present analysis. This is a good reason to reconsider them and plan for future replications with the present analysis at hand.

Podkletnov[43] described an apparatus with a weak capacity of gravity modification. The apparatus was a kind of asynchronous electric motor with a dual layered HTSC disc rotor. The operating disc allegedly shielded from earth grav-

ity objects put over it and located inside a cylindrical volume extending upwards for tens of meters. As an alternative interpretation it is possible to suggest that a repulsive force could have been applied to the target mass by an unidentified collimated radiation produced by the disc.

It is well known that the electric current in the rotor of asynchronous motors is higher than the current in the stator windings, and rotor current has maxima during acceleration and braking phases and under mechanical torque rotor load; this is a good reason to believe that the electric rotor current is what drives the phenomenon. In the second Podkletnov experiment[44], electric current with very high intensity was pulsed through the HTSC disc with a gas discharge apparatus. The current flowing through the disc produced similar effects, this time in a pulsed form and directed towards any desired direction, the intensity of the mechanical effects was more dramatic. This capability somehow confirms that the HTSC disc may emit a form of unusual radiation and the effects are very strong with higher voltages applied to the disc and the surrounding gas. According to the present analysis Podkletnov may have built and observed an HTSC Gaser, surrounded by electromagnetic fields capable of inducing the directional emission of massive gravitons. In the Podkletnov device the two layers, with different microscopic structures, but both made with YBCO, were probably characterized by different s-wave/d-wave Cooper pair densities. Because of the measured different critical temperatures, they were certainly characterized by different binding energies of cooper pairs, and transitions were possible. Unfortunately no direct measurement of the Cooper pair states was made on the Podkletnov devices.

The momentum back reaction on the source of massive gravitons was ignored in the Podkletnov apparatus, but it was possibly observed by Poher and described in Patent WO 200709369945. Poher experiment still adopts a dual layer HTSC both for propelling the disc itself and transferring linear momentum to nearby objects. Poher introduced a new hypothetical particle, the "Universon" to build a plausible theoretical framework for his experimental observations. Poher's analysis could be complementary to the one described here.

The coordinated use of concepts like a source of gravitational waves and localized energy densities can be adopted for the analysis and design of these new space propulsion systems.

Less dramatic but still measurable effects have been observed since the beginning of the space era on rotating and highly charged objects, like charged rotating gyroscopes or rotating and electrically charged ballistic missiles. All those objects may have directionally emitted massive gravitons and be consequently affected by linear momentum change. Most observations are still disputed and controversial, waiting for a generally accepted classification and understanding.

CONCLUSIONS

The theoretical foundations of gravitational wave propulsion with massive gravitons were summarized and research directions given. The possibility of producing thrust and induce motion can be the result of the technical use of gravitational waves in combination with high intensity static electromagnetic fields.

Coulomb like gravitational fields produced by colliding gravitational waves may also enable an additional, truly gravitational, propulsion technique, a gravitational pull.

This paper was developed on established principles and results of the astrophysical, the material science and the nuclear science communities applied to space travel engineering. If efficient generators of HFGWs will be constructed and operated at the MW power level, measurable effects should be obtained and it will be possible to start improving the technology. Some known experimental results do fit the presented model as order of magnitude estimates, nature of the phenomena and physical-technical requirements to obtain the claimed result. Therefore, I recommend to replicate known related experiments and to proceed in designing gravitational wave engines for the spacecraft of the future.

ε	=	dielectric constant in F·m^{-1}
$E_k = m_g c^2 \left(\frac{1}{\sqrt{1-\frac{v^2}{c^2}}} - 1 \right)$	=	relativistic kinetic energy of the massive graviton
$m_{gr} = \frac{m_g}{\sqrt{1-\frac{v^2}{c^2}}}$	=	relativistic mass of the massive graviton

$c = 2.997924 \cdot 10^{-8}\ m \cdot s^{-1}$ = speed of light in vacuum

$G = 6.7384 \cdot 10^{-11}\ m^3 kg^{-1} s^{-2}$ = gravitational constant

$\hbar = \frac{h}{2\pi} = 1.054571726 \cdot 10^{-34}\ J \cdot s$ = reduced Planck constant

$m_P = \sqrt{\frac{\hbar c}{G}} = 2.17651 \cdot 10^{-8}\ kg$ = Planck mass

$l_P^3 = \left(\frac{\hbar G}{c^3}\right)^{3/2} = 4.22419 \cdot 10^{-105}\ m^3$ = Planck volume

$E_P = m_P c^2 = \sqrt{\frac{\hbar c^5}{G}} = 4.22419 \cdot 10^{9}\ J$ = Planck energy

$t_P = \sqrt{\frac{\hbar G}{c^5}} = 5.39106 \cdot 10^{-44}\ s$ = Planck time

$G_{\mu\nu} = 8\pi T_{\mu\nu}$ = Einstein field equations in Planck units

ACKNOWLEDGEMENTS

The author whishes to acknowledge Paul Murad for reviewing and cleaning the paper and Robert M. L. Baker jr. for suggestions, discussion and a picture included in this paper. The STAIF 2 organizing committee is kindly acknowledged.
